Abstract

The effect of relative humidity (RH) on the composition and concentrations of gas-phase products and secondary organic aerosol (SOA) generated from the photooxidation of isoprene under high-NO\(_x\) conditions was investigated. The yields of most gas-phase products were the same regardless of initial water vapor concentration with exception of hydroxyacetone and glycolaldehyde, which were considerably affected by RH. A significant change was observed in the SOA composition, with many unique condensed-phase products formed under humid (90% RH) vs. dry (<2% RH) conditions, without any observable effect on the rate and extent of the SOA mass growth. There is a 40% reduction in the number and relative abundance of distinct particle-phase organic nitrogen (ON) compounds detected by high resolution mass spectrometry. The suppression of condensation reactions, which produce water as a product, is the most important chemical effect of the increased RH. For example, the total signal from oligomeric esters of 2-methylglyceric acid was reduced by about 60% under humid conditions and the maximum oligomer chain lengths were reduced by 7–11 carbons. Oligomers formed by addition mechanisms, without direct involvement of water, also decreased at elevated RH but to a much smaller extent. The observed substantial reduction in the extent of condensation-type oligomerization at high RH may have substantial impact on the phase characteristics and hygroscopicity of the isoprene aerosol. The reduction in the amount of organic nitrates in the particle phase has implications for understanding the budget of ON compounds.

1 Introduction

Isoprene (2-methyl-1,3-butadiene, C\(_5\)H\(_8\)) is a major source of secondary organic aerosol (SOA) generated as a result of its atmospheric photooxidation by the hydroxyl (OH) radical (Finlayson-Pitts et al., 2000; Henze et al., 2006; Heald et al., 2008; Van Donkelaar et al., 2007). In the urban atmosphere, the photooxidation of isoprene proceeds in the presence of nitrogen oxides (NO + NO\(_2\) = NO\(_x\)) that results in formation
of organic nitrogen (ON) compounds. Isoprene SOA has substantial influence on climate by contributing to the pool of cloud condensation nuclei (CCN) (Carlton et al., 2009). Water is ubiquitous in the atmosphere, and relative humidity (RH) may affect the mechanism of formation, chemical composition and physical properties of organic SOA (Seinfeld et al., 2001; De P. Vasconcelos et al., 1994; Poulain, 2010). RH controls the liquid water content (LWC) of the aerosol (Volkamer et al., 2009), and therefore any chemical reaction that involves water as a reactant, product, or solvent may be affected. With a typical hygroscopic growth factor of 1.1 at 85% RH for biogenic SOA (Varutbangkul et al., 2006), the particle LWC should be of the order of 30% by volume. This may be sufficient to dissolve the most soluble compounds in the particle. Isoprene photooxidation SOA has been studied under a variety of RH conditions (Carlton et al., 2009). Dommen et al. (2006) studied SOA yields from isoprene photooxidation generated under 2–84% RH (Dommen et al., 2006) and found that high RH does not considerably change the yields and gas-particle partitioning in the SOA formation process. However, the effects of RH on the molecular composition and chemistry of gas- and aerosol-phase products, and particularly on the oligomerization chemistry, have not been explored.

The role of RH in determining the SOA composition and yield is difficult to predict a priori as there are several types of processes that may be induced by LWC, with conflicting effects. One possible consequence of LWC is an increase in reactive uptake of VOC that are otherwise too volatile to partition into aerosol phase without water (Jayne et al., 1992; Liggio et al., 2005a, b). Gas phase carbonyls, like methylglyoxal, may hydrate in particles containing adsorbed water, and subsequently polymerize into less volatile products (Jang et al., 2001, 2003). In this case, water serves as a reactant during the hydration stage and accelerates oligomerization of the hydrated carbonyls, leading to an increase in the aerosol yield and increased abundance of aerosol-phase hemiacetal products. Even without the hydration step, the presence of surface water may significantly alter the efficiency of reactive uptake of VOC (Ewing et al., 2004).
Another possible consequence of increased LWC is shifting chemical equilibria for reactions between SOA constituents. Figure 1 shows the most common reactions of SOA constituents in the aqueous phase. Condensation reactions like esterification (Fig. 1a) and the aldol condensation (Fig. 1b), which produce a water molecule as reaction product, have been shown to be important in biogenic SOA formation, especially under high-NO$_x$ conditions (Surratt et al., 2006; Szmigielski et al., 2007; Altieri et al., 2008; Barsanti et al., 2005; Casale et al., 2007; Tolocka et al., 2004). Addition reactions including hemiacetal formation (Fig. 1c) and aldol formation (intermediate in Fig. 1b), where the molecular formula of the product is a simple result of adding the reactant formulas, are also important in the formation of SOA from biogenic precursors, especially under the low-NO$_x$ conditions (Surratt et al., 2006; Iinuma et al., 2009; Barsanti et al., 2004).

