Abstract

Measurements of Cloud condensation nuclei (CCN), condensation nuclei (CN) and aerosol chemical composition were performed simultaneously at an urban site of Shanghai from 6 to 9 November 2010. The variations of CCN number concentration ($N_{CCN}$) and aerosol activity (activated aerosol fraction, $N_{CCN}/N_{CN}$) were examined during a fog-haze co-occurring event. Anthropogenic pollutants emitted from vehicles and unfavorable meteorological conditions such as low planetary boundary layer (PBL) height exerted a great influence on PM$_{2.5}$ and black carbon (BC) loadings. $N_{CCN}$ at 0.2% supersaturation (SS) mostly fell in the range of 994 to 6268 cm$^{-3}$, and the corresponding $N_{CCN}/N_{CN}$ varied between 0.09 and 0.57. $N_{CCN}$ and $N_{CCN}/N_{CN}$ usually were higher in hazy case due to increased aerosol concentration in the accumulation mode (100-500 nm), and lower in foggy-hazy and clear cases. BC mass concentration posed a strong positive effect on $N_{CCN}$ in foggy-hazy and hazy cases, whereas it poorly correlated with $N_{CCN}$ in clear case. $N_{CCN}/N_{CN}$ was weakly related with BC both in foggy-hazy/hazy and clear cases. By using a simplified particle hygroscopicity ($\kappa$), the calculated critical dry size (CDS) of activated aerosol did not exceed 130 nm at 0.2% SS in spite of diverse aerosol chemical compositions. The predicted $N_{CCN}$ at 0.2% SS was very successful compared with the observed $N_{CCN}$ in clear case ($R^2=0.96$) and foggy-hazy/hazy cases ($R^2=0.91$). In addition, their
corresponding ratios of predicted to observed $N_{CCN}$ were on average 0.95 and 0.92, respectively. More organic matter is possibly responsible for this closure difference between foggy-hazy/hazy and clear cases. These results reveal that the particulate pollutant burden exerts a significant impact on $N_{CCN}$, especially $N_{CCN}/N_{CN}$ promotes effectively during the polluted periods.

1. Introduction

Cloud condensation nuclei (CCN), which constitutes an important fraction of atmospheric aerosol, can influence the microphysical and radiative properties and lifetime of cloud indirectly and consequently impact the hydrological cycle (IPCC, 2013). The elevated CCN loadings ($N_{CCN}$) tend to reduce cloud droplet size and then suppress precipitation in shallow and short-lived clouds (Lohmann and Feichter, 2005). But it can promote great convective overturning and enhance precipitation in deep convective clouds (Rosenfeld et al., 2008). Numerous aerosol properties, including particle size distribution, chemical composition and mixing state, are closely linked with the ability of particles to take up water vapor, i.e. the ability to act as CCN (Baumgardner et al., 2003; Kuwata and Kondo, 2008; Cubison et al., 2008). To date, the current assessment of aerosol indirect effects induced by increasing
anthropogenic aerosols remains poorly understood, and this brings a big uncertainty in fully picturing climate change (Andreae et al., 2005; IPCC, 2013).

Owing to advanced instrument development, the aerosol-cloud interaction and its impact on climate have attracted increasing attention in the last decades. Many ground-based measurements on CCN have been performed in diverse environments, describing a global map of CCN distribution in the surface atmosphere (Baumgardner et al., 2003; Yum et al., 2004, 2005; Reade et al., 2006; Juranyi et al., 2010; Leng et al., 2013). In urban environments, the new particle formation and growth, and haze pollution were observed recently as having a significant impact on $N_{\text{CCN}}$ (Ritesh et al., 2007; Kuang et al., 2009). In recent years, CCN studies have raised the relative importance of several influence factors controlling aerosol CCN activity, of which size has been announced as the major factor in determining the CCN activation of aerosol particles (Dusek et al., 2006; Anttila and Kerminen, 2007; Hudson, 2007; Quinn et al., 2008; Jimenez et al., 2009; Leng et al., 2013). However, how chemical composition especially organic compounds to link with aerosol activity and then CCN has not been fully understood. In fact, up to 90% of the aerosol population has been formed by carbonaceous substances, and among them 10-70% is water-soluble (Moffet et al., 2008; Stone et al., 2008). Particularly, various externally or internally-mixed particulate
components comprised in urban air mass can significantly affect the 
CCN-sized spectra of atmospheric particles (Svenningsson et al., 2006; 
Reade et al., 2006; Kuwata et al., 2007). This has posed a major challenge 
to study aerosol composition and predict CCN activity (Hagler et al., 
2007; Hings et al., 2008; Henning et al., 2010).

