Abstract

Aircraft observations made off the coast of northern Chile in the Southeastern Pacific (20°S, 72°W; named Point Alpha) from 16 October to 13 November 2008 during the VAMOS Ocean-Cloud-Atmosphere-Land Study-Regional Experiment (VOCALS-REx), combined with meteorological reanalysis, satellite measurements, and radiosonde data, are used to investigate the boundary layer (BL) and aerosol-cloud-drizzle variations in this region. The BL at Point Alpha was typical of a non-drizzling stratocumulus-topped BL on days without predominately synoptic and meso-scale influences. The BL had a depth of 1140 ± 120 m, was well-mixed and capped by a sharp inversion. The wind direction generally switched from southerly within the BL to northerly above the inversion. The cloud liquid water path (LWP) varied between 15 g m⁻² and 160 g m⁻².

From 29 October to 4 November, when a synoptic system affected conditions at Point Alpha, the cloud LWP was higher than on the other days by around 40 g m⁻². On 1 and 2 November, a moist layer above the inversion moved over Point Alpha. The total-water specific humidity above the inversion was larger than that within the BL during these days. Entrainment rates (average of 1.5 ± 0.6 mm s⁻¹) calculated from the near cloud-top fluxes and turbulence (vertical velocity variance) in the BL at Point Alpha appeared to be weaker than those in the BL over the open ocean west of Point Alpha and the BL near the coast of the northeast Pacific.

The accumulation mode aerosol varied from 250 to 700 cm⁻³ within the BL, and CCN at 0.2 % supersaturation within the BL ranged between 150 and 550 cm⁻³. The main aerosol source at Point Alpha was horizontal advection within the BL from south. The average cloud droplet number concentration ranged between 80 and 400 cm⁻³, which was consistent with the satellite-derived values. The relationship of cloud droplet number concentration and CCN at 0.2 % supersaturation from 18 flights is \( N_d = 4.6 \times \text{CCN}^{0.71} \). While the mean LWP retrieved from GOES was in good agreement with the in situ measurements, the GOES-derived cloud droplet effective radius tended to be larger than that from the aircraft in situ observations near cloud top. The
aerosol and cloud LWP relationship reveals that during the typical well-mixed BL days the cloud LWP increased with the CCN concentrations. On the other hand, meteorological factors and the decoupling processes have large influences on the cloud LWP variation as well.

1 Introduction

The marine stratocumulus (Sc) deck overlaying the Southeast (SE) Pacific Ocean is the most persistent in the world (Bretherton et al., 2004) with a monthly stratus cloud amount exceeding 40% throughout the year (Klein and Hartmann, 1993). There have been few observational studies in the SE Pacific until the last decade or so, when several research cruises were conducted to study marine Sc and marine boundary layer (BL) processes in the SE Pacific. The CIMAR-5 (Garreaud et al., 2001), East Pacific Investigation of Climate (EPIC) 2001 (Bretherton et al., 2004), Pan-American Climate Studies (PACS) Stratus 2003 (Kollias et al., 2004), and Stratus 2004 (Serpetzoglou et al., 2008) research cruises explored the BL over the subtropical SE Pacific more than 1000 km offshore. CIMAR-5 provided a transect of the SE Pacific boundary layer at 27°S between the Chilean coast (71°W) and Easter Island (110°W) during late October 1999. It revealed the east-west increase in the BL depth from less than 1000 m near the coast to over 2000 m at the far end of the transect. The other research cruises included 5–6 days of observations at the Stratus Ocean Reference Station (Stratus ORS, 20°S, 85°W) (Cronin et al., 2002; Bretherton et al., 2004; Ghate et al., 2009). The EPIC 2001 observations were made in October – the month with the maximum climatological stratus cloud amount (Klein and Hartmann, 1993; Ghate et al., 2009). During this cruise the BL at the Stratus ORS was usually well-mixed and covered by a solid Sc layer with a thickness of less than 500 m. The clouds were close to adiabatic (Bretherton et al., 2004). The most variable cloud conditions were observed in November during PACS Stratus 2003 (Kollias et al., 2004) when solid Sc, broken cloud, clear sky, and drizzle were observed. The BL depth was about 1200 m and the mean cloud
base was around 1000 m. In December during the PACS Stratus 2004 study, the BL depth reached about 1400 m and the decoupled BL structure dominated (Serpetzoglou et al., 2008). These observations revealed the complex structures and the variability in the BL and the cloud layers. Most of the previous field experiments in the SE Pacific focused on the open ocean area, but the coastal marine Sc in the SE Pacific has been largely unexplored.

The annual mean of the satellite-derived cloud droplet number concentration ($N_d$) over the SE Pacific ocean during 2000-2008 shows a narrow band of high $N_d$ along the coast between $17^\circ$ S and $30^\circ$ S, in contrast to the broad Sc area with low $N_d$ over the open ocean (George and Wood, 2010). The strong gradient of $N_d$ over this region, due to influences of both clean marine air masses and anthropogenic aerosol releases along the Chilean and Peruvian coasts, shows both temporal and spatial variations and provides a unique area to study aerosol-cloud interactions. Wood and Bretherston (2004) estimated BL depth, entrainment rate and decoupling over this region using NCEP reanalysis data and satellite observations. According to their study, the BL depths over this region are generally 100–200 m deeper than those off the coast of California, and the BLs tend to be less decoupled than those over the coastal regions of the Northeast (NE) Pacific. However, it is difficult to establish the generality of previous studies based on remote sensing observations and reanalysis products due to the absence of in situ observations. Further, previous studies have shown that the coastal BL around $20^\circ$ S has several features different from the coastal BL north or south of this region (Zuidema et al., 2009; Rahn and Garreaud, 2010a). Satellite retrievals show that the monthly mean cloud-top height in the coastal region around $20^\circ$ S could be about 300 m higher than the surrounding region (Zuidema et al., 2009). Simulation of the observed elevated inversion height in this coastal region is a major challenge for the regional atmospheric numerical modeling community (e.g. Rahn and Garreaud, 2010a, b; Wyant et al., 2010, etc.). It has been speculated that since current models can not sufficiently represent the blocking effect of the steep Andes on the flows, simulations tend to produce unrealistically large divergence in the coastal region, which
suppresses the BL depth and thins the cloud layer (Rahn and Garreaud, 2010a; Jiang et al., 2010; Wang et al., 2010). In situ observations could help the modeling community improve simulations in the coastal region by offering a variety of measurements within and above the BL.

The VAMOS (Variability of the American Monsoons) Ocean-Cloud-Atmosphere-Land Study-Regional Experiment (VOCALS-REx), which took place in the area extending from the coastal region of northern Chile and southern Peru to the remote ocean in the SE Pacific from October to November 2008, aimed at (1) further understanding aerosol-cloud-drizzle interactions in the BL; and (2) improving model simulations and predictions of the SE Pacific coupled ocean-atmosphere-land system on a variety of scales (Wood et al., 2011). For the atmospheric observation part, VOCALS gathered an intensive dataset along 20° S from 70° W to 85° W to study the BL structure, lower free troposphere, cloud properties, and precipitation. The multi-platform observations during VOCALS revealed that the Sc-topped BL depth deepens from ~1000 m near shore to ~1600 m at a distance of about 1500 km offshore (Bretherton et al., 2010). The observed BL in the coastal region is well-mixed with little or no drizzle in the Sc layer. As one component of the five aircraft and two research vessels in the VOCALS experiment, the Center for Interdisciplinary Remotely-Piloted Aircraft Studies (CIRPAS) Twin Otter aircraft focused on making observations off the coast of Northern Chile. Comprehensive in situ observations of aerosol, turbulence, cloud properties, and drizzle were also collected. These offered a unique opportunity to acquire first-hand evidence of cloud-aerosol-turbulence interactions in the coastal marine Sc over the SE Pacific ocean.

