Abstract

Carbonaceous aerosols impact climate directly by scattering and absorbing radiation, and hence play a major, although highly uncertain, role in global radiative forcing. Commonly, ambient carbonaceous aerosols are internally mixed with secondary species such as nitrate, sulfate, and ammonium, which influences their optical properties, hygroscopicity, and atmospheric lifetime, thus impacting climate forcing. Aircraft-aerosol time-of-flight mass spectrometry (A-ATOFMS), which measures single-particle mixing state, was used to determine the fraction of organic and soot aerosols that are internally mixed and the variability of their mixing state in California during the Carbonaceous Aerosols and Radiative Effects Study (CARES) and the Research at the Nexus of Air Quality and Climate Change (CalNex) field campaigns in the late spring and early summer of 2010. Nearly 88% of all A-ATOFMS measured particles (100–1000 nm in diameter) were internally mixed with secondary species, with 96% and 75% of particles internally mixed with nitrate and/or sulfate in Southern and Northern California, respectively. Even though atmospheric particle composition in both regions was primarily influenced by urban sources, the mixing state was found to vary greatly, with nitrate and soot being the dominant species in Southern California, and sulfate and organic carbon in Northern California. Furthermore, mixing state varied temporally in Northern California, with soot becoming the prevalent particle type towards the end of the study as regional pollution levels increased. The results from these studies demonstrate that the majority of ambient carbonaceous particles in California are internally mixed and are heavily influenced by secondary species that are most prevalent in the particular region. Based on these findings, considerations of regionally dominant sources and secondary species, as well as temporal variations of aerosol physical and optical properties, will be required to obtain more accurate predictions of the climate impacts of aerosol in California.
1 Introduction

Carbonaceous aerosols, comprised of soot and/or organic carbon (OC), affect climate directly through scattering and absorbing radiation and indirectly by influencing cloud formation, albedo, and lifetime (Ackerman et al., 2000; Poschl, 2005; Ramanathan et al., 2007; Rosenfeld and Givati, 2006). Soot, formed by incomplete combustion processes, is strongly absorbing and hence plays a key role in affecting climate through radiative forcing (Jacobson et al., 2000; Kanakidou et al., 2005; Ramanathan and Carmichael, 2008; Solomon et al., 2007). OC from vehicle, biogenic, and biomass burning emissions, as well as from secondary aerosol formation, can exhibit a wide range of optical properties which depend on the mixing state of particles (Hand and Malm, 2007; Jacobson et al., 2000; Kanakidou et al., 2005; Rudich et al., 2007). Soot and OC particles can form internal mixtures with one another as well as with other secondary species, such as nitrate, sulfate, and ammonium, which strongly affects their optical and physical properties (Moffet et al., 2010; Prather et al., 2008; Spencer and Prather, 2006).

Internal mixtures of OC and soot increase the absorption coefficient, leading to greater radiative forcing than predicted for either species alone (Schnaiter et al., 2005; Schwarz et al., 2008; Moffet and Prather, 2009). For example, Schnaiter et al. (2005) measured absorption amplification factors of 1.8 to 2.1 times higher for soot with coatings than without and similarly, Moffet and Prather (2009) found an absorption enhancement of 1.6 for soot particles coated with OC and secondary species over pure soot. Previous studies determined that water soluble coatings, such as sulfuric acid, lead to enhanced absorption over that of externally mixed particles (Khalizov et al., 2009; Naoe et al., 2009). In addition to absorption enhancement, coatings can alter particle hygroscopicity, which in turn affects the particle’s optical and physical properties, as particles that are more hygroscopic will absorb more water, scatter radiation more efficiently, and have a higher potential to become cloud condensation nuclei (CCN) (Hand and Malm, 2007; Mochida et al., 2006; Wang et al., 2010). Laboratory
and field studies show altered hygroscopicity for photochemically aged soot, due in part to the condensation of secondary species (Cappa et al., 2011; Furutani et al., 2008; Petters et al., 2006; Wang et al., 2010). For example, Petters et al. (2006) observed that as hydrophobic soot particles age they can become hydrophilic due to the addition of a sulfate or nitrate coating. Wang et al. (2010) determined that nitrate partitioned onto aerosols leads to increased CCN activity. Multiple studies have shown that particles can acquire coatings rapidly, sometimes in only a few hours, hence the amount of ambient particles existing as internal mixtures may represent a sizable fraction of total ambient aerosols (Jacobson, 2001; Riemer et al., 2010; Wang et al., 2010; Moffet and Prather, 2009). In addition, the aerosol optical and CCN activation properties may be sensitive to the degree of internal mixing even after 1 to 2 days (Zaveri et al., 2010).