Due to rapid industrialization in Asia for decades, anthropogenic 
particles and relevant precursor emissions have increased significantly, 
and numerous studies have indicated that the increasing anthropogenic 
aerosol loading has significantly changed cloud microphysical and 
radiative properties (Streets et al., 2000, 2008; Shao et al., 2006; Wang et 
al., 2006; Qian et al., 2006; Rosenfeld et al., 2007; Matsui et al., 2010; 
Zhang et al., 2013). In China, studies on CCN have been done widely 
such as at polluted sites located in Yufa (Wiedensohler et al., 2009), 
Beijing (Yue et al., 2011), Shouxian (Liu et al., 2011) and Shanghai (Leng 
et al., 2013), and suburban sites in Guangzhou (Rose et al., 2010, 2011) 
and Wuqing (Deng et al., 2011). To our knowledge, little attention has 
been paid on the impacts of fog or haze on CCN and activated aerosol 
particles. The increases of haze occurrences are evident in the eastern and 
southwestern cities in China (Che et al., 2009). Shanghai is a huge 
metropolis in China, and the occurrence intensity of foggy and hazy days 
on annual time scale has been increasing gradually especially in winter 
(Tie and Cao, 2009), which is deeply affected by fine particle pollution
enhancement and possibly linked with particle hygroscopicity (Ye et al., 2011).

This study presents continuous measurements of CCN and aerosol during a fog-haze episode from 6 to 9 November 2010 in Shanghai. The aim is to provide insights on CCN and aerosol activity variations under fog-haze co-occurring conditions. The instrumentation and data used in the study are described in section 2. The aerosol physical and chemical properties are introduced in section 3. Section 4 presents the evolution of CCN and aerosol activity. The relationship between aerosol and CCN is discussed in section 5. Conclusions from the study are given in section 6.

2. Methods

2.1 Observational Site

The instruments for CCN and aerosol measurements have been mounted roughly 20 m above ground on the roof of a building in the campus of Fudan University in Shanghai (31°18′N, 121°29′E) since October 2010. The site is surrounded by populated residential and commercial areas, as well as urban streets. The East China Sea is roughly 40 km east of the site, and the prevailing wind directions are southeasterly in summer and northeasterly in winter. Local time (LT) hereafter employed in this study is 8h ahead of UTC.

2.2 Measurements and Methodology

$N_{CCN}$ was measured using a continuous flow and single column CCN
counter (model CCN-100, Droplet Measurement Technologies, USA), in which an optical particle counter (OPC, 0.75-10µm) is employed to detect activated cloud droplets (Roberts and Nenes, 2005; Lance et al., 2006). The instrument was housed in an air-conditioned weather-proof container with temperature maintaining at 20°C. The ambient aerosol airflow passed through a dryer (active carbon) to lower relative humidity below 30% before entering the instrument (Leng et al., 2013). The CCN counter was calibrated using ammonium sulfate before the study, as did calibrations for temperature gradient, flow, pressure and OPC to maintain stable SS according to the DMT operation manual. In order to ensure accurately counting, zero checks were performed before and after the campaign and regularly every two months. The effective water vapor supersaturation (SS) changed alternately at 0.2% interval within 0.2-1.0%. In real atmosphere, SS varies from slightly less than 0.1% in polluted conditions to over 1.0% in clean-air stratus cloud (Hudson and Noble, 2014). The selection of SS 0.2% in the present study would benefit to the measurements in the urban environment for further analysis. Although the CCN counter can operate well under conditions of particles only in a few thousand number per cubic centimeter and corrections must need for larger concentrations (>5000cm⁻³) (Lathem and Nenes., 2011), we still used the measured $N_{CCN}$ directly at 0.2% SS in this study since it seldom reached the upper limit.
A high-resolution wide-range particle spectrometer (WPS-1000 XP, MSP) was employed to observe particle size distributions in the size range of 10 nm-10 µm. The principles of the instrument, which have been introduced in detail by Gao et al (2009), combine the Laser Light Scattering (LPS), Condensation Particle Counting (CPC) and Differential Mobility Analysis (DMA). The DMA and CPC can effectively measure aerosol particles distributed in the size range of 10-500 nm in up to 96 channels. The LPS scan the size range of 350-10,000 nm in 24 additional channels. In the present study 60 channels in DMA and 24 channels in LPS for the sample mode were chosen and 3 minutes were needed to scan the entire size range completely, as it took 2 seconds for scanning each channel. DMA was calibrated with NIST SRM 1691 and SRM 1963 PSL spheres (mean diameter of 0.269 and 0.1007 µm, respectively) to maintain DMA transfer function properly and accurate particle sizing traceable to NIST. Four NIST traceable sizes of PSL (i.e. 0.701, 1.36, 1.6 and 4.0 µm) were used to calculate LPS. The calibration and operating methodology of WPS has been described elsewhere (Zhang et al., 2010).

In addition, we have compared the aerosol size spectra measured by WPS with those measured in parallel by a calibrated scanning mobility particle sizer (SMPS, TSI 3080) with higher accuracy in the size range of 20-800 nm, including size-resolved particle concentrations and peak sizes, and a strong correlation between them was derived with correlation coefficient
The result confirms the reliability of WPS measurements for successfully characterizing the number concentration and size distribution of condensation nuclei (CN).

