Abstract

Aerosol particles play important roles in regional air quality and global climate change. In this study, we analyzed two-year (2011–2013) of measurements of submicron particles (6–800 nm) at a suburban site in western Yangtze River delta (YRD) of East China. The number concentrations (NCs) of particles in the nucleation, Aitken and accumulation modes were 5300 ± 5500, 8000 ± 4400, 5800 ± 3200 cm⁻³, respectively. Number concentrations and size distributions of submicron particles were also influenced by long-range and regional transport of air masses. The highest and lowest accumulation mode particle number concentrations were observed in air masses from YRD and coastal region, respectively. Continental air masses from inland had the highest concentrations of nucleation mode particles. New particle formation (NPF) events, apparent in 44% of the effective measurement days, occurred frequently in all the seasons except winter. Radiation and pre-existing particles were found to be the main factors influencing the occurrence of NPF events. The particle formation rate was the highest in spring (3.6 ± 2.4 cm⁻³ s⁻¹), whereas the particle growth rate had the highest values in summer (12.8 ± 4.4 nm h⁻¹). The formation rate was typically high in relatively clean air masses, whereas the growth rate tended to be high in the polluted YRD air masses. The frequency of NPF events and the growth rate showed a strong year-to-year difference. In the summer of 2013, associated with a multi-week heat wave and photochemical pollution, NPF events occurred more frequently and the growth rate was much higher than in the same period of 2012. The difference in the location and strength of sub-tropical High, which influences the air mass transport pathways and solar radiation, seems to be the driving cause for year-to-year differences. This study reported the longest continuous measurement records of submicron particles in the East China and gained a comprehensive understanding of the main factors controlling the seasonal and year-to-year variation of the aerosol size distribution and NPF in the East China. The work highlights the importance and need for long-term measurements in understanding the atmosphere system and the impact by human activities.
1 Introduction

Atmospheric aerosols affect human life by influencing both air quality and climate (e.g. Charlson et al., 1992; Menon et al., 2002; Akimoto, 2003; Heal et al., 2012; IPCC, 2013). Fine particles, especially the submicron ones, have received lots of attention due to their close connection to climate via light extinction (Malm et al., 1994), cloud droplet activation (Kerminen et al., 2005; Wiedensohler et al., 2009; Sihto et al., 2011) and precipitation formation (Gettelman et al., 2013; Lebo and Feingold, 2014), as well as due to their adverse effects on human health (Pope et al., 2002; Rao et al., 2012).

In view of the above, numerous studies have been conducted all over the world focusing on the characters of submicron particles, including their chemical composition and size distribution as well as their formation and growth in the atmosphere (e.g. Woo et al., 2001; Birmili et al., 2003; Engler et al., 2007; Zhang et al., 2007; Dal Maso et al., 2008; Laakso et al., 2008; Jimenez et al., 2009; Komppula et al., 2009; Asmi et al., 2011; Kerminen et al., 2012; Vakkari et al., 2013; Kulmala et al., 2014; Nieminen et al., 2014). In China, studies on submicron particles started about a decade ago. However, to the best of our knowledge, there are only three studies in China providing more than one year of measurements of aerosol size distributions, with two of them conducted in North China Plain (Wu et al., 2007; Shen et al., 2011) and one at Mount Waliguan in remote western China (Kivekäs et al., 2009). Therefore, knowledge about the temporal variation of submicron particles and their relationship to the climatology and human activities in China is rather poor, even in some well-developed regions such as Yangtze River Delta (YRD) in East China.

The YRD has experienced rapid urbanization and industrialization in the last two decades, which have induced large amounts of fossil fuel consumption in the region and resulted in serious air pollution (Chameides et al., 2002; Ding et al., 2013a, b; Tie and Cao, 2009; Li et al., 2011). In addition, YRD is a region influenced by typical Asian monsoon, which dominates the temporal and spatial variations of particles (Qian et al., 2003; Ding et al., 2013a). However, previous studies on aerosols in this region were
mainly on mass concentrations and chemical compositions (e.g. Huang et al., 2012; Cheng et al., 2013; Ding et al., 2013a), but studies on the number concentrations and size distributions were rather limited. In Nanjing, Herrmann et al. (2014) reported the first result of about 4-month data of aerosol size distribution at the SORPES station, a suburban site in Nanjing, and Wang et al. (2014) reported about one month data at another suburban site. Both studies were conducted during the cold season. In other regions of the YRD, Gao et al. (2009) reported an intensive campaign in the early summer of 2005 in Taicang, a small town nearby Shanghai, and Du et al. (2011) reported measurements from October 2008 to February 2009 in Shanghai. These results showed significant differences in both the diurnal patterns and NPF characters between the two seasons, and emphasize the need of continuous long-term measurements on the number size distributions of submicron particles in this region.