Despite the importance of mixing state on particle optical and physical properties, atmospheric models generally represent the particle population as an external mixture (Koch et al., 2011). Chung and Seinfeld (2002) found the assumption of external mixing state may lead to as much as $\sim 0.4 \text{ Wm}^{-2}$ underestimation in radiative forcing. Similarly, Jacobson estimated that global radiative forcing of soot increases by a factor of 2.9, when varied from an external to an internal mixture (Jacobson, 2001). Additionally, numerous studies have shown the sensitivity of climate to large aerosol perturbations (Leibensperger et al., 2012; Mickley et al., 2012; Kloster et al., 2010; Solomon et al., 2007). The potentially large effect on radiative forcing calculations due to mixing state necessitates empirical measurements to determine the extent of soot and non-absorbing species, such as OC, present in the atmosphere as internal or external mixtures.

Single particle mixing state is gradually becoming a more prevalent measurement in field studies (Brands et al., 2010; Gard et al., 1997; Murphy and Thomson, 1995; Zelenyuk and Imre, 2005). Ground-based measurements have shown the large variability in the mixing state of carbonaceous aerosols, even within just California (Chow et al., 1993, 2006). For example, Qin et al. (2012) found carbonaceous aerosols in Riverside, California were internally mixed with sulfate from photochemical processing.
during the summer, while nitrate was the dominant secondary species in the fall due to semivolatile partitioning of ammonium nitrate. In Bakersfield, California, carbonaceous aerosols were found to be internally mixed with ammonium, nitrate, and sulfate from partitioning of ammonium nitrate and ammonium sulfate (Whiteaker et al., 2002). An inherent limitation in ground-based measurements is their susceptibility to local sources. Aircraft sampling can cover large areas over short timescales, providing measurements that are indicative of an entire region and therefore may be more useful for evaluation of model predictions over large areas. Relatively few aircraft studies to date have measured single particle mixing state (Murphy et al., 2007; Pratt and Prather, 2010; Zelenyuk et al., 2010). Herein, in situ measurements of carbonaceous aerosol mixing state were determined using an aircraft-aerosol time-of-flight mass spectrometer (A-ATOFMS) over two major aircraft campaigns in California during the late spring and early summer of 2010 to elucidate (1) the fraction of carbonaceous particles that are internally and externally mixed and (2) differences in mixing state of carbonaceous particles between the two regions studied.

The Research at the Nexus of Air Quality and Climate Change (CalNex) campaign sampled aerosols over Southern California, with the goal of understanding the role of particle composition on air quality and climate change (www.esrl.noaa.gov/csd/calnex/). A large area of Northern California was characterized during the Carbonaceous Aerosols and Radiative Effects Study (CARES), a study that sought to follow the evolution of soot as particles are transported from fresh urban sources in Sacramento into the more remote Sierra Nevada foothills (campaign.arm.gov/cares/). These two studies conducted consecutively in May and June 2010 provide an assessment of particle mixing state throughout most of California.
2 Experimental

2.1 Aircraft Aerosol Time-of-Flight Mass Spectrometer

A description of the A-ATOFMS is given in detail elsewhere (Pratt et al., 2009). In brief, the A-ATOFMS measures the vacuum aerodynamic diameter ($d_{va}$) and chemical composition of single particles in real time for particles between $\sim 100–1000$ nm. After passing a Po$^{210}$ neutralizer and pressure controlled inlet (Bahreini et al., 2008), particles are focused through an aerodynamic lens (Liu et al., 1995a,b), where they are accelerated to their aerodynamic terminal velocity. The particles then pass through two continuous wave 532 nm lasers (JDSU) spaced 6.0 cm apart. The time difference between the scattering signals is used to calculate the velocity and size ($d_{va}$) of the particle. The velocity is used to queue the firing of a 266 nm Q-switched Nd : YAG laser (Quantel), operating at 0.5–1.5 mJ, for desorption and ionization of the particle. Dual polarity mass spectra are acquired after ions pass through a time-of-flight mass spectrometer (Tofwerk). The particle source is determined using positive spectra, while negative spectra provide information on the secondary species and chemical processing that the particle has undergone (Guazzotti et al., 2001; Noble and Prather, 1996; Prather et al., 2008).