In this study, we combine the in situ aircraft data with meteorological reanalysis, satellite-derived cloud properties, and radiosonde data to explore the BL structure and physical properties of clouds and aerosol over the coastal region in the SE Pacific. The goal is to characterize variations of the coastal BL, clouds, and aerosols in the SE Pacific. Section 2 describes the aircraft data and the other data supplements. The general synoptic conditions during VOCALS-REx are reviewed in Sect. 3. In Sect. 4 we
investigate the BL vertical structure. The temporal variation of BL structure is provided in Sect. 5 followed by the variations of cloud and aerosol properties in Sect. 6. Section 7 summarizes the general features of the BL, cloud, and aerosol over the coastal region in the SE Pacific.

2 Data and methods

2.1 Aircraft data

The CIRPAS Twin Otter aircraft completed 19 flights in the vicinity of Point Alpha (20° S, 72° W) off the coast of Northern Chile from 16 October to 13 November 2008. Because cloud and aerosol probe data failed on one of those flights (5 November), we only include observations from the other 18 flights in this paper. Each flight had a duration of 4.5 to 5.5 h and included at least two soundings and several 10-min horizontal legs near the ocean surface, below the cloud, near the cloud base, within the cloud, near the cloud top, and above the inversion. Fifteen of the flights started around 08:00 Local Time (LT) (11:00 UTC), with the first sounding made around 12:00 UTC, while the other three flights took off about 3 h later (see Table 1 for a list of the flights).

The data from the onboard instruments were processed and quality-controlled to provide standard meteorological turbulence, aerosol, cloud, and precipitation observations. The measured and derived variables obtained at a frequency of 10 Hz used in this study include wind speed, wind direction, vertical velocity, air temperature, air density, pressure, mixing ratio, IR sea surface temperature (SST), and cloud liquid water content (LWC) from the PVM-100 probe (Gerber et al., 1994). The cloud and aerosol data obtained at 1 Hz include accumulation mode aerosol concentration (\( N_a \)) from the Passive Cavity Aerosol Spectrometer Probe (PCASP), \( N_d \) from the measurements by the Cloud, Aerosol and Precipitation probe (CAS), cloud condensation nuclei (CCN) from the CCN Spectrometer, effective radius of cloud droplets (\( R_e \)) from the PVM-100 probe, and drizzle water content from the Cloud Imaging Probe (CIP). Descriptions of...
the instruments used on the Twin Otter for these measurements are described in Zheng et al. (2010) and Wood et al. (2011). Because the total water mixing ratio ($q_t$) and the liquid water potential temperature ($\theta_l$) are conserved during adiabatic processes, we calculated these two variables from the mixing ratio, LWC, temperature and pressure to estimate the BL structure in the next sections.

2.2 Reanalysis data, satellite measurements, and radiosonde data

Previous studies suggest that large-scale dynamic forcing impacts the Sc properties on both the inter-seasonal and synoptic time-scales (Klein and Hartmann, 1993; Roen-ndaal and Rossow, 2003). The large-scale datasets, including meteorological reanalyses and satellite observations, along with soundings launched in the nearby region, provide a comprehensive data supply for exploring the large-scale background of the BL at Point Alpha.

We adopt the reanalysis of meteorological observations from the National Centers for Environmental Prediction (NCEP)/NCAR Reanalysis Project (NNRP, Kistler et al., 2001) to study the sea level pressure and the 700-hPa geopotential height over the large region (50°W–95°W, 0°–45°S). The resolution of the NCEP NNRP data is 2.5° × 2.5° × 17 pressure levels and this data product is available at 6 h intervals. The resolution of this product is suitable for evaluating the large-scale patterns of sea level pressure and 700-hPa geopotential height.

Radiances from the Tenth Geostationary Operational Environmental Satellite (GOES-10) were used to retrieve cloud properties at 4-km resolution with the methods of Minnis et al. (2011a) for the area (75.75°W–70.75°W 23.75°S–16.25°S) in the vicinity of Point Alpha during VOCALS-REx. Wood et al. (2011) provide further description and examples of the GOES VOCALS-Rex retrievals. Cloud properties were also retrieved from 1-km Terra MODerate-resolution Imaging Spectroradiometer (MODIS) data using the same algorithms applied to the GOES-10 data (Minnis et al., 2011b). In addition, the Quick Scatterometer (QuikSCAT) L3 data provides 0.25° × 0.25° resolution surface wind twice per day. The QuikSCAT surface wind field is used to estimate the average surface divergence at Point Alpha.
During VOCALS-REx an NCAR/EOL GPS Advanced Upper-Air Sounding (GAUS) system located in Iquique, Chile (70.1° W, 20.3° S) launched Vaisala RS92 radiosondes 6 times per day. This radiosonde delivers high quality wind measurements, pressure, temperature, and humidity measurements. We adopt the radiosonde data as a supplement to describe the BL structure on the coast and compare it with that from the Point Alpha aircraft observations. Because of the diurnal cycle of continental BL and the direct influence of the Andes, the BL involves more complicated processes at this on-shore location, especially during the daytime. Although the radiosonde data have no liquid water information, the satellite retrievals indicate that the mean LWP over this coastal region is less than 30 g m\(^{-2}\) during the observations, as will be shown in Sect. 3. We assume that ignoring the contribution of liquid water to total water mixing ratio will not change the mean BL thermodynamic structure. Therefore, the potential temperature (\(\theta\)) and water vapor mixing ratio (\(q\)) calculated from the radiosonde data represent the BL thermodynamic structure.

2.3 Back-trajectories

To help establish the history of the air masses sampled by the aircraft, we use the Hybrid Single Particle Lagrangian Integrated Trajectory Model (HYSPLIT, Draxler and Rolph, 2011) to calculate back trajectories starting at Point Alpha. HYSPLIT can be set up to compute two-dimensional and three-dimensional parcel trajectories with a simple advection calculation. The input meteorological gridded data is the NCEP Global Data Assimilation System (GDAS) data with 1° x 1° resolution. For each flight, two-dimensional parcel trajectories starting at the 500-m level (within the BL) and three-dimensional parcel trajectories staring at the 2000-m level (free atmosphere) are calculated for 48 h prior to the flight time.

By comparing HYSPLIT trajectories with the observed balloon trajectories over a three-week period Dvorkin et al. (2006) found that the pure-advection scheme in HYSPLIT may cause large errors in the calculated trajectories. However, their results showed that the deviations of the calculated trajectories from the balloon trajectories
were less than 15% within 72 h. There are also uncertainties in these back trajectories due to the relatively low resolution (1° × 1°) of GDAS data and the potential errors over coastal areas. However, the general features from this analysis are sufficient for the purpose of this study, and the errors should be smallest in the early history (i.e., the first 24–48 h) of the trajectories.

3 General synoptic conditions and variations

3.1 Synoptic patterns from NCEP reanalysis

A rough picture of the large-scale meteorological conditions over the study period is given by the composite fields of sea level pressure and 700-hPa geopotential height from NCEP reanalysis. The mean sea level pressure (Fig. 1a) from 16 October to 13 November 2008 was controlled by the strength and location of the subtropical high and a low-level trough that extended from the equator along the coast to 25° S east of the northeast part of the subtropical high. The low-level trough, the subtropical high system, and the topography along the coast interact to produce conditions and processes unique to the coastal area (Garreaud and Munoz, 2004, 2005). The composite 700-hPa geopotential height (Fig. 1b) shows that a mid-latitude trough reached 20° S between the subtropical high and Point Alpha. This indicates that the study region was influenced by the subtropical high system, the continental anticyclone, and the mid-latitude trough.