Planetary boundary layer (PBL) height and aerosol vertical extinction profile were measured using a set of micro pulse lidar (MPL) system (MPL-4B-532) with pulse energy 6-10 µJ and pulse repetition frequency 2500 Hz. The MPL is an eye safe, compact and autonomous instrument, and an effective tool used widely in the world to provide available high spatial (30 m) and temporal resolution (30 s) information of aerosol vertical distributions (Menut et al. 1999; Cohn and Angevine, 2000; Brooks, 2003). The range of lidar is roughly 30 km at night and 10 km during the daytime. The description of the retrieval of aerosol parameters by the MPL will be only briefly summarized here as it has been given by He et al (2006). The vertical profile of the aerosol extinction coefficient is determined by a near end approach in solving the lidar equation (Fernald, 1984). The PBL height is determined by the MPL lidar at the altitude where a sudden decrease of scattering coefficient occurs (Boers and Eloranta, 1986). The overlap problem must be solved because it can lead to an underestimation of aerosol backscatter and extinction coefficients in the lowest altitudes having the majority of aerosols (He et al., 2006a). Outlined by Campbell et al (2002), overlap is typically solved experimentally. The system is set to point horizontally to
an averaged data sample with no obscuration, such as the late afternoon, when the atmosphere is well mixed and the aerosol loading is low. The backscattering over the target layer is roughly assumed constant. The similar calibration performed in 2009 showed the full overlap of about 4 km and data are needed to be corrected by the overlap correction function. Welton et al (2002) fully discussed the uncertainties caused by the overlap correction and He et al (2006) estimated it to be less than 10%.

An online Aethalometer (AE-31, Magee Scientific Co., Berkeley, California, USA) was employed to measure black carbon (BC) at a 5-min time resolution. The instrument was operated at an airflow rate of 5 l/min. Based on the strong absorptivity of BC to light at near infrared wavelengths (Hansen et al., 1984; Weingartner et al., 2003), BC concentration is determined using the measured light attenuation at 880 nm and the appropriate value of specific attenuation cross section proportional to BC mass (Petzold et al., 1997). The attenuation can be obtained by calculating the difference between light transmission through the particle-laden sample spot and the particle-free reference spot in the filter (Cheng et al., 2006; Dumka et al., 2010). The operation, calibration and maintenance of AE-31 have been described in detail by Cheng et al. (2010).

An online analyzer for Monitoring Aerosols and Gases (MARGA, ADI 2080, Netherlands) was employed to measure the concentration of
major inorganic water-soluble ions (e.g. Na+, K+, Mg2+, Ca2+, SO42-, Cl-, NO3- and NH4+) in ambient aerosol particles at 1-hour time resolution. An air pump controlled by a Mass Flow Controller (MFC) draws ambient air with airflow of 1 m³/hour into the Sample Box. An internal calibration method by using bromide for the anion chromatograph and lithium for the cation chromatograph was operated over the entire measurement period to ensure this instrument to identify and measure ion species successfully. Instructions for the methods of sampling, operation and internal calibration have been described in detail elsewhere (Du et al., 2011). Moreover, the mass concentrations of particulate matter (PM) with aerodynamic diameter less than 2.5 μm (PM2.5), meteorological factors and atmospheric visibility were measured by a continuous PM ambient monitor (FH62C14, Thermo), an automatic weather monitoring system (HydroMet™, Vaisala) and a automatic visibility monitor at 5-min time resolution, respectively.

2.3 Air Mass Backward Trajectory

The HYSPLIT-4 model developed by the Air Resources Laboratory (ARL) of the National Oceanic and Atmospheric Administration (NOAA), USA (Draxler et al., 2003), was employed to compute 24h air mass backward trajectories ending at 500m height (AGL) and starting at 0:00 LT and 12:00 LT for each day. By doing so, we can identify aerosols from different source regions and analyze their effects on aerosol activity to
compile a full view of the relation between fog-haze event and $N_{CCN}$. According to these calculated trajectories plotted in Figure 1, aerosol was classified into two categories: (1) maritime aerosol transported by air masses from marine areas on 6 Nov. 2010 carrying dominant oceanic particles, (2) continental aerosol in air mass traveling a long distance over inland areas on 7, 8 and 9 Nov. 2010 and carrying more anthropogenic particles (e.g. BC). Exactly, the maritime air mass originated from the China Eastern Sea, traveled northwesterly slow-moving across the Hangzhou Bay and finally arrived in Shanghai on 6 November. Then the air mass changed its pathway to southeasterly at around 12:00 am on 7 November, and originated from northern inland areas and traveled across the North China Plain (NCP) and the eastern region of China. The continental sources contained increasing industrial and agricultural emissions (e.g. biomass burning) due to long-term rapid economy growth and large population in the last few decades. We hope to better understand the impact of aerosols with or with less anthropogenic particulate pollutants on CCN in this study by comparing these two categories.

