Abstract

The present paper investigates the diurnal and seasonal variability of the aerosol total number concentration, number and volume size distribution between 10 nm and 10 µm, from a combination of a scanning mobility particle sizer (SMPS) and an optical counter (OPC), performed over a two-year period (May 2006–May 2008) at the Nepal Climate Observatory-Pyramid (NCO-P) research station, (5079 m a.s.l.). The annual average number concentration measured over the two-year period at the NCO-P is 860 cm$^{-3}$. Total concentrations show a strong seasonality with maxima during pre-monsoon and post-monsoon seasons and minima during the dry and monsoon seasons. A diurnal variation is also clearly observed, with maxima between 09:00 and 12:00 UTC. The aerosol concentration maxima are mainly due to nucleation processes during the post-monsoon season, as witnessed by high nucleation mode integrated number concentrations, and to transport of high levels of pollution from the plains by valley breezes during the pre-monsoon season, as demonstrated by high accumulation mode integrated number concentrations. Night-time number concentration of particles (from 03:00 to 08:00 NST) are relatively low throughout the year (from 450 cm$^{-3}$ during the monsoon season to 675 cm$^{-3}$ during the pre-monsoon season), indicating the level of free tropospheric background, as a result of downslope winds during this part of the day. However, it was found that these background concentrations are strongly influenced by the daytime concentrations, as they show the same seasonal variability. The resulting free troposphere (FT)/residual layer concentrations are found to be two times higher than at other lower altitudes European sites, such as the Jungfraujoch. Night-time measurements were subsequently selected to study the FT composition according to different air masses, and the effect of long range transport to the station.
1 Introduction

Rapid economic growth in the Asian regions, in particular China and India, is causing strong air pollution problems that are not confined to urban and sub-urban areas, but involve a large fraction of the Asian continent, hosting over 4 billion people. In particular, anthropogenic emissions of particles and particle precursors from industry, transport and incomplete fossil fuel combustion are rising rapidly (Richter et al., 2005; Ramanathan et al., 2008), leading to great concern about their impact on air quality and climate. It is estimated that air pollution exceeding WHO guidelines causes more than 500 000 premature deaths in Asia annually, in particular in the large Asian cities (reference). However, air pollution, in particular the particulate fraction, also affects the atmospheric energy budget with significant impacts on regional climates and precipitation dynamics.

This layer of particulate pollution that can be observed also from satellites is often referred to as brown cloud (Lelieveld et al., 2001; Nakajima et al., 2007; Ramanathan et al., 2007a, b). Brown clouds generally denote anthropogenic aerosols that not only scatter, but also absorb solar radiation due to black carbon, dust and other absorbing materials. Over the past decade, considerable research investment has begun in Asia, bringing large-scale international and national regional experiments, such as INDOEX, (Indian Ocean Experiment), ACE-Asia (Aerosol-Cloud Experiment Asia) and ABC (Atmospheric Brown Cloud), studying precursor gases and aerosol. Such experiments have led to a much better assessment of aerosol impact on the atmospheric radiative balance and the development of the Indian monsoon, as well as impacts on agriculture and human health. The water cycle dynamics and surface energy feedback appear to be triggered by aerosol direct effects (Hansen et al., 2000; Ramanathan et al., 2001). Ramanathan et al. (2005) showed that the blocking of solar radiation reaching the surface by aerosol induces Earth surface cooling, leading to a gradual spin-down of the tropical water cycle, and the eventual weakening of the Asian monsoon. Aerosols can, therefore, affect the cloud-radiation feedback, with impacts on land-atmosphere inter-
actions and precipitation in the Indo-Ganges Basin and the Himalayas. Work performed within INDOEX revealed that this haze layer can be efficiently transported far beyond the source region (Clarke et al., 2002), in particular as far as the high altitude region of the Himalayas. Atmospheric aerosols emitted in the Indian plains and lofted into the mid- and upper-troposphere by (vertical . . . thermal) wind are efficiently stacked up towards the southern foothills and slopes of the Himalayas, rising to higher altitudes and reaching the Tibetan Plateau.