In the present study, we report two-year continuous observation of submicron particles (6–800 nm) and related quantities (including trace gases, PM$_{2.5}$ mass and meteorological data) recorded at the SORPES (Stations for Observing Regional Processes of the Earth System) site in suburban Nanjing of western YRD from December 2011 to November 2013. The aim of this work is to characterize the temporal variations of particle number size distributions and occurrence of new particle formation (NPF) in the western part of YRD, and to improve our understanding on the sources and processes influencing the atmospheric aerosol population in the developed region in China.

2 Experiment and methodology

2.1 Site information and measurements

This study was conducted at the SORPES station developed in 2011 (Ding et al., 2013a). The site is located about 20 km northeast of downtown Nanjing (118°57′10″ E, 32°07′14″ N, 40 m a.g.l.). With few local sources within 2–3 km surround, it can be considered as a regional background site in the well-developed YRD of East China. More
details of the site, including trace gas, PM$_{2.5}$ and meteorological measurements, can be found in Ding et al. (2013a).

Size distribution of submicron particles is measured with a DMPS (Differential Mobility Particle Sizer) constructed at the University of Helsinki in Finland. This instrument was also involved in the instrument inter-comparison workshops conducted within the European infrastructure project EUSAAR (European Supersites for Atmospheric Aerosol Research) and ACTRIS (Aerosols, Clouds, and Trace gases Research Infrastructure Network) (Wiedensohler et al., 2012). Before entering the inlet of the instrument, the particles are cut off at 2.5 µm and then dried (using Nafion tube from December 2011 to June 2012 and silica gel dryer after June 2012). The instrument consists of one DMA (Differential Mobility Analyzer) in different flow rates and one CPC (Condensation Particle Counter, TSI Model 3772). The DMA segregates the particles into exact narrow size ranges based on different, narrow ranges of electrical mobilities of charged particles in the electrical field. Equilibrium charge is ensured by two Americium 241 sources (each about 37 kBq) before particles enter the DMA. The DMPS is a flow-switching type differential mobility particle sizer in which two different sample and sheath air flow rates for the DMA are used to cover a wide size range. In the high flow mode, the sample air and sheath air flows are 3 and 20 L min$^{-1}$, respectively, and in the low flow mode they are 1 and 5 L min$^{-1}$, respectively. The high flow mode measures the size from 6 to 100 nm and the low flow mode measures from 100 to 800 nm. The measurement time interval of the instrument is 10 min during which the total particle number concentration are measured by CPC directly and 29 channels (16 for low flow rate and 13 for high flow rate) are scanned. Weekly maintenance, including flow rate adjusting and impactor cleaning, is routinely performed. About the data assimilation in two flow modes and the test of data quality are described in Appendix.

2.2 Calculation of variables characterizing new particle formation

The calculation of particle growth and formation rates along with the condensation sink was made following the procedure described by Kulmala et al. (2012). The growth rate
The formation rate of particles of diameter $d_p$ is obtained from:

$$J_{d_p} = \frac{dN_{d_p}}{dt} + \text{CoagS}_{d_p} \times N_{d_p} + \frac{\text{GR} \times N_{d_p}}{\Delta d_p} + S_{\text{losses}}$$ (2)

where the first term on the right side is the time evolution of the particle number concentration in the size range $[d_p, d_p + \Delta d_p]$. The second term is the coagulation loss approximated by the product of coagulation sink ($\text{CoagS}_{d_p}$) and the number concentration in the size range $[d_p, d_p + \Delta d_p]$. The third term is the growth out of the considered size range where GR is the observed growth rate. The fourth term represents additional losses which were not considered in this study.

Having positive correlation with coagulation sink ($\text{CoagS}$), condensation sink (CS) describes the speed at which condensable vapour molecules condense onto the existing aerosol. It is expressed as:

$$\text{CS} = 4\pi \int_0^{d_p,\text{max}} \beta_m \left(d'_p\right) d'_p N_{d'_p} \, dd'_p = 4\pi D \sum_{d'_p} \beta_m, d'_p \, d'_p N_{d'_p}$$ (3)

where $D$ is the diffusion coefficient of the condensing vapour, $\beta_m$ is a transition-regime correction, $d'_p$ is the discrete diameter and $N_{d'_p}$ is the particle number concentration in respective size bin.
3 Results and discussions

3.1 Particle number concentrations and size distributions

3.1.1 Overall results

Figure 1a shows the averaged particle number size distribution during the studied period. It shows a typical multimodal distribution as a result of combination of three log-normal distributions in the nucleation (6–30 nm), Aitken (30–100 nm) and accumulation modes (100–800 nm). Figure 1b illustrates the average fraction of the particle number, surface and volume concentration in these three modes. It shows features similar to most other continental regions in the lower troposphere, i.e. the nucleation and Aitken mode particles (< 100 nm) dominate the number concentration, and accumulation mode particles control the surface and volume concentration (Raes et al., 2000; Asmi et al., 2011).