3. Results

3.1 Overview of the Fog-haze Event

Haze is traditionally defined as an atmospheric phenomenon that the sky clarity is obscured by dust, smoke and other dry particles, and
atmospheric visibility and relative humidity (RH) are usually less than 10 km and 80% over one haze episode (Fu et al., 2008). The high frequency of haze or hazy days is observed in winter, especially in the urban environments of northern China (Sun et al., 2006). During the haze event, the enhancement of particulate pollutants may greatly affect aerosol activity and N_{CCN}. The study performed in the Indo-Gangetic plain shows that winter haze exerts a significant impact on the fog and low-cloud formation (Gautam et al., 2007). Fog can be viewed as a lower-atmospheric near-surface cloud, and plays an important role in processing aerosol particles and trace gases (Gultepe et al., 2007; Biswas et al., 2008). On one hand, physically similar to cloud droplet, fog droplet also forms by water vapor condensing on dry aerosol particle under supersaturated conditions. On the other hand, generally formed in the shallow boundary layer containing local emissions, urban fog traps more pollutants than cloud at high altitudes (Fisak et al., 2002; Herckes et al., 2007). The fog or foggy case is defined as a weather with patterns of low visibility (<10 km) and higher RH (>90%). When 80% <RH< 90%, the weather was referred as a complex of haze and fog co-occurring (e.g. foggy-hazy) in the present study. Figure 2 and 3 show a 4-day time series of pressure, atmospheric visibility, RH, temperature, wind speed and direction, and PBL height from 6 to 9 November 2010. In fact, since RH seldom reached up to 90%, thus the period focused in the present study
were characterized as hazy and foggy-hazy cases. The haze pollution lasting at least 4 hours has been identified as one haze event by an earlier study in Shanghai, where authors paid attention to the formation of haze pollution (Du et al., 2011).

As shown in Figure 2-8, the 4-day period was classified into three parts: a hazy episode (marked in black open boxes) from 22:00 to 23:00 LT on 6 Nov. and 10:00 LT on 7 Nov. to 13:00 LT on 8 Nov., a foggy-hazy episode (marked in red open boxes) from 23:00 LT on 6 Nov. to 10:00 LT on 7 Nov., and the rest for clear case. Statistics for meteorological conditions is listed in Table 1 where the extinction profiles are averaged for a certain altitude of 500 m. During the hazy and foggy-hazy case, the average atmospheric visibility was about 4.44 km and 2.33 km, respectively, much lower than 15.4 km in the clear case. The winds from the east and the south brought clean maritime aerosol during the clear case, however, the winds from the north and the west brought polluted anthropogenic aerosol during the hazy and foggy-hazy cases. The particulate and gaseous matters, including pollutants (e.g. BC) emitted from agricultural biomass burning were transported along the air mass pathways (Figure 1), led to a significant enhancement of aerosol extinction coefficient from hourly averages of 0.5 to 1.2 km\(^{-1}\) (Figure 3). In addition, the PBL height downed to below 500 m and further suppressed the dilution of pollutants.
3.2 Physical and Chemical Properties of Aerosol

In order to visually identify aerosol evolution, particles in the size range of 10 nm to 10µm were categorized into 7 sub-size bins: 10-20 nm (nucleation mode), 20-50nm and 50-100nm (Aitken mode), 100-200nm, 200-500nm and 0.5-1µm (accumulation mode), and 1-10µm (coarse mode) (Figure 4). The similar classification has been done in the measurements at the same site by Zhang et al (2010). In this study, the integrated particle size-resolved number concentrations (N_{CN}) exhibited a regular diurnal cycle, with two peaks (9,000-16,000 cm^{-3}) almost within the traffic rush hours. The mean N_{CN} exhibited no obvious difference between the foggy-hazy (8,367 cm^{-3}) and clear (8,956 cm^{-3}) cases, but it showed a higher value (10,500 cm^{-3}) in the hazy cases, revealing a larger loading of particulate pollutants.

In general, the 20-100 nm (Aitken mode) particles are mostly dominant in all size particles probably due to local traffic emissions and meteorological conditions (Ferin e al., 1990). The temporal variation trend of Aitken mode was similar to N_{CN}. It was interesting that the particles of 100-500 nm (accumulation mode) dominated in N_{CN} in the hazy case with peak concentrations higher than 7,500 cm^{-3}, almost twice as much as the clear case (4,000 cm^{-3}). However, the foggy-hazy case is comparable to the clear case, showing a mostly unchanged evolution of the fractions of individual size bin to total particles and N_{CN}. In addition,
Figure 5 shows the average size distributions (10 nm-1 µm) for all the three cases. It is very visible that it contains relatively more large-sized (e.g. 100 nm) aerosol particles in the aerosol population during the hazy case than that during the clear and foggy-hazy cases. Especially aerosol particles larger than 200 nm (a typical CCN size at SS 0.2%) were significantly enhanced.

