Abstract

This paper describes aerosol modelling in Europe with a focus on Switzerland during summer and winter periods. We modelled PM_{2.5} (particles smaller than 2.5 µm in aerodynamic diameter) for one summer and two winter periods in years 2006 and 2007 using the MM5/CAMx air quality model system. The detailed AMS (aerosol mass spectrometer) measurements at specific locations were used to evaluate the model results. In addition to the base case simulations, we carried out sensitivity tests with modified aerosol precursor emissions, air temperature and deposition. Aerosol concentrations in winter 2006 were twice as high as those in winter 2007, however, the chemical compositions were similar. CAMx could reproduce the relative composition of aerosols very well both in the winter and summer periods. Absolute concentrations of aerosol species were underestimated by about 20%. Both measurements and model results suggest that organic aerosol (30–38%) and particulate nitrate (30–36%) are the main aerosol components in winter. In summer, organic aerosol dominates the aerosol composition (55–57%) and is mainly of secondary origin. The contribution of biogenic volatile organic compound (BVOC) emissions to the formation of secondary organic aerosol (SOA) was predicted to be very large (>95%) in Switzerland. The main contributors to the modelled SOA concentrations were oxidation products of monoterpenes and sesquiterpenes as well as oligomerization of oxidized compounds. The fraction of primary organic aerosol (POA) derived from measurements was lower than the model predictions indicating the importance of volatility of POA, which has not yet been taken into account in CAMx. Sensitivity tests with reduced NO_x and NH₃ emissions suggest that aerosol formation is more sensitive to ammonia emissions in winter in a large part of Europe. In Switzerland however, aerosol formation is predicted to be NO_x-sensitive. In summer, effects of NO_x and NH₃ emission reductions on aerosol concentrations are predicted to be lower mostly due to lower ammonium nitrate concentrations. In general, the sensitivity to NH₃ emissions is weaker in summer due to higher NH₃ emissions.

Interactive Discussion

1 Introduction

Atmospheric aerosols are known to have adverse health effects. They also play an important role in climate change by modifying the radiative balance of the atmosphere (IPCC, 2007). PM_{10} concentrations in Switzerland frequently exceed the national ambient air quality standards (20 and $50 \mu\text{g m}^{-3}$, annual and daily averages, respectively). Several long-term PM measurements as well as data obtained from field campaigns show that the organic portion is highly abundant (Lanz et al., 2010; Hueglin et al., 2006). Organic aerosol (OA) is composed of both directly emitted primary OA (POA) and secondarily formed SOA. OA has significant effects on climate and human health, but its sources and evolution in the atmosphere are not yet fully understood. New studies indicate that oxygenated organic aerosol (OOA) is formed from OA and its precursor gases, which becomes increasingly oxidized, less volatile, and more hygroscopic (Jimenez et al., 2009). Analysis of the submicron aerosol in Switzerland revealed that only a small fraction of OA originates from freshly emitted fossil fuel combustion, and that a high fraction is composed of OOA (Lanz et al., 2010). This conclusion was based on analyses of the organic aerosol mass spectra by positive matrix factorization (Lanz et al., 2007) and by multi-linear engine 2 (Lanz et al., 2008). Modelling organic aerosol is among the most demanding aspects of air quality simulations because the formation processes and evolution are poorly understood. In spite of the recent improvements in air quality models, organic aerosols can be underestimated by several factors (Hodzic et al., 2010a). The recently-developed volatility basis-set approach (Donahue et al., 2006) improved the agreement between organic aerosol model results and aerosol mass spectrometer (AMS) measurements (Robinson et al., 2007; Dzepina et al., 2009; Tsimpidi et al., 2010; Hodzic et al., 2010b).

Several PM measurements during January 2006 in Switzerland found exceptionally high concentrations (Lanz et al., 2008). Additional measurements were made at Payerne in June 2006 and in January 2007 within the frame of EMEP (European Monitoring and Evaluation Programme). These detailed aerosol measurements provide a

good data base to test models under different meteorological conditions over the complex terrain of Switzerland. In this study, we used the MM5/CAMx model system to simulate the air quality in Europe in one summer (June 2006) and two winter periods (January 2006, January 2007), focussing on the particulate matter in Switzerland.

2 Modelling method

2.1 Model setup

We used the CAMx (Comprehensive Air Quality Model with extensions) model, version 4.51 (Environ, 2006) to simulate air quality in January 2006, June 2006, and January 2007. The meso-scale model MM5, version 3.7.4 (PSU/NCAR, 2004) was used to generate the meteorological fields for CAMx. Three nested model domains were used in a Lambert Conic Conformal projection using 1-way nesting to cover a large part of Europe, central Europe and Switzerland with horizontal resolutions of 27 km × 27 km, 9 km × 9 km, and 3 km × 3 km, respectively (Fig. 1). The MM5 simulations with 31 terrain-following σ -levels up to 100 hPa, were initialized by data from COSMO7 analysis (COSMO, 2002). Four-dimensional data analysis (FDDA) using COSMO7 data was applied only for domains 1 and 2. The planetary boundary layer (PBL) height was calculated using the Eta PBL option, with the Mellor-Yamada scheme (Janjić, 1994). The CAMx simulations used a subset of 14 of the MM5 σ -layers, of which the lowest had a thickness of about 40 m at a surface pressure of 950 hPa. The model top was set at $\sigma = 0.55$ which corresponds to a geometric layer top of about 7000 m above sea level. The initial and boundary concentrations for the first domain were obtained from the global model MOZART (Hollingsworth et al., 2008). The photolysis rates were calculated using the TUV photolysis pre-processor (Madronich, 2011). The required ozone column densities were extracted from TOMS data (NASA/GSFC, 2011). Dry deposition of gases was based on the resistance model of Wesely (1989). Surface deposition of particles occurs via diffusion, impaction and/or gravitational