Single-particle mass spectra were imported into Matlab (The MathWorks, Inc.) using the YAADA software toolkit (www.yaada.org). An adaptive resonance theory-based clustering algorithm (ART-2a, vigilance factor of 0.80, learning rate of 0.5, 20 iterations, and regroup vigilance factor of 0.85) was used to group spectra into clusters based on similar mass spectral characteristics (Allen, 2002; Rebotier and Prather, 2007; Song et al., 1999). Data from each campaign were grouped and then analyzed separately using ART-2a. Greater than 95 % of ART-2a analyzed particles were grouped into clusters which were further combined manually into 11 general particle types based on characteristic ion markers. Mass spectral peaks were identified according to the most probable ions at a given mass-to-charge ($m/z$) ratio. Particle source classifications were established based upon characteristic peaks identified in previous studies, however
these labels do not reflect all of the species present in a particle type, i.e. the presence of secondary species such as sulfate or nitrate. Calculated standard errors of number fractions were small, < 1%, hence were not included in this discussion.

### 2.2 CalNex – Southern California

Measurements were taken onboard the Center for Interdisciplinary Remotely-Piloted Aircraft Studies (CIRPAS) Twin Otter. Flight operations were based out of Ontario, CA through the Guardian Jet center, a part of the Los Angeles (LA)/Ontario international airport. There were nine flights during the study period of 5–18 May 2010, with each flight lasting ~ 4 h with a usual start time of ~ 11 a.m. local time (PDT). All flight tracks are shown in Fig. 1 and flight dates can be found in SI Table 1. Flights were focused in the LA basin, often making multiple circuits over the area. Results from the CalNex campaign are referred to as Southern California hereafter. Particle concentrations and size from 100–3000 nm were measured by a Passive Cavity Aerosol Spectrometer Probe (PCASP), and two Condensation Nuclei Counters (CPC, TSI models 3010 and 3025), detecting particles down to 10 and 3 nm, respectively. The A-ATOFMS collected data for 8 out of 9 flights, measuring the chemical composition and size of 75,969 particles during this study.

### 2.3 CARES – Northern California

Flights were operated out of the McClellan airfield in Sacramento, CA from 2–28 June 2010 onboard the Department of Energy Gulfstream-1. This study focused on the surrounding urban Sacramento area and Sierra Nevada foothills, thus results from this campaign are interchangeably referred to as Northern California. Usually each sampling day consisted of a flight in the morning, ~ 8 a.m. local, and in the afternoon, ~ 2 p.m. local, with most flights lasting ~ 4 h. Flight dates are given in SI Table 1, while the flight paths for all 22 flights during the study are shown in Fig. 1. More details on the campaign and instrumentation aboard the aircraft can be found elsewhere (Zaveri...
et al., 2012). Gas-phase concentrations of SO$_2$ and NO$_x$, as well as other species were measured in flight. Total condensation nuclei (CN) concentrations were measured using the same CPC models used in the CalNex campaign (TSI models 3010 and 3025). Number concentration and size for particles with sizes from 55–1000 nm were detected using an Ultra-High Sensitivity Aerosol Spectrometer (UHSAS) probe (Droplet Measurement Technologies). For direct comparisons of gas-phase species and particle concentrations between CalNex and CARES, representative average concentrations were calculated using data from the California Air Resources Board (CARB, http://www.arb.ca.gov) ground based measurements from North Main Street in LA and from Del Paso Manor in Sacramento to represent CalNex and CARES, respectively. The A-ATOFMS was on-line for 20 of 22 total flights, chemically analyzing 60, 230 particles.

3 Results

3.1 Particle sources throughout California

As shown in Fig. 2a, predominant particle sources by number fraction in the boundary/residual layers of both campaigns were identified as biomass burning (BB), highly processed (HP), soot mixed with OC (Soot-OC), OC, and soot, which represented 28, 22, 21, 16, and 5 % of total particle counts measured by the A-ATOFMS in both studies, respectively. BB originated from agricultural and residential burning, which is most prevalent in the rural regions of Northern California. These spectra are characterized by an intense potassium peak at $m/z$ 39$^+$ (Fig. 3a) in addition to less intense OC and soot peaks at $m/z$ 12$^+$, 24$^+$, 27$^+$, 29$^+$, 36$^+$, and 43$^+$ (Bi et al., 2011; Guazzotti et al., 2001; Hudson et al., 2004; Silva et al., 1999). HP are particles for which only negative ion spectra were acquired. Since the core, which is shown in the positive ion spectra, was not obtained, the source of these particles cannot be identified, but they are hypothesized to be carbonaceous particles that have
undergone extensive processing. Size distributions of these particles are nearly identical to those of Soot-OC particles \( (R^2 = 0.98) \) and to a lesser extent BB and OC particles \( (R^2 = 0.93 \) and 0.89, respectively), lending support to the hypothesis that they are most likely heavily coated soot particles. Thus, these particles will be included as carbonaceous aerosol in subsequent discussions.