Since this study occurred during the local austral spring season, the daily sea level pressure fields (not shown here) show that, the SE Pacific high system was strongest during the first several days (16–18 October), with the 1020-hPa isobar extending over the ocean area south of 20° S. As the study progressed, the SE Pacific high system weakened and varied due to the mid-latitude wave activity. At the end of the study period, the 1020-hPa isobar moved to the open ocean area south of 25° S and west of 80° W. The day-to-day 700-hPa geopotential height (not shown here) exhibited patterns
with troughs developing from the mid-latitudes extending to north of 25° S (29 October–2 November, 13 November). Meanwhile the subtropical high was strong and occupied the region west of 80° W. Therefore, the longitudinal component of the general flow over this region increased during these troughing periods.

### 3.2 Composite cloud properties from satellite observations

As noted in Sect. 2.1, every flight mission time was about 4.5–5.5 h (see Table 1). During the flight missions, the GOES-derived cloud properties were available every 30 min. To estimate the mean conditions of the large-scale cloud background, we averaged the GOES-derived low cloud amount (%), liquid water path (LWP; g m\(^{-2}\)), and \(R_e\) at a horizontal resolution of 0.5° × 0.5° when the aircraft was flying.

During the flight observing times, the mean low cloud amount (Fig. 2a) around Point Alpha was around 70 %, which was about 10 % lower than that over the open ocean west of 73° W. The coastal region had less than 60 % cloud amount except for a long narrow band extending from (17° S, 74° W) to (19° S, 71.5° W) with cloud amounts >80 %. A climatological study using 18 yr of satellite measurements (O’Dell et al., 2008) shows that the cloud LWP over the coastal region exhibits a doubly peaked diurnal cycle in October, with peaks at 07:00 and 19:00 LT, the former of which is around the flight observing time. Therefore, the long narrow band with high cloud amounts and LWP mentioned above could be a part of the diurnal cycle and be linked to a wave of positive vertical velocity driven by the topography of the Andes moving from the coast of Peru in the late afternoon (Garreaud and Muñoz, 2004).

The GOES-10 average cloud LWP over Point Alpha during the observing time periods was about 27 g m\(^{-2}\) in comparison with the average value of about 43 g m\(^{-2}\) around 75° W, 20° S (Fig. 2b). \(R_e\) over Point Alpha averaged less than 8.5 µm (Fig. 2c), while \(R_e\) offshore was greater than 9.5 µm. The satellite retrievals during the observation time indicate that clouds over the study region were generally thin, bright and slightly broken compared with those in the adjoining areas possibly due to both meteorological and aerosol forcing.
The average surface divergence (16 October–13 November) field from QuikSCAT winds (Fig. 3) reflects the complexity of this field in the coastal regions and the sensitivity of the divergence calculations to the retrieved wind field, which is smoothed by time averaging. The large area was mainly controlled by divergence related to large-scale subsidence above the inversion, except in the narrow convergence zone along the coast west of Point Alpha due to the topography of the steep Andes as mentioned in a previous study (Rahn and Garreaud, 2010a). The average surface divergence at Point Alpha is about $3 \times 10^{-6}$ s$^{-1}$. However, its variability might be large since Point Alpha is located near the transition zone between the typical subtropical Sc deck with strong surface divergence and the coastal area impacted by mesoscale processes such as gravity waves moving from the coastline (Rahn and Garreaud, 2010a). Further, since the QuikSCAT winds were available whenever the measurement swath of QuikSCAT covered this region, the composite surface wind and divergence fields include diurnal variations.

### 3.3 Back trajectories

The back trajectories for the observed air masses (Fig. 4) at Point Alpha indicate that for the 18 flights the air masses within the BL (Fig. 4a) were mainly from the coastal regions south of Point Alpha, 48 h prior to observation. The air masses traveled toward Point Alpha over the ocean. The trajectories also indicate that most of the observed air masses stayed over the ocean for more than 24 h prior to the flights, and were advected by southerly to southwesterly flows. The air masses above the inversion (Fig. 4b) traveled longer distances from broader regions than those within the BL due to synoptic variability 48 h prior to the observations. The origins of the above-inversion air masses are as follows: north of Point Alpha along the coast of Peru during 4 flights; in the vicinity of Point Alpha during 7 flights; over the continent during 1 flight; over the ocean west of 77° W during 5 flights; and over the ocean and south of Point Alpha during only 1 flight. The flight observations (as shown in the next section) and the numerical simulations (Garreaud and Muñoz, 2005; Wang et al., 2010) indicate that the horizontal
winds switch directions between the BL and above the inversion over the region due to the thermal wind balance and the blocking of the Andes. Overall, the back trajectories indicated that most of the above-inversion air masses moved in a direction opposite to those of the air masses within the BL.

3.4 Synoptic variations

Time evolution of sea level pressure and 700-hPa geopotential height around Point Alpha and Iquique indicate that the synoptic pattern over the coastal region did not vary as much as over the open ocean south of 25° S (Fig. 5). The NCEP sea level pressure at Point Alpha fluctuated between 1013 and 1018 hPa. The sea level pressure was also calculated from the aircraft 30-m level run observations on corresponding days; it tended to be about 3 hPa higher than the NCEP values. Both showed the sea level pressure at Point Alpha gradually decreasing by about 5 hPa by the end of the study period; however, the magnitude of the pressure change is not significant enough to be considered a seasonal signal because of the uncertainty of data and the potential synoptic variations. The NCEP 700-hPa geopotential height at Point Alpha revealed a relatively constant pattern, which varied from 3130 to 3180 m during the study period. Three 700-hPa geopotential height minima occurred on 22 October, 1 November, and 13 November. Meanwhile, the NCEP 700-hPa geopotential height at Iquique showed the same minima on the same days, which might be linked to midlevel troughs. Comparing these results with the 700-hPa geopotential height calculated from the Iquique radiosonde measurements, the NCEP 700-hPa geopotential height was about 25 m higher in October, and the bias clearly decreased in November. The synoptic evolution over this region altered the BL depth, the low-level wind, and the moisture properties, which will be discussed in Sect. 4.
4 Boundary layer vertical structure

4.1 Thermodynamic profiles

The typical Sc topped BL is well mixed and capped by a strong inversion (Albrecht et al., 1988). Previous studies have revealed that the inversion height \( z_i \) could be an important indicator of the structure of the BL in terms of decoupling, cloud cover, etc. (Albrecht et al., 1995a). However, excluding the variation of \( z_i \) could help better estimate the composite thermodynamic and dynamic structures within the BL. In this study, \( z_i \) is quantified as the height at which the vertical gradient of \( \theta_l \) is the largest.

Figure 6 shows the profiles of \( \theta_l \), \( q_t \), and LWC using a height scale normalized by \( z_i \). In general, the profiles of \( \theta_l \) and \( q_t \) show a well-mixed BL capped by a sharp inversion during most of the flights. Within the BL \( \theta_l \) was about 289 K and the change across the inversion (denoted by \( \Delta \theta_l \)) ranged from 10 to 17 K. The average \( q_t \) within the boundary layer was about 7.6 g kg\(^{-1}\) and the change across the inversion (denoted by \( \Delta q_t \)) varied from \(+2\) to \(-8\) g kg\(^{-1}\) (Table 2). During most of the flights \( q_t \) decreased sharply above the inversion. However, during two of the flights (1–2 November), \( \Delta \theta_l \) was relatively small, and \( q_t \) increased above the inversion due to a moist layer above the inversion related to the synoptic system discussed above. The soundings launched at Iquique also captured the moist layer above the inversion from 31 October to 8 November (Fig. 7a) and the time-height diagram of the meridional winds at Iquique (not shown) indicate a clear southerly wind above the inversion around the similar period. The enhanced southerly wind from 31 October to 8 November combined with the 700-hPa geopotential height (Fig. 5) may be due to synoptic systems that passed by and modified the flow pattern in this region. The time-height diagram of the potential temperature at Iquique (Fig. 7b) shows that the BL depth varied between 700 m and 1400 m over the course of the observation period.