Interactive Discussion

settling. Separate scavenging models for gases and aerosols were implemented in CAMx to calculate the wet deposition (Environ, 2006). The CB05 gas-phase mechanism was used (Yarwood et al., 2005). We performed the simulations for the same periods as the detailed field campaigns where measurements were conducted with an aerosol mass spectrometer (AMS) at Zurich in January 2006 (Lanz et al., 2008) and at Payerne in June 2006 and January 2007 (EMEP campaigns) (Lanz et al., 2010).

Simulated aerosol species with particle sizes smaller than 2.5 μm included sulphate, nitrate, ammonium, POA, SOA and elemental carbon (EC). The condensable organic gases (CG) are formed from the oxidation of the aromatic precursors TOL (toluene) and XYL (xylene), as well as of the biogenic precursors isoprene, monoterpenes and sesquiterpenes (see Table 1 for the SOA precursor reactions). Partitioning of condensable organic gases to secondary organic aerosols was calculated using a semi-volatile equilibrium scheme called SOAP (Strader, 1999). Properties of CG/SOA pairs used in CAMx are given in Table 2. It was assumed that the SOA oligomerized to a non-volatile form with a lifetime of about 1 day (Kalberer et al., 2004). Oligomerization slowly forms organic aerosol oligomers called SOPA (anthropogenic) and SOPB (biogenic), and it was shown to increase SOA yields (Morris et al., 2006). Aqueous sulphate and nitrate formation in cloud water were calculated using the RADM aqueous chemistry algorithm (Chang et al., 1987). Partitioning of inorganic aerosol constituents between the gas and aerosol phases was modelled with ISORROPIA (Nenes et al., 1998). The model results for each episode were evaluated mainly at locations where detailed aerosol measurements were available: Zurich (January 2006) and Payerne (June 2006 and January 2007). In addition to the base case simulations, sensitivity tests were performed with modified parameters such as precursor emissions (two simulations with a 50% emission reduction of either NH_3 or NO_x), air temperature ($\pm 5^\circ\text{C}$) and deposition (on/off).

2.2 Emissions

Gridded emissions from various sources refer to a specific year. To harmonize data from different sources and reference years, emissions were converted to a common reference year, 2005. The annual emissions and time functions for Europe were provided by the Freie Universität Berlin (FUB) (Bultjes et al., 2002). The spatial resolution was 0.125 deg × 0.25 deg. The region of Lombardy in northern Italy was treated differently using hourly emissions (CITY-DELTA, 2011). Emissions in Switzerland were also calculated separately. Annual road traffic emission data with a spatial resolution of 250 m as well as the spatial distributions of total annual NMVOC emissions from industry and households with a resolution of 200 m were provided by INFRAS (Heldstab and Wuethrich, 2006; Keller and de Haan, 2004). The total NMVOC emission was split into the CB05 species following the rules of Passant (2002). Annual NO_x, PM_{2.5} and PM₁₀ emissions from residential activities, heating, industry, off-road traffic, rail transport and agriculture/forestry on a 200 m resolution as well as ammonia emissions from manure, waste treatment and road traffic on a 1 km resolution were taken from Meteotest. Industrial and residential emissions include substantial percentages of biomass burning. In Switzerland, about 75% of the residential PM₁₀ emissions, 10% of the industrial and 23% of the agricultural and forestal emissions are released by biomass combustion. Currently, the annual PM emissions from road traffic are about 3–4 times higher than those from domestic wood burning in our inventory. Primary particulate emissions were split as 40% elemental carbon (EC) and 60% OA.

Biogenic emissions for the CAMx domains were calculated using European and Swiss land use inventories and MM5 meteorological data. For each European country the deciduous and coniferous forest fractions were split into separate tree species according to Simpson et al. (1999). Inside Switzerland, the global data were replaced by data of the “Arealstatistik” (100 m resolution) issued by the Federal Office of Statistics (BFS, 1999) and by forest data (1 km resolution) taken from the “Landesforstinventar” (Mahrer and Vollenweider, 1983). About 24% of the Swiss area is covered by forests

Interactive Discussion

of which 71% are coniferous. Norway Spruce (*picea abies*) and fir (*abies alba*) are the most abundant species (49% and 15% of the trees, respectively). Monoterpenes are the most important biogenic VOC species in Switzerland, emitted mainly by Norway Spruce and fir trees. Isoprene in Switzerland, on the other hand, is emitted mostly
5 by oak trees, which constitute only 2% of the Swiss forests. The method for the estimation of biogenic emissions is given in Andreani-Aksoyoglu and Keller (1995), which was updated using recent literature data. The emission rates of sesquiterpenes were assumed to be 10% (in moles) of those of monoterpenes, based on data relevant for Swiss forests in Steinbrecher et al. (2009).