In order to provide reliable estimates of the impact of particles on air quality and climate, information on source emissions and temporal and spatial variability of their chemical, physical and optical properties, are urgently required. The ABC project of the United Nation Environmental Program (UNEP) has been coordinating a network of stations in Asian countries on the Indian and Pacific oceans, with the aim of monitoring the extension and composition of atmospheric brown clouds. Most of these stations are located in coastal or island environments, providing little information on the aerosol concentrations in the higher Himalayan mountain environments. Lack of direct information on the nature of aerosol particles sampled in the high altitude regions is, therefore, still limiting the more precise quantification of aerosol impact on the atmospheric energy budget, especially far from emission sources.

The atmospheric impact of this changing area is, in fact, best evaluated by long term measurements, located at a background site not influenced by local pollution. While pollutants are released from different sources with a high time variability, and interact with each other in a complex manner, observations of seasonal and diurnal pollutant variations at a remote high altitude site provides insight on the horizontal and vertical extent of the anthropogenic influence on the broader regional and global atmospheric scale.

Particle size distribution and number concentration of are among the major aerosol parameters constraining (1) aerosol radiative forcing, as they directly relate to the optical properties of an aerosol population, (2) cloud forming capacity of an aerosol population, as they directly relate to the number of available cloud condensation nuclei.
Aerosol number size distributions have been characterized at other high altitude stations, by Raes et al. (1997) at the Izana station (m.a.s.l.), Weingarter et al. (1999) and Nyeki et al., 1998 at the Jungfraujoch station in the Swiss Alps, (3450 m a.s.l.) and, more recently, at Mt. Norikura (2770 m a.s.l.), Japan (Nishita et al., 2007), at the top of Mount Lemnon (2790 m) in Arizona, USA (Shaw, 2007), puy de Dôme, central France (1465 m) (Venzac et al., 2009) and Monte Cimone, Italian Northern Apennines (2165 m) (Marinoni et al., 2008). The only information available for Asia concerns Mt. Waliguan (3816 m), inland China (Kivekäs et al., 2009) and the study of Komppula et al. (2009) at the Mukteshwar station (2180 m), in Northern India. Of all the studies listed above, only a few report long-term records allowing for seasonal variation analysis.

The objective of the present paper is therefore to report and analyze a unique data set of aerosol size and number concentration measured at the 5079 m a.s.l. Himalayan Nepal Climate Observatory-Pyramid (NCO-P) site over a two-and-a-half-year period. The measurements are used to characterize aerosol variability far from local sources and, in particular, its seasonal variability. Additional classification using air mass back-trajectories is subsequently used to provide a robust statistical description of aerosol physical properties.

2 Site Description and instrumental set-up

The NCO-P (Nepal, 27.95 N, 86.82 E,) is described in detail by Bonasoni et al. (2010). Here, only information relevant to the scope of the present paper will be provided. NCO-P is located in the Khumbu valley at 5079 m a.s.l., ideally situated between China (CCN), and (3) the health impact of aerosols, as they provide useful information on the lung-penetrating fraction of the aerosol population. An accurate knowledge of long-term particle number and size variability is therefore clearly relevant to aerosol and climate sciences. In particular, very little information exists to date from Asian remote sites, especially for the high altitude regions of the Himalayas.
and India to study the long-range and regional transport of anthropogenic pollutants. The station is equipped to perform continuous measurements of chemical (organic and inorganic, soluble and insoluble), physical (mass and number size distribution) and optical (absorption and scattering coefficients) properties of aerosol. The aerosol size distribution is measured with the scanning mobility particle sizer (SMPS) technique using a TSI Inc. 3010 Condensation Particle Counter and a custom-made Differential Mobility Analyzer (Villani et al., 2008) assembled, tested and quality controlled according to EUSAAR recommendations (http://www.eusaar.net/). Calibration of the SMPS is performed once a year during the annual station maintenance campaign, using calibrated latex spheres (from 100 to 400 nm) directly nebulized into the SMPS inlet. Good agreement between expected and measured particle sizes has been consistently found since the beginning of operations. Measurements were performed with a two-minute resolution from March 2006 to August 2008 without instrumental failures except during the summer 2006 (06/08 to 17/09).