Soot-OC, formed primarily through fossil fuel combustion and subsequent coagulation with or condensation of semivolatile organic species, has intense \( C^+_n \) peaks \( (^{12}C^+, ^{24}C_2^+, ^{48}C_3^+) \) with weaker OC peaks, \( m/z \) \( ^{27}C_2H_3^+, ^{29}C_2H_5^+, ^{37}C_3H^+, ^{39}C_3H_3^+/K^+, \) \( ^{43}C_2H_3O^+ \) (Spencer and Prather, 2006; Moffet and Prather, 2009) (Fig. 3b). Peaks at \( m/z \) \( ^{27}C_2H_3^+/CHN^+, ^{29}C_2H_5^+, ^{37}C_3H^+, ^{39}C_3H_3^+/K^+, \) and \( ^{43}C_2H_3O^+/CHNO^+ \) are indicative of OC species from vehicle and biogenic emissions (Fig. 3c). Peaks at \( m/z \) \( ^{50}C_4H_2/C_3N^+, ^{59}C_3H_9N^+, \) and peaks at \( m/z \) \( ^{12}C^+, ^{24}C_2^+, ^{48}C_3^+ \), similar to soot, were occasionally also seen on OC particles but at significantly lower relative intensities (Spencer and Prather, 2006). Figure 3d shows soot spectra which consist of almost entirely \( C^+_n \) peaks out to the high mass range, i.e. \( m/z \) \( ^{12}C^+, ^{24}C_2^+...^{180}C_{15}^+ \), and \( C^-_n \) peaks from \( m/z \) \( ^{12}C^-, ^{24}C_2^-...^{72}C_6^- \) in negative spectra. Other carbonaceous and non-carbonaceous particle types like vanadium mixed with OC (V-OC) (Ault et al., 2009), high mass OC (HMOC) (Silva and Prather, 2000), amine (AM) (Angelino et al., 2001; Pratt and Prather, 2010; Sorooshian et al., 2008), biological (BIO) (Fergenson et al., 2004; Pratt and Prather, 2010; Russell, 2009), dust (D) (Pratt and Prather, 2010; Silva and Prather, 2000), and sea salt (SS) (Gard et al., 1998) each represented < 3% of total aerosol and are described in detail in the Supplement. Negative ion spectra were absent in 13% of particles for both studies, with the majority of these occurring during the CARES (24%) rather than the CalNex campaign (4%). This is dependent on both instrument sensitivities and the amount of processing the particle has undergone. A more detailed discussion of only positive ion spectra is given in the Supplement.
3.2 Particulate secondary species in California

For particles with the same base chemical signature (i.e. biomass, soot, OC, etc.), relative peak areas (RPA) qualitatively reflect the amount of a species on a particle in relation to other species (Bhave et al., 2002; Gross et al., 2000; Prather et al., 2008). Previous studies in California have shown that the presence of ammonium nitrate (Sorooshian et al., 2008; Langridge et al., 2012) and ammonium sulfate (Qin et al., 2012) can influence single particle mixing state. During this study, partitioning of methanesulfonic acid (MSA) and organosulfate (OS) to particles was likely to occur in the vicinity of marine and heavily forested areas where MSA and OS, respectively, originate (Gaston et al., 2010; Hatch et al., 2011). To examine the mixing state of particles with biogenic, marine, and anthropogenic species, single particle mixing state was examined by identifying peaks of ammonium (\( {^{18}}\text{NH}_4^+ \)), sulfate (\( ^{97}\text{HSO}_4^- , ^{195}\text{H}_2\text{SO}_4\text{HSO}_4^- \)), nitrate (\( ^{46}\text{NO}_2^- , ^{62}\text{NO}_3^- , ^{125}\text{H(NO}_3)_2^- \) (Silva and Prather, 2000), MSA (\( ^{95}\text{CH}_3\text{SO}_3^- \) (Gaston et al., 2010), and/or OS (derived from glycolic acid (\( m/z = 155 \)), 2-methylglyceric acid (\( m/z = 199 \)), and isoprene epoxydiol (\( m/z = 215 \)) (Hatch et al., 2011). Other secondary species were investigated, but no significant trends were seen. A particle is considered to contain these species if the RPA for \( m/z \) ratios indicative of those species exceeds 0.5 % of the mass spectrum. For example, a particle contains sulfate if the RPA at \( m/z = 97 \) or \( = 195 \) is greater than 0.5 % of the ions in the entire mass spectrum.