As shown in Table 1, the average (± SD) total particle number concentration (NC) over the diameter range 6–800 nm during the two-year period was 19 200 ± 9200 cm$^{-3}$, with the values of 5300 ± 5500 cm$^{-3}$ in the nucleation mode (6–30 nm), 8000 ± 4400 cm$^{-3}$ in the Aitken mode (30–100 nm) and 5800 ± 3200 cm$^{-3}$ in the accumulation mode (100–800 nm), respectively. Compared with the other three reported long-term studies in China, the total particle NC measured at SORPES in Nanjing are comparable to those measured at the urban site in Beijing (about 32 700 cm$^{-3}$ in the size range of 3–1000 nm) (Wu et al., 2008), higher than those measured at a rural site near Beijing (about 11 500 cm$^{-3}$ in the size range of 3–1000 nm) (Shen et al., 2011), and about 10 times higher than those measured at Mount Waliguan, a background site in a remote region of western China (about 2100 cm$^{-3}$ in the size range of 12–570 nm) (Kivekäs et al., 2009). One typical feature of submicron particles at SORPES is the very high concentration of accumulation mode particles, being several times higher than typical concentrations measured in Europe or North America (200 to 2900 cm$^{-3}$).
compared to 5700 cm$^{-3}$ at SORPES in the size range of 100–500 nm) (Stanier et al., 2004; Asmi et al., 2011; Wang et al., 2011).

### 3.1.2 Seasonal variations

The average seasonal variations of the total particle number concentration and number concentrations in the three modes are presented in Fig. 2. During the two-year measurement period, nucleation mode particles had elevated concentrations in early winter and spring. Aitken mode particles show a similar pattern, except that they had a weaker month-to-month variability than nucleation mode particles and peak in summer. Compared with the other two modes, accumulation mode particles showed a weaker seasonal variation with a peak in January and lowest concentrations in July. As accounting for almost 70% of the total particles, the nucleation and Aitken mode particles dominated the seasonal cycle of the total particle number concentration. The exact values and SDs of the particle number concentrations in different seasons are given in Table 1. Seasonally, the nucleation and Aitken mode particles showed the highest concentrations in spring (6200 ± 5900 cm$^{-3}$ and 8500 ± 4000 cm$^{-3}$, respectively), whereas highest concentration of accumulation mode particles were observed in winter (6500 ± 3000 cm$^{-3}$). The geometric mean diameter (GMD) of the particles and condensation sink (CS) revealed also seasonal variation (Table 1), with the highest values observed in winter (97 ± 26 nm, 4.8 × 10$^{-2}$ ± 2.3 × 10$^{-2}$ s$^{-1}$).

Generally, the seasonal patterns of NC of submicron particles at SORPES were related to the long-range transport associated with the Asian monsoon climate and also anthropogenic emissions. Figure 3 presents the seasonal variations of four meteorological variables (temperature, pressure, radiation and rainfall) during the two-year measurement period. In winter, few rains and lower boundary layer favor the accumulation of pollutants and result in high particle loadings. In summer, the dominantly rainy and unstable weather (e.g. convection and monsoon precipitation) leads to low particle number concentrations, especially for accumulation mode particles. Radiation
connected with NPF events and local direct emissions from vehicles influenced the NC of nucleation and Aitken mode particles. In addition, an evident holiday effect can also influence the observed temporal variation. For example, the low particle loadings in all the modes can be identified in February (see Fig. 2) when Chinese have the winter break to celebrate the Spring Festival (Ding et al., 2013a).

Biomass burnings (BB) is an important source of accumulation mode particles in early summer (Ding et al., 2013a, b), so the burning of wheat straw in northern and middle part of East China (Wu et al., 2008; Shen et al., 2010) is the plausible cause for the observed particle NCs peak in June (Fig. 2d). The average NC of accumulation mode particles during BB events in June (BB event is defined as potassium concentration $K^+ > 2 \mu \text{g cm}^{-3}$ and $K^+/\text{PM}_{2.5}$ ratio > 0.02 at SORPES, $K^+$ was measured using MARGA) is $31,700 \text{ cm}^{-3}$, that is almost 5 times higher than the corresponding NC in non-BB event days ($5300 \text{ cm}^{-3}$). Relatively large (> 100 nm) particles are emitted directly from BB (Reid et al., 2005; Li et al., 2007), or formed rapidly after emissions by the combination of NPF and various particle growth processes (Hennigan et al., 2012; Vakkari et al., 2014). Such particles are able to promote atmospheric heterogeneous chemistry by providing a large surface area (Nie et al., 2014), influence the global climate by enhancing the CCN capacity (Hennigan et al., 2012), and even change the everyday weather (Ding et al., 2013b).