Supermicron size distributions were acquired with an optical particle counter (OPC) GRIMM 190 over the diameter range 0.25–32 µm. SMPS and Grimm 190 size distributions were merged, using the SMPS size distributions up to 405 nm and Grimm data beyond this size. Number size distributions were fitted to a sum of log-normal distributions, the nucleation mode geometric mean diameter being between 15 and 27 nm, the Aitken mode geometric mean diameter between 35 and 65 nm and the accumulation mode geometric mean diameter between 110 and 200 nm. Because the various impacts of particles (direct and indirect radiative impact, deposition on the snow surface, etc.) should be calculated under the local atmospheric conditions, concentrations are given, unless mentioned otherwise, at the local pressure, whose seasonal average varies between 550 hPa during the dry season and 553 hPa during the monsoon and post-monsoon seasons.

As explained in detail by Bonasoni et al. (2010), meteorological conditions at the station are driven on the seasonal scale by the monsoon activity, and on the diurnal scale by thermal wind developments in the valley. On an annual time scale, the site
is under the influence of the Indian summer monsoon from the beginning of June until September, while the winter season lasts from December to February (Bollasina et al., 2002). Onset and offsets are described in detail with their year to year variability for the 2006–2008 period in Bonasoni et al. (2010). The station is located at the uppermost point of a valley, with mountain and valley winds whose strength varies according to the time of the day and the season. A strong valley wind (S–SW) prevails during the afternoon, and a weaker down-slope breeze prevails during night-early morning. Compared to the other seasons, the monsoon season is characterised by a weaker mountain breeze and lower diurnal variations of temperature, due to the frequently cloudy conditions occurring at the measurement site (Bollasina et al., 2002; Bonasoni et al, 2010). As a result of valley wind circulation, aerosol particles transported from lower altitudes in the valley are expected to reach the measurement site during the day, and free tropospheric aerosol particles to be transported there during the night.

3 Results

3.1 Seasonal variation of total number concentration

3.1.1 Seasonal variability analysis

Integration of the SMPS and OPC size distributions gives access to the total number concentration of particles from 10 nm up to 32 µm (CN\text{tot}). The annual average number concentration measured over the two-year period at NCO-P is 860±55 cm\(^{-3}\). The variability of CN\text{tot} during the considered observation period is shown Fig. 1. In the figure, the record is split between daytime (hereinafter defined from 10:00 to 18:00 Nepal Standard Time (NST) and nighttime concentrations (from 03:00 to 08:00 NST). The monthly mean concentrations of particles at NCO-P during daytime vary from 840 cm\(^{-3}\) (monsoon season) to 1500 cm\(^{-3}\) (pre-monsoon season), with an averaged yearly concentration of 1300 cm\(^{-3}\). During nighttime, concentrations are lower, varying from 450 cm\(^{-3}\) to 6544 cm\(^{-3}\).
(monsoon season) to approximately 675 cm$^{-3}$ (pre-monsoon season), with an averaged concentration of 580 cm$^{-3}$, 50% lower than daytime concentrations regardless of season.

CN$_{tot}$ shows two clear yearly maxima, observed for both daytime and nighttime concentrations: one during the pre-monsoon season, the other during the post-monsoon season. The seasonal variations are obviously different from those observed in more temperate regions, where only one maximum is often observed during the summer period, due to a higher frequency of boundary layer air masses reaching the sites during warm seasons (Nyeki et al., 1998; Marinoni et al., 2008; Venzac et al., 2009).

The variability of the monthly mean and the day/night difference are the result of several factors. The first is related to the variability of the regional PBL dynamics characterizing the Himalayan foothills, which does not reach high altitude sites with the same frequency throughout the year, the second is the seasonality of the regional PBL concentrations themselves, and the last is the occurrence of new particle formation (NPF) events, which might be promoted by thermal wind circulation and high altitude photochemistry.