Most particles in California were found to be internally mixed with secondary species, with nearly 88 % of particles containing sulfate, nitrate, MSA, OS, or ammonium individually or internally mixed together. Commonly, particles contained sulfate (82 %) or nitrate (82 %), and 76 % of particles had both, but, as discussed below, the magnitude of these species varied greatly between Southern and Northern California.
3.3 Southern California aerosol mixing state

In the LA basin, frequently capped by a temperature inversion, a prevailing sea breeze transports air to the east toward the outflow pathways for the basin. Most Twin Otter flights in Southern California were carried out at low altitudes, < 700 m, sampling within the boundary layer. The number fractions of the main carbonaceous aerosol types from Southern California differed greatly from those in California as a whole, as shown in Fig. 2b. Particles were generally highly aged, as seen by the high fraction of HP aerosols in the region (33%). Particles are often entrained within the basin, where they can undergo significant atmospheric processing (Schultz and Warner, 1982; Ulrickson and Mass, 1990). Soot-OC, BB, OC, and soot were the other main particle types present, comprising 21, 18, 13, and 7% of A-ATOFMS total particle counts in Southern California. V-OC, AM, HMOC, and BIO represented 3.0, 0.8, 1.4, and 0.5% of total particles, respectively. Excluding HP particles, nearly 96% of submicron particles measured by the A-ATOFMS in Southern California contained carbonaceous material. Representative soot (36C3+, 48C4+, 60C5+) and OC (27C2H3+, 29C2H5+, 37C3H+, 43C2H3O+) ions > 0.5% of the mass spectrum were present in 62% and 63% of total particles, respectively (Fig. 4, left panel) (Spencer and Prather, 2006). Normally soot is emitted at sizes below the detection limit of the instrument (100 nm). The fact that particles with intense soot peaks were seen indicates that soot particles had grown into the A-ATOFMS size range. Secondary species, such as nitrate, sulfate, and OC, contribute to this growth, but the extent each component plays in particle growth is unknown. OC RPA cannot be compared directly to sulfate and nitrate RPA as their ion formation mechanisms are different. However, OC and soot RPAs can be compared to determine the relative amount of OC mass on a particle. If the magnitude of OC peaks is low, then other species must have contributed to the growth of soot into larger sizes. To elucidate the magnitude of soot with OC in the same particle, a ratio of OC:soot was calculated by dividing the total RPA for each species by the other. These ratios form a distribution of values that represents all of the variance in magnitude of these
species on particles ranging from pure OC to pure soot. Since these ratios are calculated for a single particle, they are not dependent on laser fluence or matrix effects, assuming that the entire particle is completely ablated and that matrix effects suppress the selected ions equally (Morrical et al., 1998; Wenzel and Prather, 2004). It should be noted that OC particles could contain a soot core that was not ablated fully, which would affect these calculations, and that HP particles were not included in this analysis since they did not contain positive ions (Steele et al., 2003; Morrical et al., 1998; Pratt and Prather, 2009).

OC : soot ratios for particles in Southern California are shown in Fig. 4, right panel. For visual clarity, the OC : soot ratio has been normalized so that ratios < 1 will approach −1 as it proceeds to −∞ (i.e. soot without OC) and a ratio > 1 will approach 1 as the ratio proceeds to +∞ (i.e. OC without soot). Further details on these calculations can be found in the Supplement. It should be emphasized that as ratios approach −1 or 1, they are exponentially increasing, while nearing zero the RPA of each species is essentially the same. As expected, a distribution of OC : soot ratios exists, demonstrating the variability in mixing state observed in Southern California. As shown in Fig. 4, right panel, a nearly equal number of particles have ratios above and below 0, although pure soot has nearly seven times as many particles as pure OC. On days when OC dominates the mass spectra, influences from BB were significant, which is expected since BB is composed of nearly 62% OC by mass for smoldering fires (Reid et al., 2005). Soot likely originated from fossil fuel vehicle emissions in the LA basin (Ying and Kleeman, 2006).

Most particles in Southern California had been processed to some degree, as indicated by ~ 96% of particles producing negative ion spectra with secondary species. Similarly, Metcalf et al. (2012) found that most soot particles were present with coatings of varying thicknesses during the CalNex study. Nitrate appeared on 95% of particles, with 90% of particles containing sulfate peaks (Fig. 5, left panel). Ratios of sulfate : nitrate RPAs, calculated in the same manner as OC : soot ratios, for every particle (including HP) are shown in Fig. 5, right panel. Most particles contain more nitrate
than sulfate, but still a significant number of particles contain more sulfate than nitrate. This largely corroborates reported findings from other measurements during CalNex (Langridge et al., 2012; Metcalf et al., 2012). To see if there is preferential partitioning of nitrate or sulfate to any particular source, the ratios in Fig. 5, right panel were split into particle sources. Most particle sources have very similar ratio distributions that cover a wide range of sulfate : nitrate values, indicating that nitrate and sulfate partitioned to particles regardless of the original source/core. SS and V-OC are the only exception, as both of these types are present with ratios exclusively favoring nitrate. Nitrate is known to heterogeneously replace chloride on SS particles as they age, which may explain the preference of nitrate to SS observed in peak ratios (Gard et al., 1998). Ault et al. (2010) measured V-OC particles near to the emission source and hypothesized that vanadium acted as a catalyst to produce sulfate from SO$_2$. In the present work particles were measured farther from the source and are processed to a higher degree such that nitrate might have replaced sulfate on those particles. This analysis demonstrates that peak ratio distributions may be used to identify different processing mechanisms when preferential partitioning of species to distinct types is observed.