Figure 6 shows the temporal variations of eight major inorganic water soluble ions in aerosol particles and four gaseous pollutants sampled during this study period. Measurements for \( \text{SO}_4^{2-} \), \( \text{Cl}^- \) and \( \text{NO}_3^- \) were unavailable from 10:00 LT on 7 Nov. to 8:00 LT on 8 Nov. Substantially, the average concentration of aerosol total water soluble ions (TWSI) in the hazy case (54.52 µg m\(^{-3}\)) was comparable to the foggy-hazy case (50.37 µg m\(^{-3}\)), and roughly 2 times that of the clear case (26.22 µg m\(^{-3}\)). For the percentage of individual ions in TWSI, \( \text{NH}_4^+ \) and \( \text{K}^+ \) were relatively higher by a factor of 1.8 in the hazy and foggy-hazy cases than in the clear case. Despite the lack of \( \text{SO}_4^{2-} \) and \( \text{NO}_3^- \) partly during the hazy case, we can still conjecture their promotion on the basis of their gaseous precursor evolution of \( \text{SO}_2 \) and \( \text{NO}_2 \).

Gaseous pollutants are released into the atmosphere from natural and anthropogenic emissions. Among them, \( \text{SO}_2 \) is known as one of the most important gaseous pollutants and a precursor responsible for acid rain. Also, it can participate in the formation of new particles through
converting into gaseous H$_2$SO$_4$, which is the most common nucleation species due to its low vapor pressure at typical atmospheric temperature (Zhang et al., 2006b; Urone et al., 1968). Secondary aerosols produced from the formation of new particles contribute more to the global aerosol burden than primary aerosols and are important sources of CCN (Merikanto et al., 2009; Yu et al., 2008). Recent studies have shown the enhanced solubility of SO$_2$ due to its reaction in fog droplets during a severe fog measured in the North China Plain, and this finding has provided important support for better understanding of the acidity in clouds (Zhang et al., 2013). NO$_2$ mainly comes from vehicle traffic emissions in urban areas (Wang et al., 2006). Nitrogen oxides (NO, NO$_2$, N$_2$O$_5$) undergo heterogeneous reactions with aerosol particles (e.g. sea salt or dust) during they are transported in the atmosphere (Elizabeth et al., 2006). Thus, high gaseous pollutant content can result in larger CN loadings and subsequently more CCN particles in the atmosphere. On the whole, the loading of these precursor gases in the foggy-hazy and hazy cases exceeded that in the clear case, specifically NO$_2$ by a factor of 2 and SO$_2$ by a factor of 1.5. Moreover, SO$_2$ and NO$_2$ concentrations reached their peaks around 0:00 LT on 8 November corresponding to the highest levels of CCN and aerosol activity, implying their potential effects on CCN production, which will be discussed in the next section.

3.3. CCN Concentration and Aerosol Activity
3.3.1 CCN and Aerosol Activity

Figure 7 presents the temporal variations of \(N_{CCN}\) and activated aerosol fraction (\(N_{CCN}/N_{CN}\)) at SS 0.2\%, \(N_{CN}\), and BC during the campaign. Totally, \(N_{CN}\) fell in the range of 4,270-15,771 cm\(^{-3}\) and averaged at 9,344 cm\(^{-3}\), and \(N_{CCN}\) varied between 994 cm\(^{-3}\) and 6,268 cm\(^{-3}\) and averaged at 2,929 cm\(^{-3}\). High \(N_{CCN}/N_{CN}\) (0.41) and \(N_{CCN}\) (4,362 cm\(^{-3}\)) were observed during the hazy case, followed by the foggy-hazy (0.29, 2,377 cm\(^{-3}\)) and clear (0.28, 2,432 cm\(^{-3}\)) cases (Table 2). The temporal variation of \(N_{CCN}/N_{CN}\) and \(N_{CCN}\) was closely related with aerosol particle size spectra and chemical composition such as accumulation mode (100-500 nm) and water soluble ion content (Figure 4 and 6). Figure 8 gives the temporal variations of number concentrations of larger aerosol particles (e.g. particles larger than 80 nm and 100 nm) and their corresponding ratios with \(N_{CCN}\) at SS 0.2\%. The larger aerosol particles showed significant increase during the hazy case and varied strongly correlated with \(N_{CCN}\). More fractions of particles larger than 80 nm were activated into CCN during the hazy case (86\%) and foggy-hazy case (84\%) than that during the clear case (76\%).

Although in different SS conditions, \(N_{CCN}\) was measured at other urban or urban-like environments such as the west coast of Tasmania (32 cm\(^{-3}\)) and the west coast of Korea (5,292 cm\(^{-3}\)) at SS 1.0\% (Yum et al., 2004, 2005), and Mexico city (3,000 cm\(^{-3}\), Ireland (208-346 cm\(^{-3}\)) and Vienna
(820 cm$^{-3}$) at SS 0.5% (Baumgardner et al., 2003; Reade et al., 2006; Burkart et al., 2011). An even larger $N_{CCN}$ (6,000 cm$^{-3}$) was measured at SS 0.17% in Beijing (Deng et al., 2011). The average $N_{CCN}/N_{CN}$ of this study (0.32) was higher than that measured in Vienna (0.13 at SS 0.5%, CN 13-929 nm) and Finland (0.1-0.3 at SS 0.2%, CN 3-1000 nm). The increased $N_{CCN}/N_{CN}$ was derived at larger SS in urban environments such as Shanghai (0.47 at SS 0.8%, CN 10-10,000 nm) and Korea (0.64 at SS 1.0%, CN 10-500 nm) (Yum et al., 2005; Burkart et al., 2011; Sihto et al., 2011; Leng et al., 2013).