10 2.3 Meteorology

2.3.1 Winter 2006

Before evaluating the results of chemistry-transport model CAMx, we analysed the meteorological variables because they are essential for the dispersion and vertical mixing of pollutants. We modelled the meteorological parameters between 1 January and 10 February 2006. We classified the meteorological conditions into 5 periods
15 using the time series of measurements at various meteorological stations in Switzerland (see Fig. 2 for Payerne). During the first period (1–5 January), the measured air temperatures were mostly above zero, wind speed was moderate and there was no precipitation except at the beginning. The second period (6–16 January) was characterized by low-wind speed and an extended fog layer over the Swiss Plateau (region
20 between the Jura and the Alps), as well as lower temperatures. Then a warm front arrived, causing precipitation, higher wind speed and a rapid temperature increase in the third period (17–22 January). Mixed conditions prevailed during the fourth period (23 January–4 February). In the last period (5–10 February), temperatures and wind
25 speed increased. The model reproduced the wind direction and precipitation quite well most of the time. However, there was some difference (with a maximum of $\pm 5^\circ\text{C}$) between the measured and modelled temperature in the lowest model layer. The effect

Interactive Discussion

temperatures were overestimated by the model. This implies that the model underestimates the radiative cooling during the night. Strong radiative cooling at night leads to strong stratification which in turn is associated with high pollution levels. Inadequate representation of this phenomenon in the model probably contributes to an underestimation of pollutant levels after 12 June. During the first period the night-time surface inversion was not very strong. In the second period however, there was a surface inversion with a strong gradient that was not properly reproduced by the model. After 17 June (period III), there were several days with rain and the model performance varied as a result of these varying meteorological conditions. In general, MM5 could reproduce most of the parameters such as wind direction, precipitation and temperature reasonably well at the surface except low-wind speeds.

2.3.3 Winter 2007

January 2007 was warmer and had different meteorological conditions than January 2006 (Fig. 7). Temperatures were above zero except for a few days. During the first period (1–12 January), the wind speed was moderate to strong and some precipitation occurred. The second period (13–17 January) was dry and the wind speed was low. In the third period (18–25 January), the wind speed became higher and the temperature started decreasing. The wind speed was low again in the last period (26–31 January). The model-measurement agreement becomes worse under low-wind conditions (in the second and fourth period) as seen in the case of the previous year.

2.3.4 Modificiation of the wind fields

Meteorological variables such as wind speed and planetary boundary layer height (PBL) are the crucial parameters for the vertical mixing and dispersion of pollutants and thus these have a strong effect on surface concentrations. The simulation of the wind fields over complex terrain is known to be challenging (Liu et al., 2007; Baertsch-Ritter et al., 2004). In spite of using FDDA techniques to obtain more realistic

meteorological data, the modelled wind speeds still show discrepancies compared to measurements, especially over regions where wind speeds are low both in winter and summer periods (see Figs. 2, 6 and 7). Wind speed is crucial for the photochemical modeling as high speeds dilute air pollution plumes and reduce pollutant concentrations. The average measured wind speeds at 12 surface meteorological stations were 1.7 m s^{-1} , 1.8 m s^{-1} , and 2.5 m s^{-1} for January 2006, June 2006 and January 2007, respectively whereas the simulated wind speeds in the lowest layer of the smallest domain were 2.8 m s^{-1} , 2.9 m s^{-1} , and 3.5 m s^{-1} . In a sensitivity test, reducing the wind speed by a factor of two in all domains and layers improved the results of the low-wind speeds significantly. Therefore, the reduced wind speeds were used in further simulations for the low-wind periods. The used procedure ensured mass conservation. We changed only the horizontal wind fields (u , v) for each vertical layer. Since only these fields are transferred to CAMx, which then calculates the vertical component w at the layer interfaces internally, the mass conservation is fulfilled. The comparison of wind speeds before and after the modification is shown at some stations for each simulation period (Fig. 8).

An example for the effect of reduced wind speed on pollutant concentrations in each episode is shown in Fig. 9. Carbon monoxide (CO) can be used as a proxy for the quality of the meteorology since its concentration does not change rapidly due to chemical reactions. The CO concentrations were underestimated during the low-wind periods where there were significant differences between model predictions and measurements of wind speed. Reducing the wind speed after 12 June improved the model performance for CO. The comparison of the modelled PM concentrations ($\text{PM}_{2.5}$) with the AMS measurements is also shown in Fig. 9. Modelled PM concentrations increased by a factor of 2–3 when wind speeds were reduced in low-wind periods and matched measurements much better. All the simulations with CAMx discussed in the following sections were performed with modified wind speeds.