Large nitrate fractions can be attributed to high NO$_x$ concentrations over Los Angeles, an average of 32 ppb for the study period (CARB). In addition, ammonium nitrate originates from animal husbandries surrounding the Los Angeles area near Chino, which have been shown to be a large source of ammonia in the region (Kleeman and Cass, 1998; Singh et al., 2002; Sorooshian et al., 2008; Ying and Kleeman, 2006). Ammonium was found to be present in 37% of total particles, so the high nitrate seen in CalNex could in part be due to the presence of ammonium nitrate. Nearly 98% of particles internally mixed with sulfate were also mixed with nitrate, whereas only 93% of particles internally mixed with nitrate were mixed with sulfate in Southern California. MSA was present on 52% of total particles in Southern California, indicating that sulfate originating from marine sources was prevalent in the region, as expected due to the close proximity of LA to the ocean (~30 km) (Ying and Kleeman, 2006). A small
fraction of particles contained organosulfate peaks (28%), likely due to smaller biogenic influence in the LA basin.

3.4 Northern California aerosol mixing state

The Sacramento region is characterized by consistent southwesterly flow that carries air into the Sierra Nevada foothills during the day and recirculates the air back towards Sacramento at night, forming a residual layer of aged air the next day (Zaremba and Carroll, 1999; Fast et al., 2012). Most flights sampled at low altitudes, < 700 m, in either the boundary layer or residual layer. Number fractions of particles in Northern California are shown in Fig. 2c. Unlike in Southern California, BB represented a more significant fraction of particles (41%), due to increased residential and agricultural burning in the rural regions in Northern California. HP particles did not represent as large a fraction in Northern California, comprising only 9% of particles versus 33% in Southern California. Furthermore, only 76% of particles contained negative ion spectra, suggesting that particles in Northern California had not undergone as much processing as in Southern California. Often the lack of negative ion spectra is attributed to the presence of water (Neubauer et al., 1998, 1997), however relative humidity (RH) was lower on average during the CARES study (39 ± 14%) compared to CalNex (49 ± 30%), hence the potential impact of water on suppressing negative ion spectra should be less relative to CalNex.

As was observed in Southern California, OC and soot-OC comprised a significant fraction of total aerosol in Northern California, 21% and 20%, respectively. Pure soot was present at lower number fractions (3%) than in Southern California (7%), though a better representation of soot and OC content can be found through peak areas and peak area ratios. Significant soot and OC peaks were found in 84% and 87% of total particles, respectively (Fig. 6, left panel). Single particle ratios of OC : soot (Fig. 6, right panel), which are directly comparable between studies, indicates that OC was more significant in Northern California as compared to Southern California, with nearly 64% of ratios > 1, hence having greater OC content. This fraction is significantly higher than
that in Southern California (48%) and is likely due to the heavily forested Sierra Nevada foothills lying to the northeast of Sacramento, which act as a source of biogenically derived OC particles.

In contrast to Southern California, most particles in Northern California were primarily mixed with sulfate rather than with nitrate. Sulfate peaks were internally mixed with 72% of particles in Northern California (Fig. 7, left panel). Of those particles containing sulfate, 59% contained nitrate, though sulfate markers were usually many times more prominent than nitrate markers on the same particle. Few particles contained only nitrate (~3%), while 13% of particles comprised only sulfate. Figure 7, right panel shows the sulfate: nitrate ratios for particles containing sulfate or nitrate in Northern California. 80% of particles contained more sulfate than nitrate and ~51% of those particles had a ratio > 10:1. Similar to Southern California, ratios covered a wide range of values, though in Northern California ratio distributions did not indicate preferential partitioning of sulfate or nitrate to any particle type, with the exception of SS which was present with high ratios of nitrate, as in Southern California. The decreased prevalence of nitrate in Northern California can be attributed to lower NO_x emissions in Northern California as compared to Southern California, with 1 h averages of 4 and 32 ppb, respectively, from measurements at ground sites in Sacramento and LA (CARB). Ammonium was present in amounts similar to those in Southern California, representing nearly 42% of total particles, suggesting the presence of ammonium sulfate. Recently published findings from AMS measurements at the T1 rural ground site during CARES, near the Sierra Nevada foothills, determined that much of particulate sulfate was indeed present as ammonium sulfate (Setyan et al., 2012).