The increase of LWC will likely impede esterification and aldol condensation by shifting the chemical equilibrium towards the reactants but have little effect on the formation of hemiacetal, which does not involve water directly. However, an enhancement of aldol formation due to LWC is also possible in special cases due to keto-enol equilibrium shifts. For example, in malonic acid particles, the concentration of the reactive enol form increased by an order of magnitude for particles exposed to 90% vs. 2% RH (Ghorai et al., 2010). The suppression of oligomerization results in more volatile aerosol constituents, which may reduce the SOA yield.

Due to the different effects of high RH – enhancement in the reactive uptake of hydrolysable VOC and suppression of condensation oligomerization reactions – the composition of SOA will likely be affected by RH and the change in the extent of oligomerization may be positive or negative depending on which type of reaction is dominant. For the same reason, the aerosol mass may also change. In this work, we investigate the effect of RH on the molecular composition of SOA produced by isoprene photooxidation using high-resolution mass spectrometry and the effect of RH on the SOA mass yield by traditional techniques.
2 Experimental

SOA was generated under high-NO\textsubscript{x} conditions (isoprene: NO\textsubscript{x} \(\approx 1:3\)) in the absence of seed aerosol in a 5 m\textsuperscript{3} Teflon chamber surrounded by a bank of UV-B lights. Particle number concentration was monitored by a scanning mobility particle sizer (SMPS Model 3080, TSI Inc.), ozone was monitored by a Thermo Model 49i photometer, NO and NO\textsubscript{y} were measured with Thermo Model 42i chemiluminescence analyzer, temperature (\(\pm 1^\circ\text{C}\)) and relative humidity (\(\pm 2\%\)) were monitored by a calibrated Vaisala type HMT330 probe, and volatile hydrocarbons (isoprene and first-generation products) were observed in real time by a proton-transfer-reaction time-of-flight mass spectrometer (PTR-ToF-MS, Ionicon Analytik). The PTR-ToF-MS had a mass resolving power of around 5000 at \(m/z\) 69.07 (protonated isoprene). Its response was calibrated with respect to isoprene and common isoprene photooxidation products. Prior to each experiment, the Teflon chamber was filled with zero air humidified to desired value of RH using a Nafion multi-channel humidifier (Perma Pure FC125). NO was introduced in the chamber by adding a calibrated volume of an NO primary standard (Praxair, 5000 ppm in N\textsubscript{2}). The initial mixing ratio of NO was 600 ppb. There was also up to 100 ppb of NO\textsubscript{2} present initially, presumably formed during mixing of the 5000 ppm NO standard with the air in the chamber. A measured volume of liquid hydrogen peroxide (H\textsubscript{2}O\textsubscript{2}, Aldrich 30\% v/v), corresponding to 2 ppm H\textsubscript{2}O\textsubscript{2} in the chamber, was injected into a bulb and carried into the chamber with a flow of zero air. A measured volume of isoprene (Aldrich, 99\% purity) was similarly injected with a microliter syringe corresponding to an initial mixing ratio of 250 ppb. After all the precursors were injected, the mixture was exposed to the UV-B radiation, producing OH by photolysis of H\textsubscript{2}O\textsubscript{2}. The OH concentration of \(~4 \times 10^7\) molec cm\textsuperscript{-3} was estimated from the observed decay rate of isoprene.

The initial values of RH were <2\% for “dry” experiments and \(~90\%\) for “humid” experiments. These values were chosen to maximize the differences in the SOA composition induced by the particle LWC without the risk of water condensation in the chamber. The
actual RH experienced by the reacting mixture was somewhat lower due to a slight rise
in temperature (\(<5{\degree}C\)) in the chamber during the photooxidation. For the remainder of
the article, we will be referring to these conditions as “dry” and “humid”.

The sheath flow in the SMPS’s differential mobility analyzer (DMA) column was main-
tained at low RH (\(<10\%\) when DMA was connected to the humidified chamber). We
assumed that most water evaporated quickly upon contact of aerosol flow (0.3 SLM)
with the sheath flow (3 SLM). Therefore, the SMPS measurements could be converted
into the dry aerosol mass concentration. A particle density of 1.2 g cm\(^{-3}\) typical of bio-
genic SOA was assumed for the dry SOA material (Zelenyuk et al., 2008), regardless
of the humidity in the chamber during the SOA formation.