3 Results and discussion

3.1 Total aerosol

The modelled $PM_{2.5}$ refers to the sum of primary aerosol (EC and POA) and secondary inorganic (particulate nitrate, sulphate, ammonium) and organic aerosol (SOA). The predicted monthly average $PM_{2.5}$ concentrations in the European and Swiss domains (27 km and 3 km resolutions, respectively) are shown in Figs. 10–12 for all episodes. In January 2006, the modelled concentrations reach up to $70 \mu\text{g m}^{-3}$ around the Ruhr area (Germany) and Krakow (Poland) where there are substantial industrial emissions (Fig. 10). Primary aerosol dominates modelled $PM_{2.5}$ at Krakow whereas aerosols are mainly secondary around the Ruhr area. Elevated levels can be seen around the large urban areas as well. Monthly average $PM_{2.5}$ concentrations in the high-resolution Swiss domain ($3 \text{ km} \times 3 \text{ km}$) are highest over the Swiss Plateau (region between Jura mountains and Alps) and they exceed the national ambient air quality standards especially in areas downwind of Zurich (modelled daily averages are as high as $65 \mu\text{g m}^{-3}$) and Basel. The short-term standard for PM_{10} concentrations averaged over 24 h is $50 \mu\text{g m}^{-3}$ in Switzerland. The long-term measurements suggest that the $PM_{2.5}/PM_{10}$ ratio is about 0.75 (Gehrig and Buchmann, 2003). High concentrations are also predicted in the southern part of the modelled domain.

The second winter episode in January 2007 was much warmer than January 2006. As seen in Fig. 11, the distribution of predicted $PM_{2.5}$ particles in January 2007 is similar to the case in January 2006, however, concentrations are lower.

In summer, the distribution of $PM_{2.5}$ particles in Europe is different from winter, as exemplified in Fig. 12. Although highest levels can still be seen around the Ruhr area (mainly particulate nitrate and primary aerosols) and Krakow (mainly primary aerosols and particulate sulphate), large urban areas are predicted to have much lower $PM_{2.5}$ concentrations in summer than in winter. The model predicted that a significant contribution to $PM_{2.5}$ in the European domain is due to SOA especially in the region from Berlin to the Adriatic sea (Fig. 13).

Interactive Discussion

There were detailed AMS (PM₁) measurements at Zurich in January 2006, and at Payerne in June 2006 as well as in January 2007. In addition, there were daily PM_{2.5} measurements at Payerne in June 2006 and January 2007. Moreover, hourly PM₁₀ measurements were available in all three episodes. A comparison of model predictions for PM_{2.5} with the available measurements in all episodes is shown in Fig. 14. Clearly the particle concentrations were higher in January 2006 than in the other episodes. In January 2006, model results and measurements were similar during the high-wind periods (I and III), and the different measured size fractions yielded quite similar results. In the low-wind periods (II and IV), on the other hand, model results were lower than measurements on some days and there was a large difference between the measured PM₁₀ and PM₁ concentrations in the second period indicating increased coarse mode levels. In June 2006, model results matched both PM_{2.5} and AMS (PM₁) measurements (which were very similar) rather well. The high PM₁₀ concentrations measured on 20–21 June 2006 correspond to a Saharan dust event observed at that time. In January 2007, PM levels were lower than during the previous year, and the model reproduced the measured PM_{2.5} concentrations reasonably well.

3.2 Chemical composition

The predicted chemical composition was compared with the AMS measurements. Although the model results consist of PM_{2.5} and the AMS measures particles smaller than 1 μm, they can be compared with each other since the difference between PM₁ and PM_{2.5} measurements is usually rather small, as seen in Fig. 14. Both measurements and model results suggest that in winter particulate nitrate and organic aerosol are the main components of aerosols (Fig. 15). This is the case for both winter episodes in 2006 and 2007 at Zurich and Payerne, respectively. On the other hand, organic aerosol dominates the particle composition in summer. The model reproduces the relative contribution of aerosol species very well both in the winter and summer periods. The absolute concentrations from the AMS measurements are about 20% higher than model predictions in winter and summer 2006. In winter 2007, measured and

modelled concentrations were similar except for modelled OA which was 17% lower than the measurements. The model results were evaluated using the statistical parameters such as the mean fractional error (MFE) and the mean fractional bias (MFB) recommended by Boylan and Russell (2006) for aerosols. The statistical evaluation of model results is shown in Table 3 for all the episodes. The lowest Root Mean Square Error (RMSE) was obtained for EC in all episodes. The acceptable model performance criteria ($MFE \leq +75\%$ and $MFB \leq \pm 60\%$) were met for all species only in January 2007. Most of the aerosol species were underestimated in the cold winter period January 2006.