### 3.1.3 Diurnal pattern in different seasons

The diurnal cycles of particle number size distributions had similar patterns in spring, summer and autumn, which were connected to the events of new particle formation and growth, showing the typical “banana” shape during daytime (Fig. 4a–c). However, obvious differences could be observed for the starting time and strength of NPF in different seasons. A detailed discussion on NPF events will be given in Sect. 3.2. In winter, direct emissions from vehicles might play a key role in the diurnal cycle of particle number size distributions, such as the peak concentrations in all of the three modes during the rush hours in the morning and late afternoon (Fig. 4d).
In order to investigate the detailed diurnal variations of the particle NCs in different modes, we selected typical seasons of spring and winter to compare their diurnal patterns in the three modes (Fig. 5a–c). For nucleation mode particles, peak concentrations appeared at noontime in spring but at the early morning or later afternoon in winter. The later suggests a possible influence from human activities, such as vehicle emissions under conditions of a low mixing layer. For the Aitken mode particles, in spring the highest concentrations were seen about two hours after the appearance of the peak in the nucleation mode, which was due to the growth of nucleated particles to larger sizes (Fig. 5b). In winter, Aitken mode particles had peaks at the same time or a bit later than what the nucleation mode particle did. The diurnal variation of the accumulation mode particle number concentration (Fig. 5c) was controlled by the development of the boundary layer in both seasons, having a pattern similar to that of the PM$_{2.5}$ concentration (Ding et al., 2013a).

### 3.1.4 The influences of air masses

Figure 6 shows backward trajectory cluster analysis for the SORPES site. Using the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model Version 4.9 (Draxler and Hess, 1998) driven with Global Data Assimilation System (GDAS) output, 5 clusters of trajectories were identified based on hourly 2-day backward trajectories for the period of December 2011–November 2013. The results show that air masses arriving at the SORPES site generally came from the inland continent (C2 and C3, 14.8 and 13.0%, respectively), coastal North China (C1, 30.6%) or Yangtze River Delta (C4 and C5, 41.6% in total). The air mass transport pattern was controlled by Asian monsoon (Ding et al., 2013a), with winter monsoon bringing regional pollution from the North China Plain (C2, C1 and C5) and summer monsoon bringing the YRD regional pollution (C4) or biogenic emissions from the South China to the site (C3). Being located in the most western part of the YRD, SORPES is a unique site to investigate the impact of different regional air masses.
The statistics of the particles number size distributions and diurnal variations of NC in the three modes for the three different air masses (Coastal (C1), Continental (C2 and C3) and YRD (C4 and C5) air masses) are shown in Fig. 7. The coastal air mass had the lowest accumulation mode particle loading during the whole day (Fig. 7d). With low pre-existing particle loading and favorable meteorological conditions, e.g. sunny days with high radiation, NPF events easily occur and cause high amounts of nucleation and Aitken mode particles during the daytime (Fig. 7b and c). The continental air mass had highest levels of nucleation mode particles (Fig. 7b) because such air masses are always associated with sunny days and low humidity. In addition, since the site is located in the northeast of downtown Nanjing, continental C3 air masses generally bring fresh, directly-emitted particles, i.e. Aitken mode particles, to the site. The YRD air masses, passing through the YRD city clusters, always led to the highest accumulation mode particles loadings (Fig. 7d), lowering concentrations of nucleation mode particles (Fig. 7b) via higher coagulation/condensation sinks.

3.2 New particle formation (NPF)

3.2.1 Population statistic about NPF

During the 2-year measurement period, the sampling days were classified into NPF event days, non-event days and no-data/undefined days with the criterion whether a burst occurred for the nucleation mode particles. By following the method used by Dal Maso et. al. (2005) and Kulmala et al. (2012), the event days were further classified into Class I when the formation and growth rate can be calculated with confidence, and Class II when the formation and growth rate cannot be calculated or done in accurate ways.

The numbers of the four types of sampling days are given in Table 2, and the percentage of event days (the ratio of Class I days or Class II days to event days and non-event days) in each month are shown in Fig. 8a. Due to instrument maintenance, data from 111 days of the two-year period were unavailable for the event classification. Only few
of the days at SORPES were considered as undefined days (11 days), for which it was hard to determine whether a NPF event occurred or not. Overall, NPF event days (including Class I and Class II days) accounted for 44% of the analyzed days (sample days excluded no-data/undefined days). This frequency is a bit higher than observed in the other two long-term measurements in China (urban Beijing ∼ 40%, SDZ ∼ 37%).