One can gain insight into the source of sulfur species by examining the presence of MSA (originating from marine air) and OS (originating from biogenic aerosol) on single particles. While OS and MSA peaks were detected on 35% and 50% of particles, respectively, sulfate was present on 72% of particles, and usually exhibited higher peak intensities. Fast et al. (2012) hypothesized that a significant fraction of SO_2 present in the CARES region originates from the oil refineries in the Carquinez Strait, near San
Francisco, as no substantial sources of SO$_2$ exist in the Sacramento area. While anthropogenic SO$_2$ from this source is likely responsible for the high sulfate present on single particles, some days were observed to have high fractions of particles containing OS and MSA, indicating significant contributions from natural sources. For example, on 14 June, nearly 70% of the particles contained OS, and on 3 June, 72% of particles contained MSA. These elevated fractions occurred toward the beginning of the study and, as will be discussed in the following section, particle composition exhibited significant temporal variability during the CARES study.

3.5 Temporal differences in Northern California aerosol: NoCal-1 and NoCal-2

The particle sources during CalNex were quite stable over the duration of the study. However, a noticeable shift in particle composition, particulate mass, and meteorology occurred during CARES after 21 June (SI Fig. 1). The sources and processes contributing to these two periods were quite different. To examine these differences in detail, the CARES study was separated into two periods, Northern California-1 (NoCal-1) and Northern California-2 (NoCal-2), representing fights from 2–19 June 2010 and 21–28 June 2010, respectively. NoCal-1 was relatively clean compared to NoCal-2, which was influenced more by local sources, evidenced by an increase of particulate matter < 2.5 µm (PM$_{2.5}$) by 12% measured at the CARB Del Paso Manor site, from 5.7 to 8.0 µgm$^{-3}$ for NoCal-1 and NoCal-2, respectively. Mean gas-phase concentrations of SO$_2$ and NO$_x$ measured in flight increased as well from NoCal-1 to NoCal-2 by 23% and 25%, respectively. Similarly, Fast et al. described increased O$_3$ and weaker winds during the same approximate period as NoCal-2 (Fast et al., 2012). Mean CPC particle concentrations decreased by ~32% (using CPC model 3025), while larger particles measured by the UHSAS, which are detected more efficiently by the A-ATOFMS, increased in number by 56%. Correspondingly, A-ATOFMS average particle counts per flight increased between the first and second half of CARES by 71%.

As shown in SI Fig. 1, the relative fractions of particle types for each flight during CARES change after 19 June 2010, which coincides with an increase in average
PM$_{2.5}$ mass. NoCal-2 exhibited significantly higher fractions of Soot-OC and BB than in NoCal-1 (Fig. 8), an increase of 17 and 19%, respectively, and a corresponding decrease in the fraction of OC, suggesting less biogenic influence in the region. Interestingly, particulate chemistry in NoCal-2 and Southern California was remarkably similar, with the exception of the relative magnitudes of sulfate and nitrate on particles. Since it is unlikely that a new source of soot emerged from Sacramento during NoCal-2, the increased detection of soot-containing particles resulted from the growth of preexisting soot particles through condensation of organic vapors and SO$_2$, manifested as more soot-OC mixed with sulfate in A-ATOFMS data. The number fractions of particles containing peaks of soot, 75% and 90%, and OC, 78% and 93%, for NoCal-1 and NoCal-2, respectively, were similar in magnitude during both periods but increased in NoCal-2 (Fig. 9, left panel). However, a comparison of the OC : soot ratio distributions from NoCal-1 to NoCal-2 indicates a shift in the OC : soot ratio distribution towards a nearly identical distribution as that observed in Southern California (Fig. 4, right panel), where nearly half of the ratios favored soot (Fig. 9, right panel). In contrast, the OC : soot ratio distribution for NoCal-1 (Fig. 9, right panel) was dominated by OC. Higher CPC concentrations during NoCal-1 indicate that soot particles were present over the urban Sacramento region during this first period, but at sizes below the A-ATOFMS detection limit (< 100 nm). A-ATOFMS size distributions were broader for NoCal-2, also indicative of growth of particles (SI Fig. 2). During NoCal-1, OC content can primarily be attributed to biogenically derived OC from the surrounding forested regions, whereas during NoCal-2 OC primarily existed as a coating on a soot core similar to observations in Southern California. With higher NO$_x$ emissions, soot particles in LA exhibit higher number fractions mixed with nitrate observed by the A-ATOFMS. Similarly to LA, higher SO$_2$ and NO$_x$ concentrations during NoCal-2 led to the faster growth of soot, and an increase in the fraction of ratios favoring soot measured by the A-ATOFMS.