Particle nucleation events at NCO-P have been discussed in detail by Venzac et al. (2008), showing that NPF events take place very frequently at NCO-P and throughout the valley. Such events are favored by sunny conditions and take place in the morning hours (09:00–11:00 NST) simultaneously with the local wind shift from downslope to upslope conditions. This effect clearly contributes to increasing daytime CN$_{tot}$ concentrations with respect to nighttime. Because the frequency and intensity of NPF events change according to season, the monthly averaged record is unevenly affected by this feature. The seasonality of the NPF event frequency shows high frequency during the port-monsoon season, and also, surprisingly, during the monsoon season (Venzac et al., 2008). The contribution of NPF events to the total aerosol number concentration will be further discussed in Sect. 3.2., dealing with size distributions.

Moreover, upslope thermal winds bringing air from the polluted Nepal plains (Panday et al., 2009; Bonasoni et al., 2010) also contribute to higher concentrations during
Our observations are in agreement with those of Kompulla et al. (2009), who observed at Mukteshwar station, located in the Indian foothills of the Himalayas, the lowest particle number concentrations during the rainy season and highest ones during the pre-monsoon season. The main reason for the low monsoon total number concentrations is the very efficient washout of particles by rain before they reach the measurement station. This effect would best be observed on the accumulation mode particles. In fact, Nishita et al. (2007) observed at Mt Norikura, in Japan, a clear decrease of the number concentration of particles in the accumulation mode, linearly correlated with the cumulative precipitation amounts during the 24 h preceding the sampling time. The decrease in particle number concentrations of the accumulation mode were found to be mostly explained by incloud scavenging at Mt Norikura, and could therefore be one of the causes of the low concentrations observed in the present study during the monsoon season. It cannot be excluded that additional, although minor loss results from inadequate sampling of cloud drops during cloud formation at the station, since the SMPS measurement line is not equipped with a whole air inlet. The good agreement in seasonal variations of the total particle concentrations between the NCO-P and Mukteshwar stations may indicate an efficient transport of pollution aerosols from the valleys to extremely high altitudes. However, regional pollution aerosols are mostly found in the accumulation mode, and a detailed investigation of their contribution to the total aerosol number concentrations will be performed to confirm or disprove this hypothesis in Sect. 3.2.

The last effect is linked to atmospheric dynamics. The development of the PBL height over the Indian plains is favored during warm periods, and is minimum during the cold seasons. When the PBL height is low, it less frequently reaches high altitude sites, where minimum aerosol concentrations are everywhere recorded during winter. In fact, relatively low particle concentrations were also observed during the cold dry season. Contrary to European high altitude stations, however, the summer period (monsoon) is not characterized by the highest concentrations. In fact, over South Asia, PBL height has a pronounced seasonal variation, with highest values during the pre-
monsoon (e.g. Vernekar et al., 2003), which could also partly explain the high pre-monsoon total number concentrations observed at NCO-P.

3.1.2 Comparisons with total number concentrations at other altitude sites

Yearly averaged particle concentrations can be compared to other high altitude sites. In order to do so, in this Sect. 3.1.2 the concentrations are corrected to the sea level pressure, i.e. 1013 hPa, for NCO-P and all other high altitude sites. After pressure correction, the NCO-P average median concentration is 1580 cm\(^{-3}\). From measurements performed in the foothills of the Indian Himalayas at the Mukteshwar station (2180 m a.s.l.), Komppula et al. (2009) reported an average particle (10–800 nm) number concentration more than two times higher (3480 cm\(^{-3}\)) than NCO-P. Still on the Asian continent, at Mount Waliguan (3816 m a.s.l.), the yearly median total concentrations are very similar to those sampled at Mukteshwar, reaching 3280 cm\(^{-3}\) (Kivekäs et al., 2009). The lower height of these stations compared to NCO-P implies that the PBL air is sampled more frequently, influencing the average yearly concentrations. In addition, both stations are also closer to major pollutant source areas.