In spring, summer and autumn, NPF events took place in more than 50% of analyzed days (56, 55 and 50%, respectively), which is more frequent than at other measurement sites in China, including as Taicang (44%), Hong Kong (34%) and Xinken (26%) (Gao et al., 2008; Guo et al., 2012; Liu et al., 2008). In contrast, in winter only 15 NPF event days during two-year measurement period were identified. This frequency is similar to another work in Shanghai (Du et al., 2012), but quite different from that in Beijing where winter is the second season favorable to NPF (Wu et al., 2007; Shen et al., 2011). One explanation for this could be that there are more “clean” days in winter in Beijing because of frequent cold fronts (Wehner et al., 2008). Such fronts were generally not strong enough to improve the air quality in Nanjing. In June, continuous rainy days (“Plum rain” in China) with low radiation also inhibit the NPF events. There was a great difference in the frequency of NPF events in summer between the two years: 41% in 2012 and 66% in 2013 (Fig. 8a).

Figure 8b gives the variability of start and end times of the Class I event days. Since the cut-off diameter of the DMPS was 6 nm, the start and end times were defined here as the times when the 6–7 nm particles started to increase and decrease back to the background level (i.e. ∼ 50 cm⁻³). Generally, the start time was somewhere between the sunrise and midday, and no evident nocturnal events were identified. The seasonal variation of the start time followed that of sunrise, which is similar to reported elsewhere around the world (e.g. Woo et al., 2001; Boy and Kulmala, 2002; Kulmala et al., 2004; Hamed et al., 2007; Wu et al., 2007). However, at some days the start time was just one hour after the sunrise. Most of such events took place in summer and were associated with marine air masses that had been transported over the polluted area in YRD. This topic will be studied further in our future work.
The formation rate of 6 nm particles ($J_6$) and growth rate of 6 to 30 nm particles (GR$_{6-30\text{nm}}$) during the Class I event days are illustrated in Fig. 8c and d. The statistical results are given in Table 2. The formation rates were highest in spring with the value of 3.6 ± 2.4 cm$^{-3}$ s$^{-1}$, followed by summer (2.1 ± 1.4 cm$^{-3}$ s$^{-1}$) and autumn (2.1 ± 1.9 cm$^{-3}$ s$^{-1}$), whereas the lowest formation rates were observed in winter (1.8 ± 1.6 cm$^{-3}$ s$^{-1}$). The maximum formation rate was 10.9 cm$^{-3}$ s$^{-1}$ on 3 April 2013. The observed formation rates are comparable to other measurements in China, e.g. 3.3–81.4 cm$^{-3}$ s$^{-1}$ in Beijing, 0.7–72.7 cm$^{-3}$ s$^{-1}$ at SDZ and 2.2–19.8 cm$^{-3}$ s$^{-1}$ (3 October–5 November 2004) in PRD (for $J_3$), 0.97–10.2 cm$^{-3}$ s$^{-1}$ (25 October–29 November 2010) in Hong Kong (for $J_{5.5}$), and 1.2–2.5 cm$^{-3}$ s$^{-1}$ (5 May–2 June 2005) in Shanghai (for $J_{10}$) (Wu et al., 2007; Shen et al., 2011; Liu et al., 2008; Guo et al., 2012; Gao et al., 2008). Concerning the nuclei growth rates, the highest values of 12.8 ± 4.4 nm h$^{-1}$ were observed in summer, followed by spring (10.0 ± 3.4 nm h$^{-1}$), winter (9.5 ± 3.3 nm h$^{-1}$) and autumn (8.9 ± 2.9 nm h$^{-1}$). The maximum growth rate was 22.9 nm h$^{-1}$, observed on 29 August 2013. The values of growth rates presented in this study for Nanjing are slightly higher than reported for the other two long-term measurements in China, i.e. 0.1–11.2 nm h$^{-1}$ in Beijing and 0.3–14.5 nm h$^{-1}$ with mean value of 4.3 nm h$^{-1}$ at SDZ (Wu et al., 2007; Shen et al., 2011). Condensation sink that tends to limit to NPF, was generally lower on event days compared with non-event days (3.1 × 10$^{-2}$ s$^{-1}$ for Class I, 3.6 × 10$^{-2}$ s$^{-1}$ for Class II, and 4.2 × 10$^{-2}$ s$^{-1}$ for non-event days).