The photooxidation time was 2 h, after which the SOA loading was \(\sim 40\ \mu g \ m^{-3}\). At
that time, isoprene completely decayed and first generation products (methyl vinyl ke-
tone, methacrolein, and 3-methylfuran) were also nearly completely removed. The
concentration of ozone after the experiments increased to about 200 ppb. The exper-
iments were performed in an identical manner, within a span of several days, with the
only difference being the initial chamber RH. At least three samples were generated
for each set of conditions. PTR-ToF-MS spectra showed excellent reproducibility in
the time dependence of concentrations of isoprene and its major oxidation products.
Blank experiments were performed identically to the sample experiments, but in the ab-
ence of UV radiation. The blank and background particle mass concentrations were
\(<0.01\ \mu g \ m^{-3}\). Aerosols were collected using a 30 L min\(^{-1}\) micro-orifice uniform depo-
sition cascade impactor (MOUDI) on aluminum foils and PTFE substrates (Whatman
2 \(\mu m\)). Samples from stages 6–10 (0.056–0.56 \(\mu m\) particles) were used in the analysis.
The substrates with collected samples were placed in plastic holders, vacuum-sealed
in polyethylene bags, and frozen in anticipation of off-line analysis.

The SOA samples were analyzed using a high-resolution linear ion trap (LTQ-) Or-
bitrap™ (Thermo Corp.) mass spectrometer. The instrument was equipped with an
electrospray ionization (ESI) and nanospray desorption electrospray ionization (nano-
DESI) sources (Roach et al., 2010). ESI is well-suited for analysis of SOA samples
extracted in water- and/or organic solvents, and is the common technique for the analysis of dissolved organic matter. Nano-DESI, a sensitive ambient ionization technique that can detect nanograms of SOA material on surfaces without sample preparation prior to analysis, is better suited for the analysis of labile molecules (Roach et al., 2010). Both techniques were used to obtain spectra in both positive and negative ionization modes. Analyte molecules are detected as [M+H]⁺ and [M+Na]⁺ ions in the positive ion mode and as [M-H]⁻ in the negative ion mode. A mixture (1:1 v/v) of acetonitrile and water (Acros Organics, HPLC grade) served as the solvent in ESI and the eluent in nano-DESI. The concentration of analyte in ESI was ca. 40 µg mL⁻¹ (resulting from extraction of substrates into 1 mL of the solvent). The solvent-analyte contact time in nano-DESI on the substrate surface was in the range of 1–3 min. Background mass spectra were taken on substrates obtained from blank experiments; they were not significantly different from pure solvent spectra. The mass resolving power of the instrument was 60 000 m/Δm at m/z 400. Mass calibrations with a commercial standard mixture of caffeine, MRFA, and Ultramark 1621 (MSCAL5, Aldrich) were performed in intervals of several hours in both ionization modes to maintain high mass accuracy (0.5 ppm at m/z 500). Data were collected for a mass range of m/z 50–2000. The spray voltage was 4 kV and the solvent flow rate was 0.5 µL min⁻¹.

3 Results

3.1 SOA yield and gas-phase reaction products

PTR-ToF-MS was used to simultaneously track all ionizable VOC, including isoprene itself, with 18 s time-resolution. The humidity of the sampled air affects the extent of the PTR ionization. Under normal operation conditions, humidity will alter the PTR ion concentrations by less than 5% (Hewitt et al., 2003). However, the ion signal of VOC with proton affinities (PA) similar to the PA of water (697 kJ mol⁻¹), like formaldehyde (718 kJ mol⁻¹), may be affected by more than 5% due to the backward protonation of...
H$_3$O$^+$ primary ions at higher sample inlet humidity. This RH effect theoretically decreases ion signal under higher inlet flow RH. For these compounds, the ion signals were corrected at the relevant drift potential ($U_{\text{drift}} = 600$ V) using the procedure reported by Inomata et al. (2008).

We generally do not observe significant differences in the PTR-ToF-MS time-dependent traces of the major VOC products monitored between the dry and humid conditions. Figure 2a shows the decay of isoprene and the formation of the first- and second-generation products methacrolein (MAC), methylvinyl ketone (MVK), 3-methylfuran (3MF), and methylglyoxal (MGLY). MAC and MVK are detected as an isobaric pair. The time-dependent traces of formaldehyde (FORM), acetaldehyde (ACET) and acetone (ACE) are shown in Fig. 2b. FORM may be lost more slowly to photooxidation in the presence of water vapor, which is consistent with the behavior of isoprene. Non-volatile products like 2-methylglyceric acid (2MGA) were not detected by PTR-ToF-MS.