As expected, $N_{CN}$ behaved in diurnal cycle with an apparent pattern of bi-modal distribution, and $N_{CCN}$ showed a similar temporal variation (Figure 7). $N_{CN}$ and BC usually peaked, and reached their highest values of 15,000 cm$^{-3}$ and 35 µg m$^{-3}$ during the rush hours (i.e. 7:00-9:00 and 16:00-19:00 LT), indicating that the anthropogenic pollutants emitted from vehicles contributes to a large part of CN and BC loadings. In addition, the favorable meteorological conditions such as low wind speed, temperature and planetary boundary layer (PBL) height also posed a great influence on PM$_{2.5}$ and BC loadings (Figure 3). For example, the low wind speed (about 2 m s$^{-1}$) and PBL height (around 0.5 km) favored the mass accumulations of PM$_{2.5}$ and BC reaching their maximums of 242 and 35 µg m$^{-3}$ at 0:00 on 8 Nov. The later disappearance of the haze pollution was mostly owing to the wind speed increasing to 6 m s$^{-1}$ and
the PBL height rising to 1.4 km (Figure 2). Temperature is known as a large factor influencing PBL height and thereby indirectly impacts PM$_{2.5}$ and BC. In addition, the wind was frequently northwest direction and brought large amount of anthropogenic particles (e.g. BC) to Shanghai during the foggy-hazy/hazy cases, while it blew from easterly or northeasterly (marine area) before and after the polluted cases (Figure 1, 2 and 7).

In a broad view, $N_{CCN}$ showed a sharp increase starting at 0:00 LT on 8 Nov., and rose from 994 cm$^{-3}$ to 6268 cm$^{-3}$ within less than 10 hours. Similar to $N_{CCN}$, BC also rose from 10 µg m$^{-3}$ to 35 µg m$^{-3}$ during the same period. $N_{CN}$ was consistent with $N_{CCN}$, and they varied almost synchronously. However, $N_{CCN}/N_{CN}$ changed in one step mostly opposite to $N_{CCN}$ and $N_{CN}$ (Figure 7). The possible reason for this contradictory tendency of $N_{CN}$ enhancement vs. $N_{CCN}/N_{CN}$ reduction is that the unactivated nanoparticles, which burst partly from primary emissions of vehicles and/or partly from secondary particles due to the chemical reactions of atmospheric gaseous precursors (Figure 5) (Du et al., 2011), contributes relatively larger to $N_{CN}$ other than $N_{CCN}$.

3.3.2 Black Carbon and CCN

As a part of hydrophobic aerosols, pure BC particles acquire hydrophilic coatings as they age in the atmosphere, and then the aged BC becomes sufficiently hydrophilic and serves as CCN for cloud
condensation formation (Ritesh et al., 2007). On the other hand, BC particles can release sensible heat by effectively absorbing solar radiation, thereby increasing the critical supersaturation of CCN and preventing aerosol to act as CCN (Conant et al., 2002). Biomass burning emits a large amount of trace gases and carboneous particles into the atmosphere, and leads to changes in climate and precipitation, as well as aquatic and terrestrial ecosystem (Andreae et al., 2004). The wild fires contribute a significant fraction of global CCN burden (Pierce et al., 2007; Andreae et al., 2009). Large quantities of active agricultural fire sites were detected from satellites over China on 7 November 2010 (Figure 1), whereas no obvious wild biomass burning activities were observed during the rest days. Based on the calculated 24-h air mass backward trajectories, the air mass that passed right through the agricultural fire regions in the Jiangsu and Anhui provinces on 7 November reached the sampling site in the next day, bringing large quantities of aged BC particles after a long range transport. This resulted in a severe increase of particle mass concentration and a significant enhancement of aerosol extinction coefficient on 7 and 8 November (Figure 3). As discussed in section 3.2, NO₂ and SO₂ concentrations increased synchronously during the whole period (Figure 6), and they would undergo heterogeneous reactions on the surface of BC particles to change particle microphysical and chemical properties, making BC particles sufficiently hydrophilic to act as CCN (Ritesh et al.,
Relationship analyses between \( N_{CCN} \), \( N_{CCN}/N_{CN} \) and BC were calculated using hourly-averaged data, and the correlation coefficients (\( R^2 \)) are presented in Figure 9. Surprisingly, BC strongly correlated with \( N_{CCN} \) (\( R^2 = 0.85 \)) in the foggy-hazy and hazy cases, whereas they showed a poor linear relationship (\( R^2 = 0.25 \)) in the clear case. The possible reason is BC particle aging by heterogeneous reactions with gaseous pollutants (e.g. \( \text{NO}_2 \) and \( \text{SO}_2 \)) to be activated CCN during pollutant atmospheric transport (Ritesh et al., 2007). In addition, so many studies have proposed that the aged BC is efficient CCN (Dusek. et al., 2006; Anttila and Kerminen, 2007; Hudson, 2007). However, \( N_{CCN}/N_{CN} \) was poorly related with BC for both foggy-hazy/hazy and clear cases (\( R^2 = 0.43 \) and 0.07, respectively), indicating that BC maybe a relatively more important contributor to unactivated particles especially in nanoscale sizes (e.g. traffic emission) than activated CCN.