In Europe, yearly averaged CN\(_{\text{tot}}\) seem to be ubiquitously lower at different mountain sites (i.e. possibly in the free troposphere). At Jungfraujoch the annual average number concentration of particles (10–750 nm) is 900 cm\(^{-3}\) (Weingartner et al., 1999), while at the puy de Dôme (1465 m a.s.l.), whose lower altitude permits PBL air to be sampled more frequently, the yearly average concentration is 3080 cm\(^{-3}\). In order to exclude the direct influence of PBL, the sampling period considered was when the altitude sites were presumably in the free troposphere, i.e. at night (03:00–08:00 NST).

The average night-time yearly concentration measured at NCO-P is 1050 cm\(^{-3}\). It was calculated from Komppulla et al. (2009) that the average seasonal concentration at night varies from about 1500 cm\(^{-3}\) during the monsoon season to about 4500 cm\(^{-3}\) during the pre-monsoon season, with a yearly average of 2600 cm\(^{-3}\) at the Mukteshwar station at 2180 m asl. Such values are still significantly higher than the ones measured at NCO-P, but the Mukteshwar station, despite its high altitude, seems to be frequently...
located within the PBL, even at night (Hyvärinen et al., 2009). At puy de Dôme, CN-tot varies between 700 cm\(^{-3}\) during winter to 2700 cm\(^{-3}\) during summer for nighttime conditions, while the yearly nighttime concentration is 1400 cm\(^{-3}\). At this altitude, the site is not fully in the free troposphere at night, but still in the residual layer (Venzac et al., 2009). At Jungfraujoch, nighttime CN-tot is 461 cm\(^{-3}\) (Nyeki et al., 1998), which is roughly two times lower than the concentrations measured at NCO-P, despite its lower altitude. At the top of Mt. Lemnon, Arizona, Shaw (2007) measured a mean particle number concentration of 1465 cm\(^{-3}\) in the size range (12–390 nm) during late winter and spring (February–May) at night time, when conditions are expected to represent the free troposphere. This average concentration is significantly higher than the one reported here for NCO-P, although similar to those reported for puy de Dôme. The relationships between stations, even when located in the free troposphere, are not straightforward when considering only total number concentrations. It can be said, however, that altitude is not the only factor influencing the CN-tot background in the free troposphere. The analysis of the size distributions will contribute to a better understanding of these connections, and of the seasonal variations observed in the total number concentrations.

3.2 Daily variation of size distributions

Geometric mean diameters are reported Table 1. According to the different seasons and night/day data sorting, the number size distributions peak at 15–27 nm for the nucleation mode, 35–68 nm for the Aitken mode and 110–200 nm for the accumulation mode particles.

While Komppula et al., 2009 report size distributions dominated by the accumulation mode except during the rainy season, at NCO-P a very important presence of the Aitken and nucleation modes is observed, during both valley and mountain breezes, except during the pre-monsoon season, when the accumulation mode dominates. Consequently, except for the pre-monsoon season, it is concluded that PBL aerosols might only partly contribute to the aerosol load sampled NCO-P.
As detailed in Venzac et al., 2008, the diurnal variation of the aerosol number concentration shows a clear increase onset around 09:00 NST for all seasons, which can lead to a multiplication by 2 to 4 of the concentrations. The resulting daily total number concentrations are found to be surprisingly high for this high altitude, with a mean hourly value peaking at 2000 cm$^{-3}$ during the post-monsoon season at noontime. The size of the particles responsible for this increase in concentrations appears to be the smallest detectable by the SMPS (10 nm) at the onset of the increase, with a growth in size later in the day, up to 50 nm, i.e. the nominal size of the Aitken mode found at night in the free troposphere in the area. NPF has been identified as one of the processes responsible for the aerosol number concentration increase during the day (Venzac et al., 2008), and seems to be responsible for the total particle concentration increase observed during the post-monsoon season, as also suggested by nucleation mode integrated concentrations three times higher than during the dry season (Table 1). In fact, NPF frequency was found to be high during the post-monsoon season.