To quantify how well mixed the BL was, we calculated the decoupling parameters \( \alpha_q \) and \( \alpha_\theta \) (Wood and Bretherton, 2004), which measure the relative difference between the surface and the upper part of the BL.
\[\alpha_\theta = \frac{\theta_l(z^-_i) - \theta_l(0)}{\theta_l(z^+_i) - \theta_l(0)} \quad (1)\]

\[\alpha_q = \frac{q_l(z^-_i) - q_l(0)}{q_l(z^+_i) - q_l(0)} \quad (2)\]

where \(\theta_l(z^+_i)\) and \(q_l(z^+_i)\) are \(\theta_l\) and \(q_l\) just above the inversion, \(\theta_l(0)\) and \(q_l(0)\) are at the surface, and \(\theta_l(z^-_i)\) and \(q_l(z^-_i)\) are just below the inversion.

If these values are close to zero, the BL tends to be completely well-mixed. However, the BL is not always completely well-mixed due to solar radiation, drizzle, and BL deepening. Previous observations (e.g. Albrecht et al., 1995a) suggest that if \(\alpha_q\) exceeds a certain value (~0.3), the Sc layer may break up and transition into trade wind cumulus.

Values of \(\alpha_q\) and \(\alpha_\theta\) from each flight sounding were calculated and their respective averages are 0.08 ± 0.06 and 0.14 ± 0.09, which are within the regime of “well-mixed”. The results imply that for most of this season the BL over Point Alpha was well-mixed (\(\alpha_q < 0.1\) and \(\alpha_\theta < 0.15\)), except for 29 October, 4 November and 8 November, during which the BL was decoupled and some small cumulus developed below the Sc layer as indicated by the LWC profiles and the flight reports. Because of the synoptic forcing (1 November and 2 November, Fig. 6), the air above the inversion was no longer dry. On 1 November, an \(\alpha_\theta\) of 0.42 reflects that drizzle processes enhanced the BL decoupling. The BL on November 2 with an \(\alpha_\theta\) of 0.15 was less decoupled than that on 1 November.

### 4.2 Wind profiles

The vertical profiles of the horizontal wind are shown in Fig. 6d–e. On most of the flight days, the wind speed and wind direction were nearly constant within the BL. The wind speed within the BL ranged between 1 and 7 m s\(^{-1}\) with an average value of ~4 m s\(^{-1}\), which is lower than the BL wind speed (>7 m s\(^{-1}\)) over the remote ocean during VOCALS-REx (Bretherton et al., 2010; Wang et al., 2010). The wind speed at Point
Alpha was also lower than the average BL wind speed of 7–8 m s\(^{-1}\) off the southern California coast during DYCOMS-II (Stevens et al., 2003). The wind direction below the inversion was mostly southerly (150\(^\circ\)–250\(^\circ\)), turning to northerly (270\(^\circ\)–30\(^\circ\)) above the inversion. On 24 October and 4 November, the wind direction shifted sharply from southerly to northerly in the upper part of the BL. The wind direction on 30 October shifted from southerly to easterly in the upper part of the BL. The horizontal legs of observations within the BL on these three days showed the same wind patterns, which confirmed that the observed vertical wind shear within the BL was not due to sampling errors. This type of directional wind shear within the BL is not common and is probably linked to coastal processes such as the propagation of the upsidence wave (Garreaud and Muñoz, 2004; Rahn and Garreaud, 2010b).

4.3 Turbulence structure

On each flight day, several 10-min legs were flown at different levels. The turbulence and thermodynamic data gathered from these legs were processed to calculate the vertical distributions of leg-mean vertical velocity variance \(w'w'\), the total water flux \(F_{q_l}\), and the liquid water potential temperature flux \(F_{\theta_l}\) for all of the flights (Fig. 8) from Eq. (3–4):

\[
F_{q_l} = L_v \bar{\rho} w' q'_l
\]

\[
F_{\theta_l} = C_p \bar{\rho} w' \theta'_l
\]

where \(L_v = 2.45 \times 10^6\) J kg\(^{-1}\) is the latent heat of vaporization at 20\(^\circ\)C, \(\bar{\rho}\) is the air density, \(C_p = 1005\) J kg\(^{-1}\) K\(^{-1}\) is the specific heat of air.

The normalized cloud base heights were between 0.6 and 0.8 for most of the cases (Fig. 6c). In the lower part of the BL (\(z/z_i < 0.6\)), \(w'w'\) ranged from 0.05 to 0.30 m\(^2\) s\(^{-2}\), and near the cloud base or within the cloud layer the values vary substantially. For
most of the flights, $F_{q_l}$ varied between 20 and 80 W m$^{-2}$ near the surface, and then decreased with height in the lower part of the BL. $F_{\theta_l}$ ranged between $-10$ and 15 W m$^{-2}$ below the cloud and generally decreased with height. Therefore, $F_{q_l}$ tended to moisten the BL at a rate of 1.5 g kg$^{-1}$ day$^{-1}$, and $F_{\theta_l}$ heated the lower BL at a rate of about 1 K day$^{-1}$. The southerly low-level wind along the coast brought cold and dry air from the south. Based on the soundings launched along the coastline during VOCALS-REx (Rahn and Garreaud, 2010a), a rough estimate of the temperature tendency due to horizontal advection was about $-1$ K day$^{-1}$, which could approximately balance the warming by the vertical latent and sensible heat fluxes. Near the cloud top, $F_{\theta_l}$ reached about 20 W m$^{-2}$ in some flights due to cloud top radiative cooling. Within the cloud layers, $F_{q_l}$ increased and then decreased rapidly with height. The values reflect the considerable flight-to-flight diversity. The observed in-cloud vertical velocity variance ($\bar{w^'w^'}$) at Point Alpha was systematically lower than that over the remote ocean area (80° W–85° W, 20° S), which had an estimated mean value of about 0.36 m$^2$ s$^{-2}$ during VOCALS-REx (Bretherton et al., 2010). The aircraft measurements of a nocturnal non-drizzling marine Sc off the southern California coast during the first research flight of DYCOMS-II (Stevens et al., 2005) also revealed a stronger turbulence structure than that at Point Alpha. In their observations, the in-cloud $\bar{w^'w^'}$ was larger than 0.4 m$^2$ s$^{-2}$, and the maximum of 0.5 m$^2$ s$^{-2}$ was near cloud base. The difference between the in-cloud $\bar{w^'w^'}$ at Point Alpha and the mostly nighttime observations during DYCOMS-II might be partly because during the nighttime the BL is well-mixed and the marine Sc deepens, while the BL becomes less well-mixed during daytime due to solar radiation absorption (Bretherton et al., 2004). Furthermore, the different measurements and calculation methods from their studies and this study may affect the values as well.
5 Temporal variation of BL structure