The highest organic aerosol concentrations were measured in January 2006 during the low-wind period II at Zurich (Fig. 16). In general, the model could predict the low concentrations of organic aerosols reasonably well in the high-wind periods. In the winter low-wind periods (periods II and IV in January 2006 and 2007), however, the predicted OA is lower than the measured concentrations for several days. In winter 2006, about 53% of the modelled organic aerosols are predicted to be POA at Zurich. At Payerne, the fraction of POA is 38% and 26% in January 2007 and June 2006, respectively (Table 4). The modelled POA fractions are higher than those derived from measurements using factor analysis of the aerosol mass spectral data (FA-AMS) (Lanz et al., 2008). Diurnal variations of POA and SOA predicted by the model and derived from measurements are shown in Fig. 17 for all periods. Both measured and modelled POA have two peaks in the winter periods; one in the morning and the other in the evening, where measured POA is taken as the sum of hydrocarbon-like organic aerosol (HOA) and wood burning organic aerosol (WBOA). Although morning peaks are similar, the evening peak from the measurements appears much later than that of the model indicating a more important contribution from wood burning that is underrepresented in the model. The measured POA and SOA show similar diurnal variations whereas the modelled SOA has no significant diurnal variation in winter. In summer, model and measurements show similar diurnal variations, with higher POA in the morning and higher SOA in the morning and at night. In general, the modelled SOA concentrations

Aerosol modelling in Europe with a focus on Switzerland

S. Aksoyoglu et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

are lower than the measurements while POA is overestimated, especially in summer. The fact that POA is assumed to be non-volatile in CAMx can lead to too high POA and too low SOA, and better agreement can be found using the volatility basis set developed by Donahue et al. (2006) as shown for Mexico City (Hodzic et al., 2010b). Similar diurnal cycles of measured POA and SOA in winter support the hypothesis that some part of SOA might originate from the aging of POA.

The model results suggest that SOA originates mainly from biogenic VOCs in Switzerland. This is in agreement with studies using ^{14}C in Zurich showing that biogenic sources are dominant in summer (Szidat et al., 2006). The fractional compositions of modelled SOA for all the three episodes are shown in Fig. 18. In general, SOA in the model is formed basically from monoterpenes (blue), sesquiterpenes (green) and oligomerization of biogenic oxidation products (red). The contribution from anthropogenic precursors to SOA was predicted to be less than 1%. In the winter periods, monoterpenes produce more SOA than sesquiterpenes, while the opposite is true in summer. In CAMx, sesquiterpene SOA is not allowed to partition back to the gas phase at higher temperatures due to its lower volatility, therefore it remains in the aerosol phase. On the other hand, monoterpene SOA partitions to the gas phase at higher temperatures, which leads to a lower fraction in summer. One should keep in mind that the sesquiterpene emissions used in this study have a very high uncertainty. The assumption of sesquiterpene emissions as 10% of monoterpene emissions might be too high. With lower sesquiterpene emissions, the underestimation of OA would be significantly larger. The emissions will be updated and a sensitivity study will be performed in the future.

3.3 Sensitivity tests

The deviation between measured and modelled temperature in the lowest model layer was about $\pm 5^\circ\text{C}$ (see Fig. 2). The effect of this difference on aerosol concentrations is investigated by changing the temperature in the model by 5°C . The variation in temperature affects mainly particulate nitrate concentrations. The results showed that

Interactive Discussion

particulate nitrate concentrations increased by up to $5 \mu\text{g m}^{-3}$ when the temperature was decreased by 5°C (Fig. 19a). An increase in the temperature by the same amount, on the other hand, caused a decrease of the nitrate levels by $2\text{--}3 \mu\text{g m}^{-3}$.

The effect of deposition processes on the aerosol concentrations was tested by switching off both dry and wet deposition in the simulations for January 2006. The total aerosol concentrations increased without deposition (Fig. 19b). Deposition mainly affects inorganic aerosol components, especially particulate nitrate due to efficient removal of nitric acid, and the degree of change depends on the meteorological conditions.

There are very few studies in Europe about the sensitivity of aerosols to precursor emissions, mainly in UK and northern Italy (Redington et al., 2009; Derwent et al., 2009; de Meij et al., 2009). In this study, the sensitivity of inorganic aerosol formation to NO_x and NH_3 emissions was investigated in whole Europe by two simulations for both January 2006 and June 2006, where either NO_x or NH_3 emissions were reduced by 50%. Figure 20 shows the differences in monthly average $\text{PM}_{2.5}$ concentrations between the two simulations for both winter and summer in both domains. The blue colour (negative values) shows regions where a 50% reduction in NO_x results in a greater decrease of $\text{PM}_{2.5}$ than a 50% reduction in NH_3 , while the red colour shows areas that are more sensitive to a reduction in NH_3 . These results suggest that aerosol formation in most of the European domain in winter (Fig. 20, top left) is more sensitive to NH_3 emissions except in central Europe and north west of France where blue colour indicates a NO_x sensitivity. Using a moving air-parcel trajectory model, Derwent et al. (2009) predicted that aerosol formation in southern UK was ammonia-limited. This is in line with our results for that region (Fig. 20, top left). As seen in Fig. 20 for the Swiss domain (bottom left), aerosol formation in the Swiss Plateau is limited by NO_x emissions. On the other hand, the red colour in the southern part of the model domain (southern Switzerland, northern Italy) indicates a higher NH_3 sensitivity for aerosol formation. These results support our earlier studies based on short-term simulations (Andreani-Aksoyoglu et al., 2008). In summer, effects of NO_x and NH_3 emission reductions on

Interactive Discussion

aerosol concentrations are predicted to be lower mostly due to lower ammonium nitrate concentrations (Fig. 20, right). In general, the sensitivity to NH_3 emissions is weaker in summer due to higher NH_3 emissions. The land area in Europe where aerosol formation is NO_x -limited in winter is about 3% whereas it goes up to 55% in summer.