### 3.2.2 Conditions favoring NPF

In Fig. 9, we compare the quantities that may affect NPF between the event (Class I and Class II) and non-event days in different seasons. Precursors, solar radiation and pre-existing particles have been generally considered as the major factors influencing the NPF (McMurry et al., 2005; Kulmala and Kerminen, 2008; Kulmala et al., 2013). As shown in Fig. 9a and d, radiation and O$_3$ concentration were significantly higher on event days than those on non-event days, indicating that the observed NPF events in
YRD were typically photochemical influenced. Higher temperatures and lower RH favored the occurrence of NPF events. A higher temperature may enhance the reaction rates of the chemical processes producing nucleating vapors, and a lower RH may decrease the sink of these vapors as well as the sink of newly-formed molecular clusters. The relation between NPF and PM$_{2.5}$ was quite clear in all the seasons, with lower PM$_{2.5}$ concentrations favoring the occurrence of NPF events (Fig. 9e).

The role of SO$_2$ seemed to be a complex issue in YRD. Generally, high concentrations of SO$_2$, being the precursor for gaseous sulfuric acid, should promote the occurrence of NPF. In this study, SO$_2$ concentrations were higher in event days than in non-event days in both spring and summer, whereas the opposite was seen in autumn and winter. This result was in accordance with our previous study conducted in winter time that suggested NPF to occur preferably under conditions of lower SO$_2$ concentrations (Herrmann et al., 2014). In polluted regions of China, like YRD, SO$_2$ concentrations are generally at a high level with average concentrations of about 10 ppb, which is sufficient and seems not to be a limiting factor for NPF. Instead, the pre-existing particles, e.g. PM$_{2.5}$, play a more important role as coagulation and condensation sink. Given that the SO$_2$ peaks were always accompanied with a high PM$_{2.5}$ concentration in this region, especially in autumn and winter, the observed lower SO$_2$ concentrations in event days in autumn and winter are therefore understandable.

### 3.2.3 Factors influencing formation rate and growth rate

To investigate the factors that influence the formation rate and growth rate, the correlation coefficients of $J_6$, GR$_{6-30 \text{ nm}}$ and CS with meteorological quantities and gaseous pollutants were calculated (Table 3). The correlation coefficients that passed the statistical significance test ($p < 0.05$) were highlighted by asterisk in Table 3. The particle formation rate ($J_6$) was negatively correlated with RH and positively correlated with both radiation and O$_3$. No correlation between $J_6$ and SO$_2$ was seen, which supports the view that SO$_2$ concentrations are not limiting NPF in YRD. The particle growth rate was positively correlated with temperature, RH, radiation, O$_3$ and CS ($p < 0.05$).
Worth noting here is that while lower values of RH and CS appeared to favor the occurrence of a NPF event, higher values of these two quantities clearly favored the particle growth. The scatter plots of \( J_6-\text{RH} \) and \( \text{GR}_{6-30\text{nm}}-\text{RH} \) color-coded with \( \text{O}_3 \) mixing ratio are shown in Fig. 10. The negative correlation between \( J_6 \) and RH did not depend on the \( \text{O}_3 \) concentration (Fig. 10a), whereas for \( \text{GR}_{6-30\text{nm}} \) an obvious difference in the \( \text{GR}_{6-30\text{nm}}-\text{RH} \) slope could be identified for different levels of the \( \text{O}_3 \) mixing ratio (Fig. 10b). A higher slope for high-\( \text{O}_3 \) events suggests a link between the particle growth and photochemical pollutants.

In order to study further the event with high or low value of \( J_6/\text{GR}_{6-30\text{nm}} \), we conducted Lagrangian dispersion modeling for the selected days marked in Fig. 8c and d, by using the method developed by Ding et al. (2013c) based on HYSPLIT model to study the influence of air masses. Figure 11 gives the footprint, i.e. retroplume at an altitude of 100 m, of the selected high and low \( J_6/\text{GR}_{6-30\text{nm}} \) days. Air masses had an obvious influence on the formation rate and growth rate. Most low \( J_6 \) days and high GR days occurred in the air masses passing over the polluted YRD area, while all the high \( J_6 \) days and low GR days appeared in air masses that did not go through the YRD area. This confirms that the polluted YRD plume may inhibit the formation of new particles, yet simultaneously promote the particle growth. In winter when solar radiation is low, no NPF events occurred in the YRD area masses that tend to have high pre-existing particle loadings (Herrmann et al., 2014). Our finding that the polluted YRD plume induces a high GR is consistent with the studies reporting relatively high particle growth rates under urban conditions (Kulmala and Kerminen, 2008; Peng et al., 2014).