5.1 BL depth variation

Figure 9 shows the time series of inversion height $z_i$ measured from the aircraft soundings data at Point Alpha. It increased from about 1000 m at the beginning of the study period to about 1200 m by the end. On 29 October and 4 November, inversions at 1300 m and 1450 m respectively were observed. The BLs on those days were decoupled and small cumuli were observed below the Sc layer. There was a transition zone at the top of the BL, where entrainment processes were critical to the growth of the BL, the evolution of cloud depth, etc. We call this the entrainment zone, and define it based on the soundings (air temperature, $q_t$, LWC, etc.). The bottom of the entrainment zone is defined as the level where the soundings clearly started losing the BL feature and transitioning to the free troposphere, while the top of the entrainment zone is the level where these soundings totally lose the BL features. The entrainment zone (Fig. 9) was less than 50 m thick at the beginning and the end of the study period indicating that the BL inversion is very sharp; however, there were 3 days (24, 27 October and 4 November) when an entrainment zone thicker than 100 m was observed. The thicker entrainment zone reflects an interaction between the BL and the free air aloft that extended over a very large depth and can be linked to the strong vertical wind shear within the BL on 24 October and 4 November as mentioned before. On 27 October, the flight started around 12:00 LT, i.e., later than the usual 09:00 LT, which may also be a factor. The inversion levels from early morning soundings (07:00 UTC) launched at Iquique (Fig. 9), show that the BL structure at Iquique was more complicated than that at Point Alpha due to land surface and topography effects. The BL at Iquique showed double inversions on 5–6 days during the study, and thus the BL depth varied more significantly than that at Point Alpha. On average, $z_i$ at Iquique was about 1070 ± 190 m, which was close to the BL depth at Point Alpha. The steadiness of the inversion structure at Point Alpha indicates that there was not a strong coastal influence at this location.
5.2 Cloud LWP variation

The average sounding of LWC from the PVM-100 probe was integrated to represent the cloud LWP. The LWC observations from the 10-min horizontal legs within the cloud layer provide the spatial distribution of LWC. We used the standardized differences (%) between the averaged LWC from the in-cloud leg \( \langle \text{LWC}_{\text{leg}}(z) \rangle \) and the sounding LWC at the same altitude \( \text{LWC}_{\text{profile}}(z) \) to estimate the uncertainty range of the LWP estimate (Fig. 10):

\[
\text{error} \, (\%) = \frac{\left| \text{LWC}_{\text{profile}}(z) - \langle \text{LWC}_{\text{leg}}(z) \rangle \right|}{\text{LWC}_{\text{profile}}(z)} \times 100
\] (5)

The observed cloud LWP ranged from less than 20 g m\(^{-2}\) to about 180 g m\(^{-2}\). The GOES-derived cloud LWP values averaged over an area within a 20 km radius of the in situ aircraft observations locations and the 0.5\(^\circ\)-average Terra LWP values over Point Alpha at \( \sim15:00 \) UTC are generally close to those from the aircraft. This close correspondence further indicates that the observed clouds were nearly solid and homogeneous on most days during the aircraft observations, conditions for which the satellite retrievals perform best. The Terra LWP is less than the GOES average values on most days, primarily because the Terra measurements mostly occurred at the end of the flights when the clouds had thinned out. No Terra retrieval was obtained on 13 November. According to the GOES retrievals for all of the flights, the average LWP at 12:45 UTC was 62.0 g m\(^{-2}\) compared to 33.9 at 15:30 UTC. For all 18 flights, the average in situ LWP was 48.5 g m\(^{-2}\). The GOES LWP values were, on an average flight day, \( 6.7 \pm 18.4 \) g m\(^{-2}\) greater than the in situ values and had a squared correlation coefficient \( R^2 = 0.84 \). The MODIS average is \( 6.3 \pm 27.4 \) g m\(^{-2}\) less than the in situ values with \( R^2 = 0.59 \). However, the MODIS average LWP is only \( 0.8 + 8.0 \) g m\(^{-2}\) less than the GOES averages over Point Alpha at the times of the Terra overpasses for all 17 days. For those data, \( R^2 = 0.98 \).
On the days with a moist layer above the inversion (1–2 November), the cloud LWP values were $112 \pm 33$ and $158 \pm 41 \text{ g m}^{-2}$, respectively. The third highest LWP ($105 \pm 36 \text{ g m}^{-2}$) occurred on 29 October, when the BL was clearly decoupled and its depth reached 1300 m. On the days with vertical wind shear within the BL (24 October and 4 November), the BL was decoupled with thin and broken Sc, and the cloud LWPs were $10 \pm 4$ and $19 \pm 6 \text{ g m}^{-2}$, respectively. The cloud LWPs on the two decoupled days (8 November and 13 November) were $13 \pm 8$ and $28 \pm 6 \text{ g m}^{-2}$, respectively. From Fig. 10, the cloud LWPs were about $50 \text{ g m}^{-2}$ before October 29 when a synoptic system affected conditions at Point Alpha. From this point in time to 2 November the cloud LWP appears to be mainly controlled by synoptic disturbances.

5.3 Inversion and surface conditions

The inversion strength, $\Delta q_l$ and $\Delta \theta_i$, indicates the extent to which the BL can resist the entrainment of the dry, warm air from the free atmosphere aloft.

$$\Delta \theta_i = \theta_i(z_i^+) - \theta_i(z_i^-)$$

$\Delta q_l = q_l(z_i^+) - q_l(z_i^-)$

The typical Sc-topped BL has a large inversion strength in terms of $\Delta q_l$ and $\Delta \theta_i$ (Albrecht et al., 1988; Serpetzoglou et al., 2009). Figure 11 shows that $\Delta \theta_i$ decreased to 8 K on 1 November, when the moist layer was observed above the inversion. From 4 November, $\Delta \theta_i$ was relatively consistent around 15 K until it decreased to around 12 K on 13 November, $\Delta q_l$ was less than $-4.8 \text{ g kg}^{-1}$ on most flight days except 1–2 November when a moist layer above the inversion moved to this location (as shown in Figs. 6–7). The inversion strength at Iquique appeared weaker than that at Point Alpha on almost all the days. From 31 October to 13 November the inversion strength at Iquique was clearly weaker than the earlier days of the study period, which is consistent with the water mixing ratio and the potential temperature pattern (Fig. 7).
SST (Fig. 12a) increased steadily from 16.5°C on 16 October to 19.5°C on 13 November and the whole BL average $\theta_l$ increased in unison with the SST. We used monthly average SST data (1998–2008) from the Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI) to check the climatology of SST at Point Alpha. The annual cycle of the monthly SST increases from October to March. The climatological SST increase was about 1.1°C from October to December at Point Alpha, which is less than the SST increase observed during the observational period. The relatively strong SST increase observed at Point Alpha during VOCALS-REx might be due to an inter-annual variation of SST over this region related to oceanic circulations. In terms of shorter temporal variability, the SST and BL-averaged $\theta_l$ on 24 October were 1.5°C warmer than the two days before and 1°C warmer than the two days after it, probably because of some small-scale oceanic variations passing by Point Alpha. Based on the soundings, LWP, and satellite images, the cloud cover on 24 October was very thin and broken.

The wind speed and wind direction obtained from the 30-m level horizontal flight legs are shown in Fig. 12b–d. Consistent with the back trajectories and synoptic patterns discussed above, the surface wind was mainly southerly with a speed of 4 m s$^{-1}$ on most of the flight days, except on 27 October, 2 November, and 13 November, when it was southeasterly with a speed of roughly 2 m s$^{-1}$. The average surface wind speed from QuikSCAT at Point Alpha was 4.1 ± 1.5 m s$^{-1}$ and the wind direction was around 175°, which is consistent with the in situ observations.