However, there are notable exceptions to this observation: the production of glycolaldehyde (GLYC, m/z 61.03) and hydroxyacetone (HAC, m/z 75.04) increased under humid conditions (Fig. 2c). At the end of the photooxidation period, the concentration of GLYC was 33 ppb (dry) and 56 ppb (humid) in the representative samples. Similarly, the concentration of HAC was 16 ppb (dry) and 33 ppb (humid). The signal at m/z 61.03 and at m/z 75.04 may have interferences from acetic acid and lactaldehyde, respectively. However, acetic acid is not expected to be a significant product on the timescale of the experiment (Lee et al., 2006; Paulot et al., 2009). Furthermore, lactaldehyde is not observed from the oxidation of isoprene in laboratory experiments or in field observations, so we do not expect these interferences to be significant. Conversely, GLYC and HAC are important water-soluble isoprene oxidation products commonly observed in the field (Lee et al., 1998; Spaulding et al., 2003; Matsunaga et al., 2005; Zhou et al., 2009; Williams et al., 2001). GLYC is produced in the OH + MVK reaction (Tuazon et al., 1989; Atkinson et al., 1998) and HAC is produced in the OH + MAC reaction (Williams et al., 2001) following the photooxidation of isoprene. GLYC and HAC may
also be formed from prompt sources like the decomposition of alkenoxy radicals (Dibble 2004a, b) or from the degradation of hydroxy alkenyl nitrates (Paulot et al., 2009). The increase in signal of these second-generation VOC at higher RH is unexpected, and cannot be explained by backward reactions in the PTR ion source.

The effect of RH on the resulting SOA mass in the chamber was insignificant. Figure 2d shows the time-dependent SOA yield defined as the ratio of the dry SOA mass (µg m⁻³) produced over the concentration of isoprene reacted. This yield definition is not ideal as a large contribution to SOA mass arises from the oxidation of first generation products after all of the isoprene has already reacted (Kroll et al., 2005). However, for the sake of comparison, the traditional definition of SOA yield was used to gauge the relative differences between the two sets of data, without an emphasis on the absolute yield quantification. Figure 2d clearly demonstrates that RH does not substantially affect SOA yield from isoprene photooxidation. This observation agrees with conclusions of Dommen et al. (2006) who reported similar SOA yields at different RH (Dommen et al., 2006).

### 3.2 Mass spectrometry analysis of SOA samples

Figure 3 shows the stick mass spectra for isoprene photooxidation SOA generated under dry (RH < 2%) and humid (RH 90%) conditions. The horizontal axis corresponds to molecular weights of the neutral SOA compounds, which could be unambiguously assigned to C₉H₆O₆N₆ molecules from the corresponding measured m/z values. We are interested in the most complete set of compounds for our analysis regardless of their mode of detection. Mass spectra shown in Fig. 3 represent a merged set of ESI and nano-DESI data, which plots the average abundance of each feature detected in different ionization modes. The background peaks from blank samples were removed. The negative and positive mode data with ion peak assignments in m/z are converted to neutral masses and merged because negative and positive modes ionize different subsets of SOA compounds, and nano-DESI is more sensitive to labile compounds compared to ESI. Although the averaged mass spectral intensities do not represent
the relative molecular abundances in the aerosol, they can still be used for qualitative comparison between the dry and humid samples. Approximately 750 peaks were assigned in each mass spectrum, representing ~70% of all the observed peaks.

The monomer form of 2MGA was observed with high abundance in both dry and humid spectra, indicating that the formation pathway to produce 2MGA is not significantly affected by RH. Methyltetrols were not observed in the high-NOX data. Figure 3 shows that the components of SOA generated under dry vs. humid conditions were quite different. Differences in peak intensities in the dry vs. humid samples did not result from an experimental artifact as in both cases the filters contained about the same amount of deposited SOA material. Furthermore, experiments with different filter loadings, 10 µg m⁻³ vs. 40 µg m⁻³ estimated by SMPS data, under a specific RH condition resulted in similar intensity distributions (Fig. S1).

Isoprene has a relatively low molecular weight (68.063 Da) and even the heaviest products of isoprene oxidation that retain its original carbons have molecular weights under 200 Da (for example, 2-methyltetrol nitrate ester weighs 181.058 Da). Figure 3 shows that 80–90% of the observed isoprene SOA constituents have molecular weights in excess of 200 Da and therefore correspond to oligomeric molecules. In the mass spectrum of the SOA generated under dry conditions, more peaks are observed in the 400–1000 Da region, whereas for the SOA formed under humid conditions most peaks are clustered around 200–400 Da. We note that oligomers may be overrepresented in our work as larger, multifunctional molecules are more efficient charge acceptors and are easier to ionize in the electrospray. Nevertheless, it is clear that oligomerization plays an important role in the SOA formation chemistry.

The highest abundance peaks, including those explicitly labeled in Fig. 3, are generally found in both dry and humid spectra. There are ~550 common peaks observed in both samples, corresponding to approximately 73% of the assigned peaks. However, there are significant and reproducible differences in the signal-to-noise (S/N) ratios of these peaks between the dry vs. humid spectra. The S/N differences in the common peaks, under identical analytical conditions, suggest that RH affects the rate
of production of these compounds. The amount of overlap between the two spectra decreased with an increase in $m/z$. For example, the overlap was 85% for molecular weights between 100–600 Da but only 36% for the 600–1000 Da region. This trend logically implies that the formation of larger oligomers is hindered by high initial chamber RH (the discussion of the oligomers will be expanded upon in Sect. 4).