### 3.3 Causes on the high frequency of NPF in August 2013

As shown in Fig. 8, a higher frequency of NPF events occurred in July and August of 2013 compared with the same months in 2012. In August of 2013, the frequency of Class I NPF events was highest during the two-year measurement period, with 17 Class I events observed among the 24 analyzed days. Figure 12 shows the time series of particle number size distribution, \( \text{O}_3 \) and \( \text{PM}_{2.5} \) concentrations and radiation.
The daily-average O$_3$ concentration gradually increased in early August with an hourly maximum value up to 165 ppbv on 12 August 2013. Accompanied with this O$_3$ episode, the geometric mean diameter (GMD) of submicron particles and PM$_{2.5}$ concentration also increased (Fig. 12a and b). Interestingly, there were continuously multi-day NPF events in the first half of this month, even during 11–13 August when PM$_{2.5}$ reached 70–80 µg m$^{-3}$. During 17–24 August, there were also notable NPF events. Contrary to this, few NPF took place in August 2012.

Examination of average geopotential height and wind vector at the 925 hPa level during the two Augsts (Fig. 13a) suggests that in 2013 the subtropical (Pacific) High moved more to the west than that in 2012, causing a positive anomaly (high pressure) and anti-cyclone over the Southeast China (Fig. 13b). As a result, the Yangtze River Delta experienced a continuous heat wave with humid and hot air transported from the south and southwest.

In order to further understand the air masses history during the events in 2013, Fig. 14 gives the averaged “footprint” (i.e., 100 m retroplume) for the episode period. The air masses can be divided into three time periods. During 6–11 August, the air masses came from the southwest with high value of BVOCs and they also passed through the downtown of Nanjing. During this period, O$_3$ was produced and accumulated with enough precursors and strong solar radiation. High O$_3$ concentrations also caused a strong atmospheric oxidation capacity, which caused an increase in the GMD of submicron particles together with an increase in the PM$_{2.5}$ mass concentration. On 11 August, the air masses transport pathway was changed, with air masses coming mainly from southeast and the YRD city cluster, which is the most polluted area with high value of anthropogenic VOCs and other pollution gases. Therefore, the O$_3$ concentration continued to increase until 12 August and then maintained a high level until 19 August. A common character of the air masses during both of these two periods was that the air had transported over regions with high biogenic and anthropogenic emissions (see Figs. 6a, b and 14). During 19 to 22 August, the air masses were mainly from northeast and had a high humidity that caused cloudy days with low radiation.
and high wet deposition. The $O_3$ concentration, GMD of submicron particles and $PM_{2.5}$ mass concentration therefore sharply decreased on 19 August.

Despite the high levels of GMD, $PM_{2.5}$ and CS (which is not shown in Fig. 12), Class I NPF events occurred every day during the whole $O_3$ episode (from 4 to 19 August 2013). As the GMD and $PM_{2.5}$ increased, the particle formation rates became lower. This means that the high values of GMD and $PM_{2.5}$ suppressed new particle formation but could not stop the occurrence of NPF event altogether under such an atmospheric condition of a high oxidization capacity. Because of lower pre-existing particle loading after 19 August, new particle formation continued although the radiation intensity and atmospheric ozone oxidation capacity were lower. Another obvious character for the August 2013 was that, during the whole month, the particle growth rate had a relatively high correlation with RH (with $r = 0.54$), supporting the positive correlation between GR and RH illustrated above (Fig. 15).

Here the year-to-year difference in aerosol size distributions and NPF characteristics suggests that large-scale circulations together with meteorological factors had a strong impact on the aerosol number concentration. Extreme meteorological conditions are able to reshape the seasonal profile of the aerosol number concentration and NPF, which means that measurements in a specific year cannot gain a full picture of seasonal profiles. Given the fact that there are only a limited number of measurements covering more than one year, especially in China, this work highlights the importance of long-term continuous measurement.

4 Summary

This study reports a two-year measurement (from December 2011 to November 2013) period of submicron particles (6–800 nm) at the SORPES station located in suburban Nanjing in the western part of YRD, East China, with the aim to characterize the temporal variation of the particle number concentration and size distribution, and to understand the new particle formation occurring in such a polluted monsoon area.
The average total number concentrations was $19,200 \pm 9,200$ (mean $\pm$ SD) cm$^{-3}$, with $5,300 \pm 5,500$ cm$^{-3}$ in the nucleation mode (6–30 nm), $8,000 \pm 4,400$ cm$^{-3}$ in the Aitken mode (30–100 nm) and $5,800 \pm 3,200$ cm$^{-3}$ in the accumulation mode (100–800 nm). Seasonal variations of NC and size distribution were influenced by the Asian monsoon, anthropogenic activities and atmospheric oxidation capacity. The diurnal pattern of the particle number size distribution in winter showed peaks at the normal rush hours, suggesting the source from direct emissions of vehicles. Air mass long-range transportation played clear roles in influencing the particle number concentration: coastal air masses had lowest concentrations of accumulation mode particles but relatively high concentrations of nucleation mode particles, continental air masses had the highest concentrations of nucleation mode particles with frequent new particle formation, and YRD air masses had the highest concentrations of accumulation mode particles and lowest concentration of nucleation mode particles because of the elevated coagulation/condensation sinks.