On each flight day, the aircraft collected one or two 10-min legs at a height of 30 m. We used the turbulence and thermodynamic data to estimate the latent heat flux $F_L$, the sensible heat flux $F_\theta$, and the buoyancy flux $F_{\theta_v}$ directly from Eqs. (8–10):

\[
F_L = L_v \bar{\rho} w' q'
\]

\[
F_\theta = C_p \bar{\rho} w' \theta'
\]

\[
F_{\theta_v} = C_p \bar{\rho} w' \theta_{v'}
\]
where $\bar{w}'q'$, $\bar{w}'\theta'$, and $\bar{w}'\theta_v'$ are the 30-m level kinematic fluxes of moisture, heat and buoyancy, respectively. Figure 13 shows that $F_L$ at 30 m ranged from 20 to 75 W m$^{-2}$ over this period. From 30 October to 4 November, $F_L$ decreased from 55 to 25 W m$^{-2}$. The average $F_\theta$ over the study period was $7.1 \pm 2.5$ W m$^{-2}$, which tended to increase gradually from 5 W m$^{-2}$ at the beginning to about 8 W m$^{-2}$ at the end of the study period and was in step with the SST increase. On 1 November, $F_\theta$ increased significantly to about 15 W m$^{-2}$. $F_\theta v$ and $F_\theta$ varied in a similar pattern except that $F_\theta v$ was slightly larger (by about 2–4 W m$^{-2}$) than $F_\theta$.

5.4 Entrainment rates

The total water flux $\bar{w}'q'_t$ from the 10-min legs near cloud top was used to calculate the entrainment rate ($\omega_e$) in this study. If the entrainment zone is thin enough, $\omega_e$ can be estimated as:

$$\omega_e = -\frac{\bar{w}'q'}{\Delta q_t}$$  \hspace{1cm} (11)

The jump $\Delta q_t$ was positive on 1–2 November, therefore these three days were excluded from our calculation. The maximum $\omega_e$ is 2.5 mm s$^{-1}$ and the minimum $\omega_e$ is 0.4 mm s$^{-1}$ on 13 November and 4 November, respectively. On the days with a large entrainment zone (24, 27 October, 4 November), the entrainment rates were not significantly larger than the average value. However, the LWC profiles show that drier and thinner cloud layers were observed on these days. This is because the calculation method underestimates the entrainment rate when the entrainment zone is not sufficiently thin. The average $\omega_e$ of $1.5 \pm 0.6$ mm s$^{-1}$ (Table 2) tends to be lower than that obtained using reanalysis and satellite observations (Wood and Bretherton, 2004). The average $\omega_e$ was lower than the entrainment rates of 3–12 mm s$^{-1}$ (Gerber et al., 2005) estimated from the aircraft observation off
the southern California coast during DYCOMS-II. The relatively low $\omega_e$ values are consistent with the relatively weak TKE observed at Point Alpha (Fig. 8).

Possible explanations for the relatively low $\omega_e$ values in this study could be: (1) the observations during DYCOMS-II were during nighttime, when the BL was deepening and thus the entrainment rate tended to be large (Stevens et al., 2003). (2) $\omega_e$ in Wood and Bretherton (2004)'s study was derived from the balance between the divergence of $z_i$ and large scale subsidence. The large scale subsidence ($D$) at $z_i$ can be loosely defined by divergence and inversion height: $w_s(z_i) = -Dz_i$. If we adopt the same calculation as Wood and Bretherton (2004) with the average divergence from QuikSCAT during the study period (Fig. 3), the average subsidence was about 3 mm s$^{-1}$, which is greater than the average $\omega_e$ in this study. (3) In this study, some of the flight legs were about 80 m below the inversion level. According to the observational study of Gerber et al. (2005), $\omega_e$ at the inversion level could be 1.8 times larger than $\omega_e$ at the level 100 m below the inversion. Therefore, if we extrapolate $\omega_e$ to the inversion, the average adjusted $\omega_e$ would be about 1.5 times the calculated value. However, the adjustment is sensitive to the inversion level and this might increase the uncertainty in the results.

6 Aerosol and cloud properties

For each flight, the average cloud droplet concentration $N_d$ was calculated from the in-cloud legs where the cloud LWC was larger than 0.05 g m$^{-3}$ and $N_d$ exceeded 15 cm$^{-3}$. We averaged the PCASP aerosol concentrations $N_a$ during the legs above the inversion level to get the average $N_a$ above the inversion, and averaged $N_a$ during the legs below the cloud base where LWC was less than 0.05 g m$^{-3}$ to get the mean $N_a$ in the subcloud layer (Fig. 14). During the study period, the CCN Spectrometer constantly measured CCN at a supersaturation of 0.2% (denoted as 0.2% CCN) except on the first four flights, during which the CCN Spectrometer constantly measured CCN at a supersaturation of 0.5% (denoted as 0.5% CCN). To estimate the temporal variation of CCN at the same supersaturation level, we adjusted the observed 0.5% CCN to
0.2% CCN on the first four flights. On the first four flights, the CCN Spectrometer also measured 0.2% CCN on another channel for several short time intervals. We averaged the concentration difference between 0.2% CCN and 0.5% CCN when both channels were on. We then assume that the aerosol chemical composition and size distribution did not vary significantly throughout the flight mission, and estimated the average 0.2% CCN from the 0.5% values on days when the 0.2% values were not available continuously. The highest in-cloud drizzle rates were observed on 1 and 2 November, when the mean in-cloud drizzle water contents were 0.0490 g m\(^{-3}\) and 0.0075 g m\(^{-3}\) respectively. The cloud LWP was highest on these two days as well (Fig. 10). On these two days, the peak observed in-cloud drizzle volume was 0.99 g m\(^{-3}\) and 0.22 g m\(^{-3}\) respectively. Very little drizzle was observed on the subcloud flight legs flown 100 m below the cloud base where small drizzle droplets might evaporate before reaching this level. The clouds at Point Alpha were non-drizzling or had very little drizzle compared with clouds over the open ocean during VOCALS-REx (Bretherton et al., 2010).

### 6.1 Aerosol and cloud droplet number concentrations

The average \(N_a\) above the inversion ranged between 50 cm\(^{-3}\) and 250 cm\(^{-3}\) and was lower than the average \(N_a\) below the cloud base on all flight days (Fig. 14). The above-inversion \(N_a\) was lower than \(N_d\) on most days except 1 November, during which the above-inversion \(N_a\) was close to the subcloud \(N_a\) and higher than \(N_d\). The vertical \(N_a\) profiles on 18 flights (Fig. 6f) also indicate diverse concentrations within and above the BL. On most flight days, the above-inversion \(N_a\) was lower than 150 cm\(^{-3}\), except for three soundings that captured high aerosol concentration plumes (24 October, 1 November, and 13 November). On those three days with high aerosol concentration plume above inversion, the above-inversion humidity was higher than the other days as well. The low above-inversion \(N_a\) compared with the BL \(N_a\) implies that during VOCALS-REx, the main aerosol source at Point Alpha was horizontal advection within the BL from the south rather than entrained aerosol from above the inversion. Because the PCASP aerosol concentrations typically comprise 80% of the total aerosol and
those indicate the amount of aged aerosols (Pruppacher and Klett, 1997), the upwind synoptic variations were considered to largely impact on the PCASP aerosol concentration at Point Alpha by modifying the BL depth and the surface wind pattern south of Point Alpha (70° W–75° W, 20° S–30° S).