Nucleation mode particles are suspected to form along the valley and up to 5079 m a.s.l., due to the transport of precursor gases reacting by photochemistry. Komppula et al., 2009 instead found that nucleation mode particle concentrations at Mukteshwar were highest during the pre-monsoon season. Because Mukteshwar is located at the foot of the Indian Himalayas, nucleation mode particles produced at lower altitudes, with highest efficiency during spring, can be transported to NCO-P, where they are sampled after a continuous growth up to Aitken size. At NCO-P, it was shown that nucleation was a high altitude process (Venzac et al., 2008), which seems to be triggered by valley breezes, and not transported by valley breezes. Hence NPF at NCO-P does not coexist with NPF at lower altitudes.

Although NPF occurs only during the day, the nucleation mode integrated concentrations remain high during the night. This could indicate that nucleation processes occurring during the uplift of air masses from the valley are feeding the free troposphere during the day, involving higher concentrations also at night in the FT during the post-monsoon season. Recent work by Spracklen et al. (2009) shows, in fact, that...
the seasonal CN cycle observed at field stations worldwide is better simulated by including particle formation mechanisms than by increasing the number emission from primary sources.

The causes of the high particle concentrations of observed during the pre-monsoon season are various. Indeed, the nucleation mode integral concentrations are not as high during the pre-monsoon season than during the post-monsoon season. The reason why nucleation is promoted during the post-monsoon season rather than the pre-monsoon season, which exhibits the same level of radiation, is probably due to the lower accumulation mode detected by the SMPS, and hence a lower condensational sink promoting nucleation (Kerminen et al., 2001) during the post-monsoon season.

It is here confirmed that the pre-monsoon season is not favourable to nucleation, in view of the fact that the highest volume concentrations are calculated for that season (Table 2). It was found that the high pre-monsoon number concentrations are mainly attributed to high accumulation mode integral number concentrations, which are significantly higher than during the dry season (Table 1). In fact, during the pre-monsoon season, the high particle number concentrations observed in the late afternoon are partly due to the transport of accumulation mode particles (about 150 nm). Accumulation size particles are evidence of long-range transport, particles of this size having been formed and later on transformed by cloud processing, or aged by photochemical formation of particulate matter. Black carbon, a tracer for combustion processes, was observed to increase at the same time as the accumulation mode particle number concentrations during the pre-monsoon season. Moreover, it was also found in the present study that the coarse mode particle volume increased during the pre-monsoon season (Table 2), as also shown by Marinoni et al. (2010). The transport of accumulation and coarse mode particles is best illustrated by the volume size distributions, shown in Fig. 2, where it is very clear that accumulation mode particle volume increases during the late afternoon hours, especially during the pre-monsoon season. The same is observed for coarse mode particle mass, representative of dust, for all seasons except for the monsoon (Marinoni et al., 2010). During the pre-monsoon season, the
transport of regional/long-range polluted aerosols to the high glacier-altitudes in the Himalayas could have significant impacts on the local radiative balance (Marcq et al., 2010; Yasunari et al., 2010).

During the monsoon season, the coarse mode particle volume increases during nighttime. This observation is probably due to the cloud droplet scavenging of large particles by clouds during the day, which form more frequently at the station during daytime hours during the monsoon season, favored by thermal circulation and forced convection. Aerosol scavenging by cloud droplets is also clearly seen on the daytime accumulation mode particle integrated volume concentrations, which are lowest during the monsoon season. However, accumulation mode integrated number concentrations remain reasonably high during the monsoon season, compared to the other seasons, possibly because only the larger particles of the accumulation mode are activated in cloud droplets, or because new accumulation mode particles are generated along the valley trajectory path after the atmosphere is washed out. Such hypotheses are confirmed by the lower geometric mean diameter of the accumulation mode particles during the monsoon season (Tables 1). The monsoon is the only season for which nighttime concentrations are of the same order as the daytime concentrations. Again, this is likely to be due to daytime preferential cloud scavenging compared to nighttime and to the fact that, following Ueno et al. (2008), it is possible that during the monsoon, the nighttime southerly wind are representative for a “large-scale” monsoon circulation and not a mountain breeze. During the monsoon season, the Aitken mode geometric mean diameter is significantly lower than during the other seasons (35 nm against 65 nm). During the monsoon, new particle formation has been shown to be still rather frequent, despite the low radiation levels (Venzac et al., 2008). Hence the small Aitken mode mean geometric diameter possibly indicates the growth of freshly nucleated particles, visible at mid-day in Fig. 2. As a result, during night and day, the Aitken mode integrated number concentrations are the highest than in any other season.