Approximately 20% and 12% of the total number of peaks were assigned to ON molecules in the dry and humid sample, respectively. In addition to the reduction in the total number of the observed ON species, the S/N of the ON peaks in the humid mass spectra were greatly reduced. For example, C$_{12}$H$_{19}$O$_{12}$N (369.091 Da) was detected with a S/N of 212 in the dry sample vs. S/N of 44 in the humid sample. Similar drastic reduction in signal (>80%) was observed for C$_8$H$_{13}$O$_9$N (267.059 Da), C$_{16}$H$_{25}$O$_{15}$N (471.122 Da), C$_{20}$H$_{31}$O$_{18}$N (573.154 Da), and several other ON species. Most of these ON are oligomers. The only monomer nitrate observed is C$_4$H$_7$O$_3$NO$_3$ (the nitrate ester of 2MGA) and its signal is similarly low in both the dry and humid data (S/N of 1.6 and 1.5, respectively). The structural identities of selected ON were probed with high-resolution tandem mass spectrometry (MS$^n$) and the detailed discussion is deferred to a subsequent manuscript. Briefly, most of the ON molecules that are affected by RH are oligomeric organic nitrates with several 2MGA units incorporated into the structure. As an example, MS$^n$ revealed C$_8$H$_{13}$O$_9$N to be a condensation dimer of 2MGA and its nitrate ester (C$_4$H$_7$O$_3$NO$_3$ + C$_4$H$_6$O$_3$).

Figure 4 compares peaks observed uniquely in samples generated under dry or humid conditions, with those of higher abundances explicitly labeled. There were approximately 220 unique peaks in the dry dataset and 225 unique peaks in the humid dataset, representing ∼37% of all the assigned 750 peaks by count. Because all of the unique peaks were of relatively low abundance (S/N <40), their MS$^n$ analysis could not be performed. However, a visual comparison shows that a large fraction of compounds formed uniquely under dry conditions belong to the higher-MW oligomers and ON species. Some of these molecules could be attributed to high-MW condensation oligomers whose formation was hindered under the humid conditions.
For example, $C_{28}H_{44}O_{21}$ (Fig. 4) is likely a 7-unit homologous 2MGA oligomer from the $C_4H_8O_3 + (C_4H_6O_3)_n$ family (Table 1). Other molecules like $C_{11}H_{14}O_6$ are formed from heterogeneous (comprised of different monomeric units) oligomerization because their molecular formulas are not linked to repeating units of any one monomer. These molecules are less likely to form in the humid condition because high RH may hinder the formation of certain monomers. Although the number of observed unique peaks is similar for both the dry and humid data, the total ion signal for unique peaks in the dry data is much higher. This may suggest either higher physical abundance of those unique compounds in the sample or higher ionization efficiency in the electrospray.

4 Discussion

The similarity in the time-dependent concentrations of reaction products and SOA yields in the dry and humid experiments suggests that the initial gas-phase oxidation chemistry was similar. The OH yield from the photolysis of hydrogen peroxide was likely minimally affected by the additional water vapor. However, the increase in signal of GLYC and HAC indicates that water vapor indeed affected a certain subset of photochemical reactions. As GLYC and HAC are both water-soluble, they should be lost more easily to the walls with higher initial water vapor in the chamber. Therefore, the increase in the abundances of these products under higher RH conditions is unexpected. Due to the multiple sources of GLYC and HAC, the reason behind this particular RH effect is unclear and a more systematic investigation is necessary to implicate specific reactions.

The observed reduction of the organic nitrates in the particle phase under humid conditions may be due to the following reasons. First, the total organic nitrates formed in the gas phase may be reduced, which would limit the number of particle-phase nitrates by gas-particle partitioning. Typically, VOC do not fragment in the PTR ion source; however, volatile organic nitrates (RONO$_2$) may lose nitrous acid (−HONO), nitric acid (−HNO$_3$) or fragment into NO$_2^+$ (Aoki et al., 2007; Perring et al., 2009a).
As the identities of the individual nitrates are unknown, we cannot use carbon-based fragment ions formed in the PTR ion source, e.g. [M-HONO]+ or [M-HNO3]+, to trace the time evolution of the total amount of organic nitrates. We do observe a 40% decrease in the signal of NO2+ under humid conditions, which may in principle be used as a tracer ion for the total organic nitrates in PTR-ToF-MS. Unfortunately, due to strong interferences from nitric acid (HNO3) (Perring et al., 2009b), the NO2+ signal cannot be exclusively assigned to organic nitrate fragmentation. In addition, the yield of NO2+ from larger alkyl nitrates is small (e.g. 3% yield for a branched C3 nitrate, Aoki et al., 2007). The yield of NO2+ from HNO3 is not known, however, we expect a significant build up of HNO3 during photooxidation. That HNO3 is the dominant cause of the reduction in the NO2+ signal is consistent with the exceptional water solubility of HNO3. However, a humidity-induced reduction in gas-phase organic nitrates cannot be completely ruled out based on the PTR-ToF-MS observations.