The time series of the subcloud $N_a$, 0.2 % CCN and $N_d$ show large variations at Point Alpha during VOCALS-REx. The lowest $N_a$ (250 cm$^{-3}$) occurred on 1 November, while the highest was close to 700 cm$^{-3}$ on 19 October, which was nearly 2.5 times as large as the lowest value. The subcloud $N_a$ were closely correlated to the temporal variation of $N_d$ (Fig. 14) consistent with a strong coupling between the cloud and the subcloud layers in these nearly well-mixed conditions. The average $N_d$ ranged between 80 and 400 cm$^{-3}$, with a minimum of 84 cm$^{-3}$ on 1 November. The subcloud 0.2 % CCN was almost equal to $N_d$ on most of the flights. Based on a robust regression analysis, the relationship between $N_d$ and 0.2 % CCN from 18 flights is $N_d = 4.6 \times \text{CCN}^{0.71}$. Therefore, the power of 0.2 % CCN in the formula from 18 cases is close to the commonly assumed value of 0.7 (e.g. Feingold et al., 2001). Previous climatological studies (George and Wood, 2010; Painemal and Zuidema, 2010) of satellite-derived $N_d$ indicated that the October $N_d$ at Point Alpha was greater than 160 cm$^{-3}$ and the difference between the maximum and the minimum $N_d$ exceeded 150 cm$^{-3}$.

We estimated the average $R_e$ near cloud top using the same flight legs used to calculate entrainment rate. The average $R_e$ near cloud top varied between 5.5 and 8.5 µm yielding a value of 6.2 µm for all 18 flights. The comparison of the in situ $R_e$ near cloud top and the GOES-10 and Terra $R_e$ (Fig. 15) indicates that the satellite derived $R_e$ is systematically larger than the in situ observations. Moreover, the Terra values are all smaller than those from GOES. If the 4 days having cirrus contamination (see below) are excluded, the mean $R_e$ values from GOES and MODIS, respectively, are $2.4 \pm 1.6$ and $1.1 \pm 1.2$ µm larger than their in situ counterparts. The corresponding values of $R^2$ are 0.91 and 0.82 for the satellite-in situ matches. The matched GOES-derived LWP for these same 14 days exceeds the in situ values, on average, by only $3.4 \pm 19.9$ g m$^{-2}$, a difference of only 6 %. This indicates that the larger values of $R_e$ on
the cirrus-contaminated days contributed to the ∼7 g m⁻² bias in the GOES LWP noted earlier.

Because the cloud droplet size increases with height and the aircraft measurement was about 50 m lower than the cloud top, this may explain part of the bias between the satellite retrieval and aircraft measurement. However, the average from the vertical profiles was very close to the cloud-top values. The largest differences occurred on 24 and 27 October and on 1, 2, 4, and 8 November. Except for 1 and 2 November, the GOES retrievals were contaminated by overlying cirrus clouds. The cirrus clouds lead to an overestimate of $R_e$ (e.g., Dong et al., 2002). Drizzle droplets on 1 and 2 November are the most likely explanation for the large discrepancies in $R_e$ during those days. For drizzling conditions, in which the vertical structure of LWC can be quite different from the adiabatic case, $R_e$ can increase downward below cloud top. The $R_e$ retrieved using a 3.9-µm radiance corresponds to an optical depth of 5 or more for $R_e = 12$ µm and 8 or more for $R_e = 8$ µm, so it actually corresponds to a significant portion of the mass in the cloud and may not exactly correspond to 50 m below cloud top. As shown by Dong et al. (2002), $R_e$ and LWC profiles are often non-adiabatic near the cloud top in stratus clouds so differences between $R_e$ in the top 50 m and integrated over some depth in the cloud are not surprising. Furthermore, the droplets may be smaller at that level in the cloud because of entrainment of the overlying air.

The $R_e$ differences between Terra and GOES-10 are mostly due to the time differences, noted earlier, that affect the LWP comparisons (e.g., Fig. 10). The mean GOES $R_e$ at 12:45 UTC is 9.2 µm compared to 7.7 µm at 15:30 UTC near the Terra overpass. Although the GOES and MODIS retrievals essentially agree at the overpass time, there may also be some systematic algorithmic differences and spatial resolution effects that could contribute to those differences.

Despite the bias in the GOES retrievals of $R_e$, the good correlation in $R_e$ and agreement in LWP indicate that the satellite retrievals are providing a realistic representation of the variation in LWP and $R_e$. Since LWP is computed from the product of $R_e$ and optical depth from the satellite data, an overestimate of $R_e$ would imply an underestimate
of cloud optical depth. Such an underestimate may be due to calibration biases or to biases in the models used in the retrievals. Either error source will require additional study.

### 6.2 Cloud LWP and subcloud CCN concentrations

Because all 18 flight cases at Point Alpha were little-to-non-drizzling marine Sc as shown before, the temporal variations of cloud LWP and aerosol concentrations at Point Alpha offered us an opportunity to study aerosol-cloud interactions in non-drizzling Sc at a fixed location. The cloud LWP as a function of subcloud 0.2 \% CCN concentration for all flight cases is shown in Fig. 16. The synoptic variations, diurnal cycle of the BL, and the other BL processes have to take into account when the cloud LWP-aerosol relationship is tested, as they can affect the cloud LWP (e.g. Albrecht et al., 1995a; Stevens and Feingold, 2009, etc.). Ten of those flights (Bold marked in Table 1 and highlighted in Fig. 16) were made under similar meteorological conditions. The BL on those flight days were typically well-mixed, with solid non-drizzling Sc (Zheng et al., 2010). The LWP in this study was integrated with the average profile of LWC from two soundings on each day rather than with the 12:00 UTC soundings only (Zheng et al., 2010). Therefore, the LWP values in this study are slightly different from the values in Zheng et al. (2010). The remaining eight flights involved complications as discussed in previous sections such as a moist layer above (1–2 November, 13 November), strong wind shear within the BL (24 October, 30 October, 4 November), strong decoupled BL with cumulus below the Sc layer(29 October, 4 November, 8 November). The four flights marked on Fig. 16 from 29 October to 2 November demonstrated an enhanced cloud LWP compared with the other days. One of the possible explanations could be the impacts of a synoptic system related with the moist layer passing over this area. A positive relationship between the cloud LWP and aerosol in the typical well-mixed BL is observed in Fig. 16. However, this also shows that the meteorological factors and the BL processes that keep BL from being well-mixed have large influences on the cloud LWP variation.
7 Summary

The Twin Otter aircraft performed 18 flights at Point Alpha during VOCALS-REx from 16 October to 13 November 2008. These observations provided a unique dataset for defining the characteristics of the coastal marine Sc and the BL off the coast of Northern Chile. This study used these in situ observations and meteorological reanalysis, radiosonde and satellite-derived data to study the BL, clouds, and aerosol variations at Point Alpha.

The results show that the BL at Point Alpha during VOCALS-REx was usually characterized by a typical Sc-topped BL except when some synoptic systems and meso-scale processes affected this region. The BL depth was about 1140 ± 120 m and the BL was well-mixed and capped by a very sharp inversion. The wind direction switched from southerly within the BL to northerly above the inversion. The surface wind speed was lower than that over the remote ocean west of Point Alpha due to the topography. On some flight days, wind shear appeared within the BL. The wind profile from the soundings are consistent with the average wind field from the horizontal flight legs, therefore, the observed vertical wind shear within the BL stayed constant throughout the flight mission time. This phenomenon is rare and possibly due to the complex coastal processes. Compared with the BL depth west of Point Alpha over the remote ocean, the BL at Point Alpha was about 200–400 m shallower and more well-mixed (Bretherton et al., 2010). The BL depth was about 300 m higher than that over the coastal region in the NE Pacific (Stevens et al., 2003; Sharon et al., 2006). The surface wind and the surface fluxes at Point Alpha were weaker than those over the remote ocean and also weaker than the observations in the NE Pacific during DYCOMS-II. Turbulence in the coastal BL appeared to be weaker than that in the BL over the open ocean and the BL over the coastal region in the NE Pacific in terms of vertical velocity variance. The weaker turbulence in the BL at Point Alpha might contribute to the lower entrainment rate calculated from the near cloud top fluxes compared with the BL at the remote ocean west of Point Alpha and the coastal BL in the NE Pacific (Bretherton et al., 2010; Stevens et al., 2003, 2005).
Throughout the study period, the BL evolved gradually with variations influenced by synoptic systems. From the end of October to the beginning of November, the cloud LWP was higher than the other days by around 40 g m\(^{-2}\) (Fig. 10). This is most likely due to an intense mid-latitude disturbance controlling the coastal area (Rahn and Garreaud, 2010b; Toniazzo et al., 2011). On 1 and 2 November, a moist layer above the inversion moved over Point Alpha. The cloud LWP reached a maximum on these two days. The total-water specific humidity above the inversion was larger than that within the BL. The inversion strength became significantly weaker on these two days and the BL was decoupled due to drizzle.