In the following section, select nighttime measurements are chosen as representative of the free tropospheric conditions, to study the impact of the different air mass
origins on particle concentrations and size distributions.

3.3 FT/residual layer number size distributions as a function of the air mass type

Air masses are classified using a clustering method applied to LAGRANTO (Wernli and Davies, 1997) back-trajectories, as detailed in Bonasoni et al. (2010). In order to describe the dominant synoptic-scale circulation and to minimize the interference of local valley circulation, only night-time back-trajectories were considered. In this paper it is shown that SW (South-Westerly) air masses, representing 23.5% of all air masses, can be split into three sub-classes according to the statistical analysis: SW-AP (South Westerly – Arabian peninsula), SW-AS (South Westerly – Arabian Sea). The size distributions observed for the SW-AP and SW-AS sub-classes show sufficient similarities whatever the season to be considered as one single air mass type (SW) in the following discussions. SW-BG (South Westerly- Bengal Gulf) air masses occur only during the monsoon season, in replacement of the SW-AP and SW-AS origins.

Westerly air masses, representing most of the air masses (43.3%), can be also split into three sub-classes: W-NA (Westerly – North Africa), W-EU (Westerly – Europe), and W-ME (Westerly – Middle East). Aerosols found in the W-NA air masses show similarities with those found in the SW air masses, while European and Middle East aerosols show some discrepancies.

Regional (Reg) air masses (32.2%) constitute the third major class of air masses, they differ from other air masses in the fact that they originate at lower altitudes than the other air mass types (Bonasoni et al., 2010).

Within one season, significant differences are observed between aerosol size distributions sampled in different air mass types. High nucleation mode integrated concentrations during the post-monsoon season are mostly observed within the SW air masses (Fig. 3). The SW air masses are no more frequent during the post-monsoon season than during the pre-monsoon and winter seasons. Consequently, it is the conjunction of post-monsoon season and SW air masses which promotes nucleation. The
SW air masses contain the lowest levels of coarse mode PM (Marinoni et al., 2010), which would explain why, in these air masses, the condensational sink is lower and the occurrence of high levels of radiation during the post-monsoon season triggers nucleation.

The high accumulation mode integrated concentrations during the pre-monsoon season are mostly observed among the W-ME and REG air masses (Fig. 3). In the REG air masses, the high accumulation particle concentrations reflect a larger contribution of the pollution aerosol from down the valley, as observed for other pollution tracers, such as BC, which is rather high during this period in REG air masses (Marinoni et al., 2010). In the case of the W-ME air masses, however, the vertical origin is not different from the other air masses. Thus, long distance transport of pollution aerosols seem to impact significantly on the aerosol population during this season, especially when air masses originate from these regions. Also in the other seasons, and especially during the post-monsoon season, Middle East air masses bring high concentrations of accumulation mode particles. In fact, part of these aerosols found in the ME air masses are likely to be submicronic pollution (such as BC, see Bonasoni et al., 2010) or dust, as the coarse mode mass is found to be highest in this air mass as well (Marinoni et al., 2010).

During the monsoon season, all air masses contain particles with a dominant Aitken mode and low accumulation mode particle concentrations, except for REG air masses, in which the accumulation mode integrated concentrations remain high. During the monsoon season, nighttime aerosols are efficiently washed out for all sizes above the Aitken mode, while in regional air masses, accumulation mode aerosol concentrations most probably build up rapidly again from pollution originating from lower altitudes, or the activation diameter is larger because of the large concentrations of particles they contain.