4 Conclusions

The aerosols in Switzerland were modelled with the regional air quality model CAMx for one summer and two winter periods in 2006 and 2007 under different meteorological conditions. The following findings can be extracted from this study:

- Both measurements and model predictions suggest that organic particulate matter and particulate nitrate are the main aerosol components in winter. In summer, organic aerosol, which is mainly secondary, dominates the aerosol composition.
- The relative contribution of aerosol components was modelled very well. The absolute concentrations of aerosol components were in general reproduced rather well, except for the cold winter 2006 where the bias was higher than in the other periods. The acceptable model performance criteria were met for all investigated components in January 2007.
- In January 2006, the highest $\text{PM}_{2.5}$ concentrations were predicted around the Ruhr area in Germany and Krakow in Poland; secondary inorganic aerosol and primary aerosol were calculated to be the main components in those areas, respectively. In summer, secondary aerosol dominated the aerosol composition both in Europe and in Switzerland.
- The contribution of the biogenic emissions to the SOA formation in Switzerland was predicted to be very large and to originate mainly from monoterpenes and sesquiterpenes, as well as oligomerization of biogenic oxidation products.

Interactive Discussion

Aerosol modelling in Europe with a focus on Switzerland

S. Aksoyoglu et al.

- In all episodes, the predicted primary organic aerosol (POA) fraction was higher than those derived from the AMS measurements (especially in summer), probably because volatility of POA has not yet been taken into account in the CAMx model. Comparison of modelled and measured diurnal variations of POA and SOA indicates an important contribution from wood burning that is underrepresented in the model. The wood burning emissions will be updated in the near future.
- Sensitivity tests suggested that temperature and deposition have a strong effect mainly on particulate nitrate. Nitrate concentrations were inversely correlated with temperature. $PM_{2.5}$ concentrations increased significantly (mainly inorganic aerosols) when the deposition processes were switched off.
- Simulations with reduced NH_3 and NO_x emissions indicated that inorganic aerosol formation is more sensitive to NH_3 emissions in a large part of Europe (97%) in winter. The effect of NH_3 emission reductions on aerosol mass is predicted to be lower in summer (45%). On the other hand, model results suggest that aerosol formation over the Swiss Plateau is NO_x -limited in both seasons.

Acknowledgements. We thank MeteoSwiss, FUB, UBA, TNO, INFRAS, METEOTEST, EMPA, R. Alfara and J. Sandradewi for providing various data. The post-processing software provided by M. Tinguely is gratefully acknowledged. We also thank the European Centre for Medium-Range Weather Forecasts (ECMWF) for allowing the use of its Mozart data. This study was financially supported by the Swiss Federal Office of Environment (FOEN).

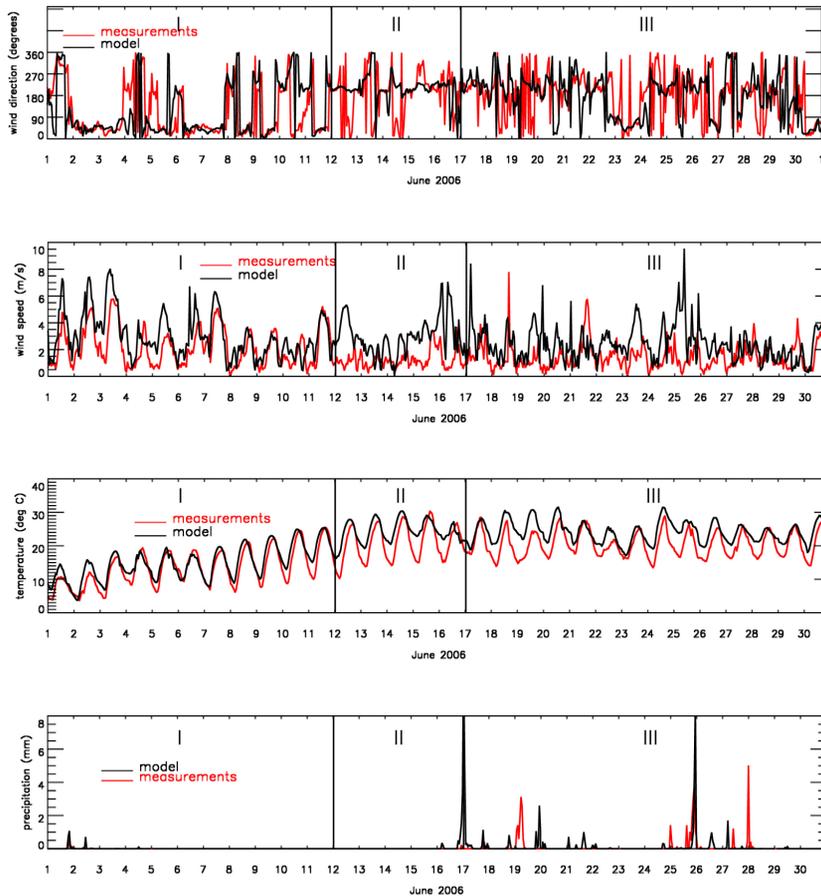

Fig. 6. Comparison of measured and modelled wind direction (deg), wind speed (m s^{-1}), air temperature ($^{\circ}\text{C}$) and precipitation (mm) at Payerne (NABEL station) in June 2006.