The accumulation mode aerosol and 0.2 % CCN measurements indicated \(N_a\) within the BL at Point Alpha varied between 250 and 700 cm\(^{-3}\) during VOCALS-REx. The main aerosol source at Point Alpha was the horizontal advection within the BL from south of Point Alpha. The average \(N_d\) ranged between 80 and 400 cm\(^{-3}\). This range was consistent with the satellite-derived \(N_d\). However, the GOES-derived cloud droplet \(R_e\) tended to be larger than that observed near cloud top, although the GOES-derived LWP was essentially the same as that determined from the aircraft vertical profiles of LWC. The aerosol and cloud LWP relationship reveals that during the typical well-mixed BL days the cloud LWP was positively correlated with the 0.2 % CCN concentrations. At the same time, meteorological factors and the decoupling processes have large influences on the cloud LWP variation as well. However, the aircraft observations could not capture the temporal evolution of the cloud layer and the processes affecting the boundary layer structure and clouds before the observations, which could also be critical for the cloud LWP variation (e.g. Albrecht et al., 1995b; Sandu et al., 2008). Additionally, only 18 flights were completed, which is insufficient for finding a statistically significant correlation. Further modeling and diagnostic studies are required to fully explain the cloud LWP variation and its relationship with the aerosol variations at Point Alpha during VOCALS-REx.
In summary, the BL at Point Alpha exhibited the typical well-mixed BL topped by a thin and non-drizzling Sc layer on days without the dominant influence of the synoptic system and the coastal processes, which could be an ideal environment to study the aerosol-cloud interaction. The variability we observed allowed us to document the complex processes in the coastal region on some flight days. This dataset will be used for the further study of aerosol-cloud interactions and the evaluation of models operating at a variety of scales to study coastal marine stratocumulus during VOCALS-REx.

Acknowledgements. The observations used in this study were made possible through the dedicated efforts of several individuals. Pilots Mike Hubble and Chris McGuire were instrumental in the development and execution of the flight plans and endured the long ferry of the Twin Otter aircraft to Iquique Chile and back. This work was supported by ONR grant N000140810465 and NOAA grant NA17RJ1226. Djamal Khelif was supported by ONR grant N000140810438. P. Minnis, K. Ayers, and S. Sun-Mack were supported by the NASA Modeling, Analysis, and Prediction Program, the NASA Clouds and the Earth’s Radiant Energy System Project, and the Department of Energy ARM Program through DE-AI02-07ER64546. Graham Feingold was supported by NOAA's Climate Goal.

Fig. 1. (a) Composite Sea Level Pressure (16 October–13 November 2008). The contours are every 2 hPa, and the shaded band marks the high sea level pressure region due to the presence of Andes; (b) composite 700-hPa geopotential height. The contours are every 20 m. The black diamond marks Point Alpha, and the black dot indicates the location of Iquique. The coastal outline is shown as a black solid line.
Fig. 2. The average fields of (a) low cloud amount (%), (b) LWP (g m$^{-2}$), (c) Re (micron) derived from GOES-10 data during the flight time (see Table 1). Point Alpha is marked as the black square box.
Fig. 3. The average surface wind (vectors) and divergence (color shading, increment = $2 \times 10^{-6} \text{s}^{-1}$) from QuikSCAT (16 October–13 November 2008). Point Alpha is marked as the black square box.
Fig. 4. (a) Two-dimensional isobaric back trajectories ending at 500 m from Point Alpha (Plus sign) for the 18 cases (color bar) with the 24-h point (Blue Circle), and the 48-h point (Square); (b) three-dimensional back trajectories ending at 2000 m from Point Alpha.
Fig. 5. Synthesis of sea level pressure and 700-hPa geopotential height (a) at Point Alpha, and (b) at Iquique from NCEP reanalysis (12:00 UTC, open symbols) and radiosonde data (~12:00 UTC, solid symbols).
Fig. 6. Profiles scaled by the PBL heights. (a) Total-water mixing ratio (g kg$^{-1}$); (b) liquid water potential temperature (K); (c) LWC (g m$^{-3}$); (d) wind speed (m s$^{-1}$); (e) wind direction (degree), and (f) Na from PCASP (#cm$^{-3}$) for all 18 flights. The gray lines indicate all individual flights, and the red solid lines show the composite soundings.
Fig. 7. Time-height section of (top) mixing ratio (g kg$^{-1}$) and (bottom) potential temperature (K) from the soundings launched at Iquique during VOCALS-REx.
Fig. 8. (a) Vertical velocity variance (m$^2$s$^{-2}$), (b) total water flux (Wm$^{-2}$), and (c) liquid water potential temperature flux (Wm$^{-2}$) vs. normalized height calculated from all the flight legs for the 18 flights. Red solid symbols are the typical well-mixed boundary layer, non-drizzling Sc discussed in Zheng et al. (2010).

Fig. 9. Synthesis of the inversion level at Point Alpha from flight data, and at Iquique from radiosonde data. The open squares indicate the early morning soundings (∼07:00 UTC), and the black bar shows the inversion zone for each case.
Fig. 10. LWP integrated from aircraft soundings on all flight days. The estimated errors in LWP are indicated as the error bars. Magenta symbols are GOES retrievals averaged over an area within a radii of 20 km of aircraft observations. Blue symbols are average Terra MODIS retrievals for a 0.5° region centered on Point Alpha taken at between 14:20 and 15:50 UTC.
Fig. 11. (a) $\Delta \theta$ (K); (b) $\Delta q_t$ (g kg$^{-1}$). The solid squares represent the values at Point Alpha measured by the aircraft, and the open circles donate the values at Iquique measured by the radiosonde system.
Fig. 12. 

(a) SST and BL-averaged \( \theta_l \), 
(b) 30-m wind vectors, 
(c) 30-m wind direction, and 
(d) surface wind vectors from flight data.
Fig. 13. (a) 30-m Latent heat flux (Wm$^{-2}$), (b) sensible heat flux and virtual potential temperature flux (Wm$^{-2}$) from flight data.
**Fig. 14.** Average subcloud aerosol (red solid square), above-cloud aerosol (red cross), subcloud 0.2 % CCN (open red square), above-cloud 0.2 % CCN (black triangle), and cloud droplet (black dot) number concentrations on all flight days.
Fig. 15. $R_e$ from the near-cloud-top legs on all flight days. The standard deviations are indicated as the error bars. Red symbols are GOES retrievals averaged over an area within a radii of 20 km of aircraft observations. Blue symbols are average Terra MODIS retrievals for a 0.5° region centered on Point Alpha taken at between 14:20 and 15:50 UTC.
Fig. 16. LWP as a function of subcloud CCN concentrations for all flight days. The horizontal error bars through these symbols indicate the standard deviation of CCN. The uncertainty of the LWP denoted as the vertical bars. Red solid symbols are the typical well mixed boundary with non-drizzling Sc discussed in Zheng et al. (2010).