### 3.4. Relationship of Aerosol and CCN

Although aerosol size distributions were measured only in the size range of 10-10,000 nm, they were still used to predict \( N_{CCN} \) according to Köhler theory (Köhler et al., 1936). Toward this end, the particle hygroscopicity “kappa” (\( \kappa \)) was used in the closure calculation. The description of the technique has been given by Petters and Kreidenweis (2007), therefore it will only be briefly summarized here. The \( \kappa \)
parameter for one multicomponent particle can be obtained through weighting each component $\kappa_i$ by their volume fractions in the mixture,

$$\kappa = \sum_i \varepsilon_i \kappa_i$$  \hspace{1cm} (1)

where $\varepsilon_i$ is the volume fraction of chemical compounds in particles, and $\kappa_i$ is the effective $\kappa$ of individual chemical composition.

Assuming aerosol particles are completely internal-mixed, a simplified $\kappa$ was calculated using water soluble inorganic ions (organic matter data is unavailable). Aerosol particle compositions were classified into three categories (Petters and Kreidenweis, 2007; Wiedensohler et al., 2009), and $\kappa_i$ and densities for each component are shown in Table 3, in which ‘others’ is defined as ‘PM$_{2.5}$-BC-inorganic ions’. The critical dry size (CDS) of particle to be activated as CCN at one SS can hence be determined by the following equation:

$$S(D) = \frac{D^3 - D_d^3}{D^3 - D_d^3 (1 - \kappa)} \exp\left(\frac{4\sigma_{s/a} M_w}{RT \rho_0 D}\right)$$  \hspace{1cm} (2)

where $\rho_0$ is the density of water, $M_w$ is the molecular weight of water, $\sigma_{s/a}$ is the surface tension of the solution/air interface, $R$ is the universal gas constant, $\kappa$ is the hygroscopicity parameter, $T$ is temperature, $D_d$ is the dry diameter, $D$ is the diameter of the droplet and $S(D)$ is the critical dry size under a given SS. Detailed information for the derivation of equation (2) can be found in Petters and Kreidenweis (2007). Equation (2) applies over the entire range of humidity and solution hygroscopicity and can be
utilized to predict the conditions of cloud droplet activation. The critical SS for a selected dry size of particle is determined from the maximum of the curve for equation (2). Computed for $\sigma_{s/a}=0.072 \text{ J m}^{-2}$ and $T=298.15 \text{ K}$, the calculated CDS varied between 60 nm and 130 nm and averaged at 102 nm. Particularly, the hourly-averaged CDS during the foggy-hazy/hazy cases was slightly lower (96 nm) than during the clear case (105 nm). So far, the comparable or relatively higher CDS has also been found in diverse regions and for various aerosol types, despite of different calculation models and SS. For example, the fresh aerosol particles emitted by an aircraft internal combustion engine have a CDS range of 146-301 nm at SS 0.7%, depending on varying operating conditions (Hitzenberger et al., 2003). Furutani et al (2008) investigated three types of aerosol masses along the southern coast of California, and the CDS was estimated at 110 nm at SS 0.6% for fresh ship exhaust, 70-110 nm for fresh anthropogenic aerosols and roughly 50 nm for aged anthropogenic and clean maritime aerosols. In Vienna, the CDS has a wide gap between 69 nm and 368 nm, and averaged at 169 nm (Burkart et al., 2011). Quinn et al (2008) observed the CDS in a narrow range of 70-90 nm for maritime aerosols in the Gulf of Mexico, and a moderate range of 90-170 nm in the ship channels of Houston with high marine traffic densities close to industrial and anthropogenic sources.

The CCN population can be effectively viewed as a subset of measured
aerosol size distributions since the operating range (10-10,000 nm) includes the majority of atmospheric particles. Therefore, the predicted $N_{CCN}$ can be calculated through integrating particles upward in size from the bottom CDS to the upper boundary. In this calculation, the predicted $N_{CCN}$ of hourly-averaged were compared with the measured ones correspondingly.