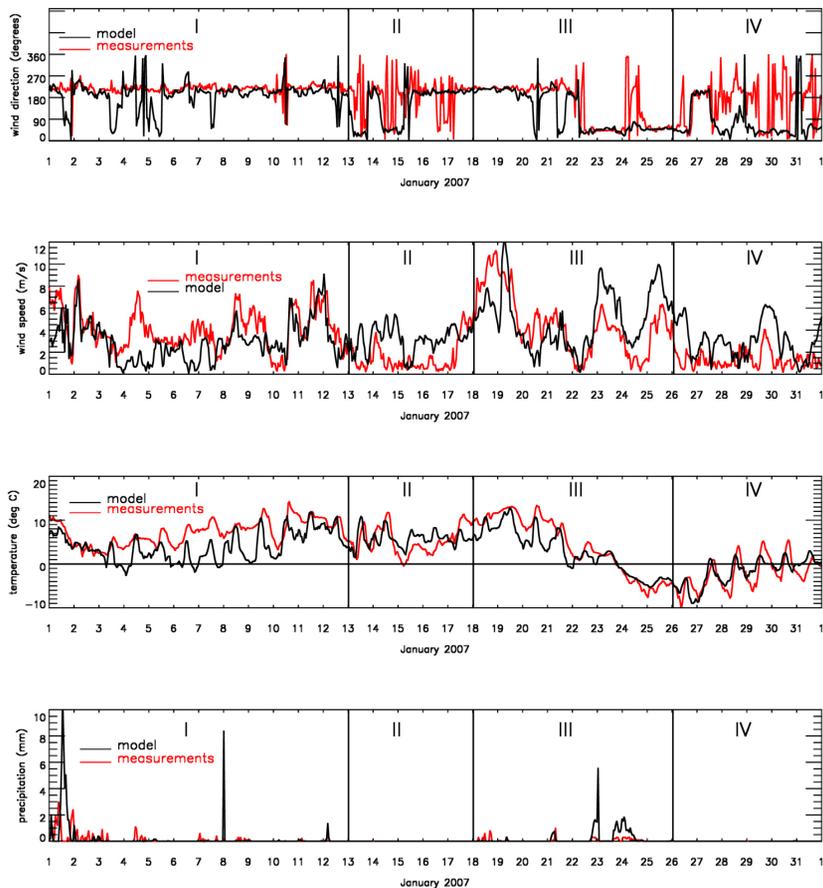

Fig. 7. Comparison of measured and modelled wind direction (deg), wind speed (m s^{-1}), air temperature ($^{\circ}\text{C}$) and precipitation (mm) at Payerne (NABEL station) in January 2007.

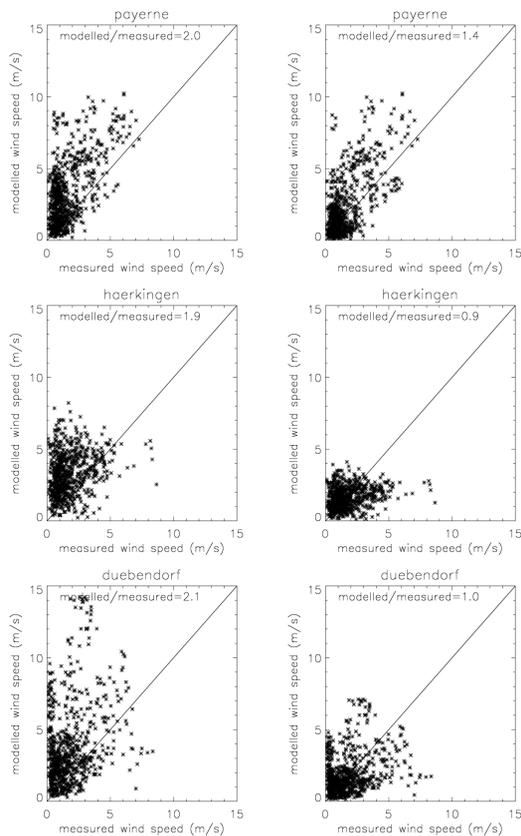

Fig. 8. Comparison of modelled and measured wind speed at Payerne (rural) in January 2006 (top), at Haerkingen (motorway) in June 2006 (middle) and at Duebendorf (suburban) in January 2007 (bottom), before (left) and after the adjustment (right). The term modelled/measured in each plot represents the slope of the correlation.