The second possibility for the observed reduction of the organic nitrates in the particle phase is that the formation of condensation organic oligomers containing a –ONO2 group may decrease under humid conditions. This, in turn, may lead to a reduction in the ion current for the ON compounds. The SOA may still contain monomer nitrates, but as monomers are likely to be less ionizable than oligomers, the observed total ON signal should decrease with a decrease in the degree of oligomerization. The negligible RH-induced change in observed signal of the monomer nitrate of 2MGA (Sect. 3.2), the only observed monomer ON species, is consistent with a similar concentration of monomeric nitrates in the aerosol and decreased oligomerization.

Finally, the particle-phase nitrates may be reduced in the humid conditions by a suppression of direct esterification of alcohols by nitric acid (HNO3), also a condensation-type process. Nitric acid concentration in these experiments may be sufficient for the efficient partitioning of HNO3 into the particle phase. If esterification of alcohols by HNO3 is the main reason for the suppression of ON in humid experiments, the reduction in the yield of organic nitrates should be smaller under more realistic atmospheric conditions with much lower NO2 and HNO3 concentrations as compared to the chamber.
Nevertheless, this process has implications for the total budget of ON compounds in particles, especially in highly-polluted urban air environments.

The high resolution mass spectra shown in Fig. 3 suggest that 2MGA is formed in comparably high abundance in both dry and humid conditions. However, the oligomerization arising from 2MGA is significantly affected by RH. For systematic assessment of the oligomerization patterns in SOA formed under the dry and humid conditions, we conducted a statistical molecular weight (MW) difference analysis for all the assigned compounds. For $x$ different compounds, there are $x^2 - x$ non-zero mass differences that can be grouped in a histogram to identify the most common MW differences. Each such difference can be assigned to a formula $C_c H_h O_o N_n$, where $c$, $h$, $o$, and $n$ can be positive or negative depending on the chemical process responsible for propagating this particular fragment through the distribution of formulas. It is possible to trace high-MW formulas to lower-MW ones by generating chemical “families” of the type $C_x H_y O_z N_w + [C_c H_h O_o N_n]_k$ where $C_x H_y O_z N_w$ is the smallest member of the family and $k$ is the number of times the difference formula is repeated. This type of analysis, which in essence identifies the most frequently repeated base formulas to use for a given distribution of compounds, is routinely performed in high resolution mass spectrometry (Altieri et al., 2008; Reinhardt et al., 2007; Nguyen et al., 2010; Hughey et al., 2002) to find monomer units that form long oligomer “families”. Our criteria for identifying monomer units using this method are: (1) observation of a large number of families which have a broad range of $k$ values; (2) ability to link the formula difference to an expected product of isoprene oxidation. It is important to note that non-homologous oligomers, i.e. those including different monomer building blocks, may also be present in large numbers but they are harder to track down with statistical tools.

MW differences corresponding to O-atom and CH$_2$ are usually the most common differences for natural complex mixtures as these groups are present in the majority of organic molecules. Indeed for humid isoprene high-NO$_x$ data, the most common mass differences were O-atom followed by CH$_2$. However, the most common difference in dry isoprene high-NO$_x$ data was a more complex unit: $C_4 H_6 O_3$ (102.032 Da). This
mass difference must correspond to the formation of oligomers via condensation reactions involving 2MGA, (Szmigielski et al., 2007; Surratt et al., 2006) a very abundant molecule in both humid and dry SOA samples. However, the prevalence of this mass difference in only the dry sample supports that 2MGA-based oligomers are much more important when the SOA is generated under dry conditions. The polyfunctional nature of 2MGA (carboxylic acid and alcohol functionality) enables the formation of very long oligomers similar to the poly-condensation of glycolic acid to make polyesters in industrial applications (Fig. 5a). The molecular formula of 2MGA is C_4H_8O_4 but with an H_2O loss at every condensation step the repeated unit becomes C_4H_6O_3.

The unit C_2H_4O_2 was also identified as a prominent repeating motif in our analysis and assigned as the addition unit of GLYC (Fig. 2c). GLYC (HO-CH_2-C(O)H) is similar to 2MGA in that it is bifunctional (it is the simplest hydroxyaldehyde) and can produce relatively long homologous oligomers (Fig. 5b). Like any hydroxyaldehyde, GLYC can oligomerize by addition to form hemiacetals, and its hydrated form HO-CH_2-C(OH)_2H can oligomerize by condensation. However, with the relatively low amount of water present in the particle (about 30% by volume under humid conditions) the contribution of the hydrated form should be small.