During the winter season, differences between different air mass originating aerosol size distributions are mostly observed in the nucleation and Aitken modes. Western air masses contain high nucleation mode integrated concentrations and low accumulation
mode integrated particle concentrations, while in the SW air masses the opposite is true. The relationships between air mass origin and aerosol number size distributions are the opposite of those observed during the pre-monsoon and post-monsoon seasons (when nucleation is promoted in SW air masses, while high accumulation mode particle number concentrations are observed in W air masses). Hence, a single air mass has different characteristics according to the season.

4 Summary and conclusions

The present work addresses the diurnal and seasonal variability of aerosol particle total number concentration and aerosol size distributions between 10 nm and 10 µm (from a combination between SMPS and optical counter) measured over a two-year period (March 2006–May 2008) at the NCO-P research station (5079 m a.s.l.).

The annual average number concentration measured over the two-year period at the NCO-P is 860 cm$^{-3}$. The integrated number concentrations show a strong diurnal variation with maxima during daytime, as observed for all high altitude stations, and for other aerosol characteristics at NCO-P (Marinoni et al., 2010; Descesari et al., 2010; and Marcq et al., 2010). The daytime maxima are linked to upslope thermal winds, both directly through the transport of pollution aerosols, and indirectly through the formation of new ultrafine particles during transport. These two processes feed the high altitude atmosphere with a contribution which is seasonally variable.

Total concentrations also show a strong seasonality, with maxima during pre-monsoon and post-monsoon seasons and minima during the dry and monsoon season. The dry season minimum is attributed to lower PBL heights involving less air mass export from the lower altitude, while the monsoon minimum is attributed to aerosol scavenging by frequent cloud and rain events. The aerosol concentration maxima are mainly due to nucleation processes during the post-monsoon season, and the transport of higher levels of pollution aerosols by valley breezes in the form of accumulation mode particles during the pre-monsoon season. Nighttime particle number concentrations
(from 03:00 to 08:00 NST) are relatively low throughout the year, indicating the level of free-tropospheric/residual layer background, as a result of down-slope winds during this part of the day. However, the nighttime values follow the daytime concentration seasonal variations, in term of both concentrations and sizes, indicating that the upper troposphere can be fed by thermal winds. In fact, also at Mt Lemmon, Shaw (2007) retains that the aerosols pumped into the free troposphere during the day remain behind at night in residual layers (Shaw et al., 2007). Total nighttime number concentrations are on average two times higher than the ones reported at the Jungfraujoch station, located in the Swiss Alps at a much lower altitude (3450 m a.s.l.). This result would indicate that up to very high altitudes, the Asian atmosphere is more concentrated with aerosol particles than in Europe.

For the purpose of studying the upper troposphere composition according to different air masses, and the effect of long range transport to the station, nighttime measurements have been analysed as a function of air mass back-trajectories. In this way, the possible interferences of local circulation were minimized, as confirmed by the lower fraction of accumulation particles with respect to nucleation, and Aitken modes compared with daytime size distribution.

Middle East and regional air masses seem to be responsible for the high accumulation mode particle integrated concentrations during the pre-monsoon season, as obtained by nighttime FT conditions. Regional air masses originate from lower altitudes, and are probably more influenced by the Asian Brown Cloud than the other air masses, which would explain a more efficient transport of pollution from the Himalayan foothills and Indian Gangetic plains. New particle formation during the post monsoon season is favored under SW air masses, which contain the lowest levels of coarse mode PM.

Acknowledgements. This work was carried out in the framework of the UNEP – ABC (Atmospheric Brown Clouds) and Ev-K2-CNR – SHARE (Stations at High Altitude for Research on the Environment) projects. The contribution of CNRS through the PICS bilateral program between CNR and CNRS and LEFE-INSU program is greatly acknowledged. The authors are also grateful to Michael Sprenger (ETHZ) for providing LAGRANTO back-trajectories based on ECMWF data. We thank Tenzing Chhottar Sherpa, Kaji Bista, Laxman Adhikary, Pema Sherpa,
The publication of this article is financed by CNRS-INSU.