NPF events were observed on 44% of the analyzed days, with the highest frequency in spring, followed by summer and autumn, but only 15 event days in winter. The average formation rates of 6 nm particles were $3.6 \pm 2.4$, $2.1 \pm 1.4$, $2.1 \pm 1.9$ and $1.8 \pm 1.6$ cm$^{-3}$ s$^{-1}$ in spring, summer, autumn and winter, respectively, and the corresponding particle growth rates were $10.0 \pm 3.4$, $12.8 \pm 4.4$, $8.9 \pm 2.9$ and $9.5 \pm 3.3$ nm h$^{-1}$. The intensity of radiation and loading of pre-existing particles seemed to be the main factors influencing the NPF events. SO$_2$ concentrations in YRD were always sufficient and appeared not to limit NPF. The particle formation rate was negatively correlated with RH and positively correlated with radiation and O$_3$ while particle growth rate was positively correlated with temperature, RH, radiation, O$_3$ and CS. Both particle formation and growth rate depended on the air mass origin, with low $J_6$ and high GR typical for polluted YRD air masses and high $J_6$ and low GR for clean air masses.

The observed frequency of NPF events and particle growth rate in summer showed a strong year-to-year variation under the influence of different large-scale circulations, such as subtropical High. Long-range transport, meteorological parameters and photo-
chemical pollutants promoted the atmospheric new particle formation and growth in the summer 2013 compared with the previous year. To quantitatively understand the processes controlling the aerosol number concentration and size distribution, or to predict their behavior, additional modeling work on NPF that relies on long-term observations should be conducted in the future.

Appendix: Performance of the flow-switching DMPS

The flow-switching DMPS has two flow modes to measure the particles in two size ranges, 6–100 and 100–800 nm, respectively. To assimilate data in the two flow modes, in this study the number concentrations of particles in the size range from 100 to 800 nm were multiplied by a factor to make the particle number size distribution smooth. The correction was done for daily data. The average correction factor was $1.05 \pm 0.11$, which means that in this size range the original inverted number concentrations increased on the average by 5%. The 10th, 25th, 50th, 75th and 90th percentiles of this correction factor were 0.92, 0.96, 1, 1.1 and 1.2, respectively.

The model of CPC used in this study was the TSI 3772 with the 10 nm default cut-off diameter when the condenser temperature is at the default value of 22°C. It was set to 10°C in this measurement, so the temperature difference $\Delta T$ between the saturator and the condenser was higher ($\Delta T > 25^\circ C$) which leads to a higher supersaturation and a lower cut-off diameter. The counting efficiency of 6 nm particles is higher than 75% (Wiedensohler et al., 2012).

The DMPS was set up so that every time before number size distribution measurement, the DMA was by-passed, and total aerosol number concentration was determined directly by the CPC (Yli-Juuti et al., 2009). The average ratio of the total particle number concentration of that integrated from the inverted size distributions and measured directly with the CPC ($N_{\text{DMPS}}$ and $N_{\text{CPC}}$) was $0.90 \pm 0.17$ and the correlation coefficient was $0.91 (p < 1 \times 10^{-6})$. The 10th, 25th, 50th, 75th and 90th percentiles
were 0.71, 0.82, 0.91, 0.99 and 1.06, respectively. These values can indicate that data quality of the DMPS was satisfactory.

Figure A1 shows the scatter plot of $N_{\text{DMPS}}$ and $N_{\text{CPC}}$ color-coded with the geometric mean diameter of the whole particle number size distribution (GMD$_{6–800 \text{ nm}}$). The ratio of $N_{\text{DMPS}}$ to $N_{\text{CPC}}$ was low when the GMD$_{6–800 \text{ nm}}$ was small but close to 1 when the GMD$_{6–800 \text{ nm}}$ was large. As the small GMD$_{6–800 \text{ nm}}$ corresponds to new particle formation events with a high concentration of nucleation mode particles, the lower $N_{\text{DMPS}}$-to-$N_{\text{CPC}}$ ratio suggests that the DMPS (including the inversion) may have underestimated the concentration of them. This is in line with the inter-comparison study presented by Wiedensohler et al. (2012) where it was found that the largest uncertainties of the size distributions were in the nucleation mode.