Therefore, the unit C_4H_6O_3 was used in our analysis to represent homologous condensation with 2MGA, and C_2H_4O_2 was used to represent homologous addition with GLYC. We examined these two important types of oligomer families in detail to discern differences in oligomerization due to the additional water vapor present in the chamber at the time of aerosol formation. We note that while these two types of oligomers are among the most abundant, there are other types of condensation and addition oligomers in isoprene SOA that respond to RH in a qualitatively similar way.

Oligomers produced from 2MGA condensation chemistry are very large and generally homologous (k_{max} = 4–9). The homologous nature of 2MGA oligomers, which dominate the signal abundance from the SOA samples generated at both high and low RH conditions may account for the semi-solid nature of biogenic SOA (Virtanen et al., 2010; Vaden et al., 2010). A number of long homologous families of the type...
C_xH_yO_z + (C_4H_6O_3)_k, with k ranging from 1 up to 9 were identified (Table 1, also see Tables S1 and S2 in the supporting information section). Table 1 reports the summed ion signal from all oligomers identified from a particular family under both dry and humid conditions. The total signals are reported as the sum of the signal-to-noise ratios within the entire chemical family. The change in signal is defined as the difference between the humid total signal relative to the and the dry total signal. As expected, RH affects the condensation oligomer chain length significantly. Homologous families of 2MGA are 2–3 monomer units shorter under humid conditions, corresponding to 7–11 fewer carbon atoms per molecule. The average decrease of condensation oligomers in SOA generated under humid conditions is 63 ± 16%, where the error in this case is the statistical spread in oligomer ion abundance between the thirteen homologous families included in Table 1.

Figure 6a shows the representative abundance distribution of the oligomers with molecular formulas C_xH_yO_zN_w + (C_4H_6O_3)_k. The trend of decreasing signal for each oligomer in the family, as well as a decrease in the length of the oligomers, at higher initial chamber RH is clearly observable. The distribution of oligomer signal shows that the most abundant oligomer in the family is not the same when SOA is generated under dry and humid conditions. For example, Fig. 6a reveals the most abundant oligomer in the family C_3H_4O_3 + (C_4H_6O_3)_k is the tetramer (k = 3) under dry conditions and the trimer under humid conditions. In general, the most abundant oligomer decreases by one monomer length in the chemical families studied in this work (Table S1). The signal distribution and oligomer length trends are similar for all the 2MGA-based families studied in this work (see Table S1 in the supporting information section).

Figure 6b shows a family of the type C_xH_yO_z + (C_2H_4O_2)_k formed by the repeated addition of GLYC (C_2H_4O_2). The signal distribution in Fig. 6b is not significantly affected by RH. The observed addition-type oligomers had k_max ranging from 3 to 6. In contrast to the condensation-type oligomers, which uniformly decreased in abundance at high RH, the addition-type oligomers did not display a clear trend (−21 ± 61%) in the total oligomer signal. However it is clear that, unlike the condensation oligomers, the
oligomer chain length and number of carbon atoms are not affected by RH due to this type of addition reactions.

The evidence from high resolution mass spectrometry offers an important conclusion: the composition of isoprene photooxidation SOA changes considerably with RH even though the SOA yield remains unaffected. The rate of production of most of the volatile oxidation products in isoprene photooxidation remained the same regardless of RH, with an important exception of GLYC and HAC (40–50% increase with high RH). The total number of aerosol-phase ON compounds also decreased by 40% in the humid mass spectra, and is most consistent with a reduction of oligomerization reactions involving monomeric ON species. There are visible differences in the mass spectra with ~37% unique products formed in either dry or humid conditions.

The common products observed under dry and humid conditions correspond mostly to condensation and addition oligomers and their relative abundance varies considerably between the two RH conditions. Our observations suggest that isoprene SOA formed under high RH conditions contain a significantly smaller number of high-MW homologous oligomers compared to the dry conditions due to a shift in chemical equilibria of the condensation reactions. The overall yield of all condensation oligomers decreased and the oligomers may be three monomer units shorter in SOA generated in humid air. In contrast, there is only a weak reduction in the number of addition-type oligomers obtained from our analysis but the data suggest the length of addition oligomers remain unchanged.

5 Atmospheric implications

The shorter chain length of oligomer esters produced under humid conditions (~5–7 monomer residues, including parent) compared to those produced under dry conditions (~8–10 monomer residues) has important implications for the physical properties of the SOA. Consider for example, the solubility behavior of straight-chain oligomer esters of hydroxyacids, such as 2-methylglyceric acid (2MGA), where an inverse relationship
between oligomer length and solubility is observed (Braud et al., 1996). Capillary electrophoresis experiments by Braud et al. (1996) determined that hydroxybutyric acid oligomers were no longer water-soluble at 5 monomer units long and glycolic acid oligomers were no longer water-soluble at 3 monomer units. Additionally, the viscosity of condensation oligomers increases with oligomer chain length (Yu et al., 2001).