The results of this closure analysis are shown in scatterplot in Figure 10 and 11. The prediction for CCN is generally success throughout the entire data set. The linear regression between predicted and measured $N_{CCN}$ produces a slope of 1.012 and an intercept of 128.3 cm$^{-3}$ ($R^2=0.95$), and the average ratio of predicted versus measured $N_{CCN}$ is 0.94 (Figure 10). The results indicate some moderate underestimate (about 6% on average) but the agreement is still excellent. The achieved closure calculation suggested that water soluble inorganic ions played a major role in contributing the $\kappa$ value. In fact, 83.8% of the $\kappa$ was expressed by SO$_4^{2-}$+NO$_3^-$+NH$_4^+$ in total (in another study by our group, not published yet), with their individual contribution to be 39.8%, 31.7% and 12.3%, respectively. In addition, it is worth note that the predicted $N_{CCN}$ at SS 0.2% was more correlated with the observed $N_{CCN}$ in the clear case ($R^2=0.96$) than the foggy-hazy/hazy cases ($R^2=0.91$), and the corresponding ratios of predicted to observed $N_{CCN}$ were 0.95 and 0.92, respectively (Figure 11). In all cases, the mean ratio of predicted to
observed \( N_{CCN} \) never reached up to 1, suggesting that organic matter would play a second role and make up the rest of \( \kappa \).

**4. Conclusions and discussion**

A continuous 4-day data obtained at an urban site of Shanghai over a fog-haze event from 6 to 9 November 2012 was analyzed for CCN and aerosol. Overall, meteorological conditions such as wind speed, wind direction and temperature exerted a great influence on PM\(_{2.5}\) and BC loadings. Human activity is an essential factor to control emissions of aerosol and CCN in urban environments. \( N_{CCN}/N_{CN} \) and \( N_{CCN} \) usually were higher in the hazy case due to increased aerosols in the accumulation mode, and lower in the foggy-hazy and clear cases. DeFelice et al (1996) also found the reduction of CCN concentration under foggy and rainy conditions in the Antarctic area. Of special interest, the low \( N_{CCN}/N_{CN} \), \( N_{CN} \) and \( N_{CCN} \) during the foggy-hazy case can plausibly explain in three aspects: (1) the limited data input introduces some uncertainties, (2) the possible physical effects such as boundary layer evolution, transportation and atmospheric dilution are not considered, (3) the plausible emergence of fog droplets and particles leads to the reduction of aerosol number concentration.

BC was correlated well with \( N_{CCN} \) in the foggy-hazy and hazy cases, while they were less linked in the clear case. Besides, there were no good agreements between BC and \( N_{CCN}/N_{CN} \), with moderate \((R^2=0.43)\) and
poor ($R^2=0.07$) correlation coefficients for the foggy-hazy/hazy cases and clear case, respectively. More BC is aged during the foggy-hazy/hazy cases, hence more CCN is activated (Dusek et al., 2006; Anttila and Kerminen., 2007; Hudson., 2007). However, there exists a different perspective. For example, BC has been found to significantly suppress cloud formation in the Indo-Gangetic plain (Ritesh et al., 2007). Pure BC particles are hydrophobic and can release heat by absorbing solar radiation, hence they would increase the critical SS of aerosol to act as CCN and further suppress the tendency of CCN to become cloud droplets. However, aged BC particles are sufficiently hydrophilic by acquiring hydrophilic coatings in the atmosphere, and become CCN and favor aerosol indirect forcing (Conant et al., 2002; Ritesh et al., 2007). In this study, BC particles moved a long-distance from inland and aged during the transporting process, thereby it favors CCN formation.

By using a simplified $\kappa$ parameter, the critical dry size never exceeded 130 nm. In spite of the absence of organic matter, the CCN closure calculation was still achieved, suggesting that aerosol major water soluble ions contribute to effective $\kappa$. The predicted $N_{\text{CCN}}$ was close to the observed during the clear case than the foggy-hazy/hazy cases having more organic matter. In summary, water soluble inorganic ions constituted the majority of particle hygroscopicity ($\kappa$) estimation, while organic matter made up the rest. It is noted that organic matter is
essential to build the exact CCN prediction models.

This paper mainly explored how \( N_{\text{CCN}} \), \( N_{\text{CN}} \) and \( N_{\text{CCN}}/N_{\text{CN}} \) vary under a fog-haze co-occurring condition, as well as the major influential factors to these activities. The results revealed that the particulate pollutant burden exerts a significant impact on \( N_{\text{CCN}} \), especially \( N_{\text{CCN}}/N_{\text{CN}} \) is effectively promoted during the polluted periods (e.g. haze). Importantly, the fog-haze transformation is highly complicated involving numerous changes of aerosol in physical and chemical properties, which remains poorly understood. The clear and hazy cases both continued more than one day with a reduced effect of diurnal variation. Foggy conditions mostly occur at night and in the morning and seldom last as long as 24 hours in Shanghai, thereby it was inevitable that the diurnal variations had some effect on the results during the foggy-hazy case spanning from 23:00 LT on 6 Nov. to 10:00 LT on 7 Nov. There presents the results of only a case, so more efforts are needed for highlighting the comprehensive effects of fog and haze on CCN in urban environments.