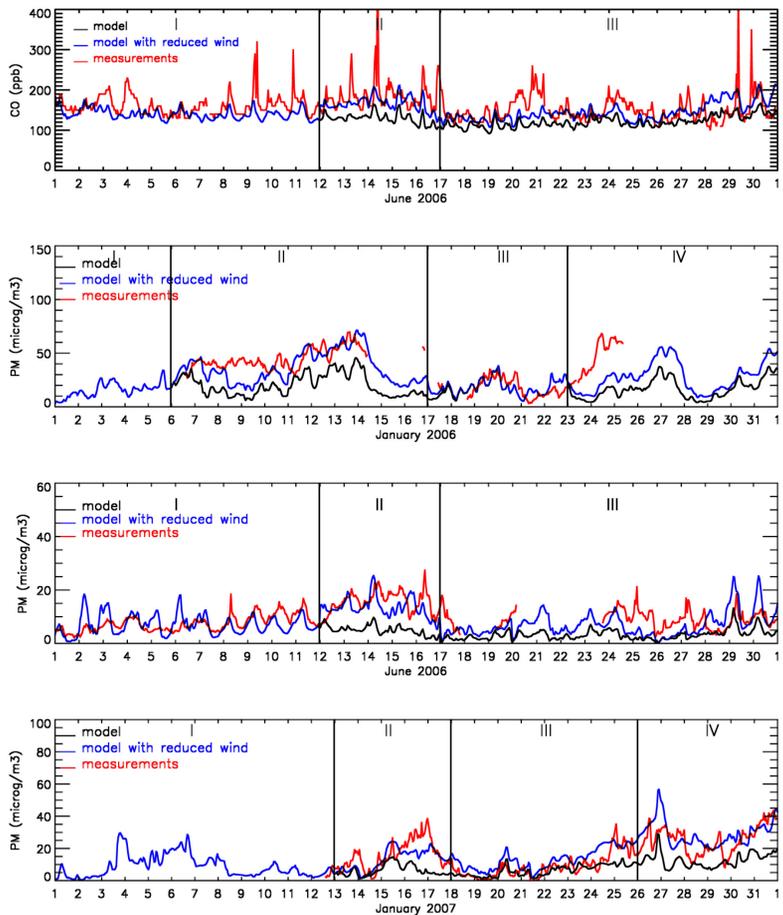

Fig. 9. Effect of reduced wind speed on CO in June 2006 (Payerne), and on PM in January 2006 (Zurich), June 2006 (Payerne), January 2007 (Payerne).

Aerosol modelling in Europe with a focus on Switzerland

S. Aksoyoglu et al.

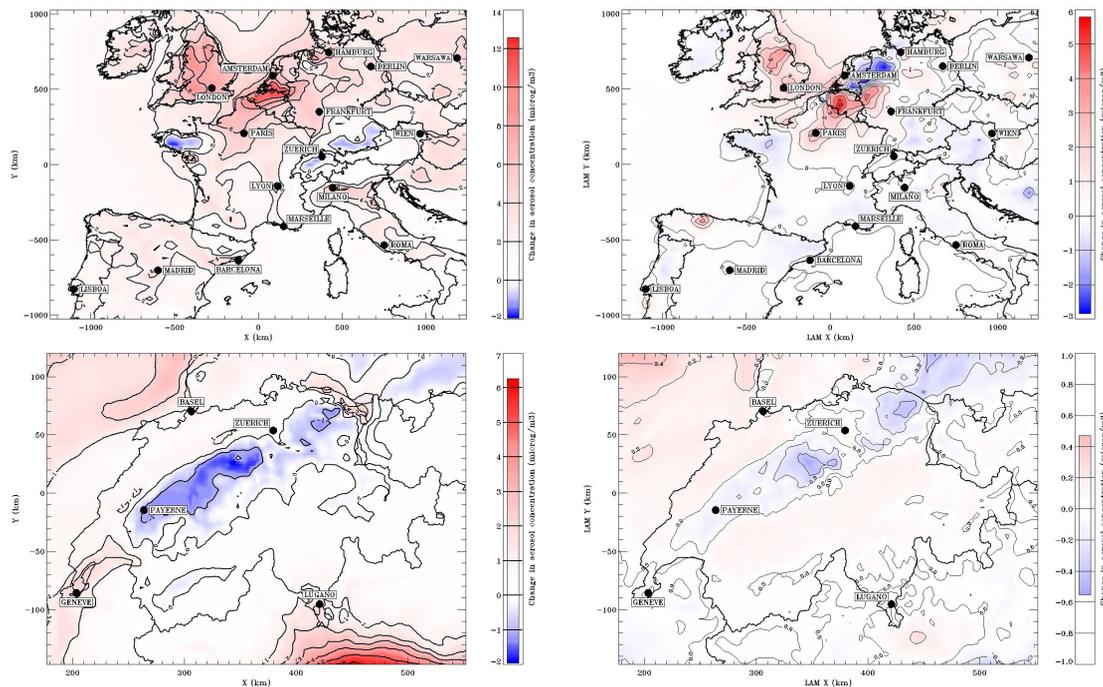

Fig. 20. Difference in monthly average aerosol concentration ($\mu\text{g m}^{-3}$) between two simulations with a 50% emission reduction of either NO_x or NH_3 in January 2006 (left) and in June 2006 (right) for both European (top) and Swiss (bottom) domains. Aerosol formation is more sensitive to NO_x emissions in blue regions and more sensitive to NH_3 emissions in red regions.