As the water-solubility and viscosity of condensation oligomers is higher in SOA produced under dry conditions, the phase characteristics of the SOA may also change; for example, more viscous organic materials may be more “glassy” than less-viscous organic materials in their amorphous state. The less-viscous SOA can absorb water into the bulk, while the water uptake of the more-viscous SOA is limited by the surface (Mikhailov et al., 2009). Therefore, the water solubility and viscosity of the isoprene SOA, influenced by the total concentration of long-chain oligomers, may affect its hygroscopicity, or CCN ability. The hydrophobicity and morphology of particles were found to be important factors in the prediction and interpretation of CCN results (Hori et al., 2003). Isoprene SOA generated under dry conditions, where the composition is dominated by long oligomer esters, may exhibit reduced CCN activity compared to those generated under humid conditions. This prediction based on mass spectrometry data is in agreement with observations made by Poulain et al. (2010) that the hygroscopicity of α-pinene ozonolysis SOA is directly proportional to the water mixing ratio present in the chamber during SOA formation (Poulain et al., 2010). Although the CCN activity of sulfate particles coated with isoprene photooxidation products generated with a variety of VOC/NOx ratios have been investigated (King et al., 2010), no CCN or hygroscopic growth factor measurements have been reported for isoprene SOA generated under humid vs. dry conditions. As biogenic SOA represents a large fraction of the tropospheric aerosol budget, a systematic study of the hygroscopic properties of SOA from isoprene, for example, as a function of initial chamber RH is warranted.

Effect of humidity on the composition and yield of isoprene photooxidation

**Table 1.** Total abundances of oligomers in the condensation and addition reactions from selected homologous families. Each condensation family is generated by a repeated addition of $C_4H_6O_3$ to the $C_xH_yO_z$ precursor listed in the first column. The addition families are built by repeated addition of $C_2H_4O_2$ to a $C_xH_yO_z$ precursor. $k_{\text{max}}$ is defined as the maximum number of homologous oligomer units attached to the parent molecule, used as indicators of oligomer length, and $\Delta C$ is the change in the total number of carbon atoms in the oligomer, calculated based on the number of carbon in the monomer unit and the change in $k_{\text{max}}$. Full data are reported in Tables S1 and S2 in the Supplement.

Fig. 1. Mechanisms of acid-catalyzed oligomeric growth by (a) esterification, (b) aldol condensation and (c) hemiacetal formation. Aldol condensation involves two steps: an addition step to yield the aldol and a condensation step to yield a β-unsaturated aldehyde. The nucleophiles in reactions (a–c) may be the enol tautomers of carbonyls. Each reaction is affected by liquid water content either through direct involvement of water in the reaction or indirectly through solvation.
Fig. 2. Time dependent concentrations of selected species in the chamber during the photooxidation. Open markers refer to dry conditions and filled markers refer to humid conditions. PTR-ToF-MS mixing ratios of (a) isoprene, methylvinylketone (MVK) + methacrolein (MAC), 3-methylfuran (3MF), methylglyoxal (MGLY) (b) formaldehyde (FORM), acetaldehyde (ACET), acetone (ACE) (c) glycolaldehyde (GLYC) and hydroxyacetone (HAC). (d) The time-dependent SOA yield from isoprene photooxidation does not change with respect to initial concentration of water vapor in the chamber.
Fig. 3. Stick spectra of all assigned compounds in high-NO\textsubscript{x} isoprene SOA samples generated under two humidity conditions. The spectra represent a merged set of ESI and nano-DESI data. The horizontal axis corresponds to molecular weights of the neutral SOA compounds. High-MW oligomeric species in the dry sample are significantly more abundant.
Fig. 4. There are approximately 200 formulas unique to the dry conditions and 225 formulas unique to the humid conditions out of 750 assigned formulas in each sample. Unique formulas with higher abundances are labeled. ON species are shown in red.
**Fig. 5.** (a) Condensation oligomerization from repeated esterification by 2MGA produces MW differences equivalent to $C_4H_6O_3$. (b) Addition oligomerization from repeated hemiacetal formation with GLYC produces MW differences equivalent to $C_2H_4O_2$. 
Fig. 6. Representative distributions of homologous oligomeric compounds in high-NO\textsubscript{x} SOA under dry (filled bars) and humid (open bars) conditions. (a) Condensation-type oligomers from repeated esterification by 2MGA (C\textsubscript{4}H\textsubscript{8}O\textsubscript{4} with one H\textsubscript{2}O lost per oligomerization step). (b) Addition-type oligomers incorporating homologous units of glycolaldehyde (C\textsubscript{2}H\textsubscript{4}O\textsubscript{2}).