Sulfate : nitrate ratio distributions were relatively unchanged between NoCal-1 and NoCal-2 (SI Fig. 3). However, the fractions of MSA and OS on total particles decreased
significantly from NoCal-1 to NoCal-2, from 66% to 38% and 49% to 24% for MSA and OS, respectively. One concludes that during NoCal-1 particulate sulfate was heavily influenced by natural sources, while during NoCal-2 anthropogenic sources dominated.

3.6 Comparison between Northern and Southern California aerosol mixing state

The most striking difference between mixing states in Northern and Southern California is the greater magnitude of single particles mixed with sulfate in the north and nitrate in the south. Figure 10 shows the difference in RPA from averaged BB, OC, and Soot-OC mass spectra obtained in Southern (top) and Northern (bottom) California. Positive intensities indicate peaks that were more prevalent in Southern California while negative intensities indicate prevalence in Northern California. All three particle types clearly indicate more intense sulfate peaks in the north and more intense nitrate peaks in the south. Both Langridge et al. (2012) and Metcalf et al. (2012) found significant contributions of nitrate and OC to the aerosol in LA as well. In contrast, previous ground-based measurements in the LA and port of Long Beach areas found higher fractions of sulfate on particles (Pastor et al., 2003; Whiteaker et al., 2002; Qin et al., 2012), and recent findings during the CalNex ship campaign (Gaston et al., 2012) observed a higher abundance of sulfate in Southern California than Northern California, though the latter is likely more indicative of port regions which are known to have large sources of sulfate from ship emissions (Ault et al., 2009).

The contributions of soot and OC to single particle mixing state were found to vary greatly depending upon the region, with soot having a larger influence in the south and OC being more prevalent in the north, as shown by measured OC:soot ratios. The largest difference in the nature of particles between Southern California and Northern California occurred during NoCal-1, when the influence of biogenic OC was the greatest in the north. During this period, the number fraction of OC particles was nearly 18% higher in the north than in the south. Both NoCal-2 and Southern California aerosol exhibited similar chemistry, with most particles containing a soot core with OC, sulfate,
4 Conclusions

Two aircraft field campaigns, CalNex and CARES, provide insight into the distribution and mixing state of carbonaceous aerosols in California during the late spring and early summer of 2010. Most submicron particles (∼97%) in California contain carbonaceous material, and nearly 88% of all particles show signs of atmospheric aging. Particles are internally mixed with secondary species, including sulfate, nitrate, MSA, OS, and ammonium. Most strikingly, nitrate is more prevalent on particles in Southern California, whereas this is the case for sulfate in Northern California. This suggests that different sources are impacting particles in the two regions.

OC : soot ratio distributions in Southern California show that most particles are soot-dominated with an OC coating, whereas OC-dominated particles from biogenic sources are more prevalent in Northern California. Single-particle measurements also show that many particles contain both OC and soot, which will lead to increased radiative absorption and scattering (Schnaiter et al., 2005; Schwarz et al., 2008; Moffet and Prather, 2009). A shift in chemistry was observed during the latter half of the CARES campaign, from OC-dominant to soot-dominant, as particles in Northern California became very similar to particles in Southern California. In addition, total PM$_{2.5}$ reflected this change in particle composition, as PM$_{2.5}$ concentrations increased significantly in the latter half of the study. This suggests similar particle mixing states are present during periods of relatively higher PM$_{2.5}$ levels in California. Thus, regionally specific mixing states, as well as temporal changes in mixing state, will need to be taken into account for accurate regional aerosol-climate modeling.
Acknowledgements. We would like to acknowledge the University of California San Diego-Pacific Northwest National Laboratory Aerosol Chemistry and Climate Institute and the California Air Resources Board Agreement #09-333 for providing the funding for this work. Stephen R. Springston provided in flight gas phase concentrations during the CARES campaign. The authors are also grateful to the flight crews during the CARES and CalNex studies, most notably John Hubbe, Jason Tomlinson, Scott Hersey, Andrew Metcalf, and Haflidi Jonsson, as well as Jessie Creamean and Melanie Zauscher of the Prather Group for their help with this project. The Twin Otter portion of this work was supported by NOAA grant NA090AR4310128. Funding for data collection onboard the G-1 aircraft was provided by the Atmospheric Radiation Measurement (ARM) Program sponsored by the US Department of Energy (DOE), Office of Biological and Environmental Research (OBER). This research was also supported by the US DOE’s Atmospheric System Research (ASR) Program under Contract DE-AC06-76RLO 1830 at PNNL.
