Abstract

Organic carbon (OC), elemental carbon (EC), water soluble organic carbon (WSOC) and main ions were measured in a total of 1510 PM$_{2.5}$ daily aerosol samples collected from May 2008 to April 2013, in Athens, Greece. OC and EC concentrations were $2.1\pm1.3\ \mu g\ m^{-3}$ and $0.54\pm0.39\ \mu g\ m^{-3}$, accounting for $11\pm3\%$ and $3\pm1\%$ of PM$_{2.5}$ mass respectively, with an average OC/EC ratio of $4.7\pm3.1$. Significant correlation was found between OC and EC during the whole period, indicating emissions by common primary sources at a regional scale. WSOC concentration ranged from 0.03 to 10.6 $\mu g\ m^{-3}$, with an average of $1.5\pm0.9\ \mu g\ m^{-3}$. By considering Finokalia (Crete) station as a reference, it was estimated that during the warm season in Athens $67\pm7\%$ of emitted OC and $53\pm12\%$ of emitted EC is regional, while during cold months, the regional contribution for OC is only $33\pm7\%$ and for EC $29\pm8\%$. Furthermore, secondary organic carbon (SOC) was calculated for the warm period of the year (April to October). The estimated SOC constituted about $75\pm6\%$ of PM$_{2.5}$ organic carbon in Athens, highlighting significant aging processes, at a regional scale. In the period 2011-2013 and during wintertime, an increase in OC and EC levels was observed, attributed to increase of wood burning for domestic heating due to the economic crisis.
1 Introduction

Atmospheric aerosol constitutes a crucial factor of air pollution since it presents adverse effects on health, environment and Earth radiative balance (EPA, 1996; WHO, 2003). Carbonaceous aerosol contributes to global warming, and black carbon is considered as the second most important agent of global warming after CO₂ (Probert and Tarrant, 1989; Robock and Graf, 1994; Galdos et al., 2013). Recent epidemiologic studies, have displayed the risks of exposure to increased levels of carbonaceous aerosols, revealing notable associations with cardiovascular mortality and morbidity (Ostro et al., 2010; Lipsett et al., 2011; Krall et al., 2013).

The carbonaceous content of atmospheric particles has been the objective of several studies as it represents an essential fraction of particulate matter (Alastuey et al., 2004; Na et al., 2004; Putaud et al., 2004; Querol et al., 2004; Yu et al., 2004; Yttri et al., 2007; Pey et al., 2010; Pio et al., 2011). These studies provide evidence for the relative importance of road traffic and wintertime high energy consumption, combined with unfavorable meteorological conditions, and summertime traffic but also secondary organic aerosol as major sources of carbonaceous aerosol in Europe. The formation mechanisms of organic carbon (OC) and elemental carbon (EC) have been under scrutiny during the last decade (Saylor et al., 2006; Pio et al., 2007; Schwarz et al., 2008; Pio et al., 2011; Grivas et al., 2012; Bougiatioti et al., 2013), placing emphasis on their biogenic and/or anthropogenic origin and subsequent effects.

Athens is located in Eastern Mediterranean, a well-known crossroad of long range transported aerosol from discrete regional sources that are superimposed on other significant local sources of pollution (Lelieveld et al., 2002; Vrekoussis et al., 2005). A description of the Athens basin and prevailing meteorological conditions has been provided in the literature (Chaloulakou et al., 2005; Grivas et al., 2008; Kanakidou et al., 2011; Theodosi et al., 2011; Grivas et al., 2012). Studies performed in Athens basin demonstrated the prevailing emissions of carbonaceous aerosol all year round, namely vehicles, fuel combustion and long-range transport (Chaloulakou et al., 2005; Sillanpaa et al., 2006; Grivas et al., 2012; Pateraki et al., 2012; Remoundaki et al., 2013). Nevertheless, it is essential to mark that there are limited studies concerning PM₂.₅ fraction of aerosol in Athens and the works performed so far have been conducted for short time periods (4 – 11 months), mainly at urban locations.
This is the first to our knowledge, long-term (2008-2013) uninterrupted data record of carbonaceous aerosol in an extended area already burdened by long range transport (Eastern Mediterranean) and, in particular, an urban agglomeration with degraded Air Quality-AQ (Athens) and thus enhanced health risk. The long measurement duration and the completeness of the data series allowed the performance of thorough and concise investigation of carbonaceous aerosol properties, sources and variability in the area, as a major contribution of this work. Additionally, the study covers a five year period that includes years before and during the economic recession occurring in Greece, enabling additional investigation of the significant impacts of the crisis on AQ. In particular, industrial activity was decelerated, vehicles' use was limited and wood burning replaced conventional fuels for domestic heating due to the high heating oil prices. The latter, in many cases is reported to have a significant contribution to air pollution levels (Molnar et al., 2005; Sandradewi et al., 2008; Schmidl et al., 2008; Grange et al., 2013). Finally, a direct comparison between the urban background site of this study and a remote background site considered as reference for the extended Eastern Mediterranean area (Finokalia, ACTRIS supersite, Aerosols, Clouds, and Trace gases Research InfraStructure Network, http://www.actris.net/), helped us shed light on regional patterns and processes, discriminating between regional and local emission sources.

2 Experimental

2.1 Sampling site

The measurements were conducted at the National Observatory of Athens premises in Penteli (38°2.94′N, 23°51.78′E, 495mas.l.). The site is located on top of a hill facing the city of Athens to S-SW (17 km from the city center), while to the N-NE sector it is surrounded by the Penteli Mountain. The major sources of air pollution in the close vicinity are expected to be vehicular emissions and residential heating. More details about the Greater Athens Area morphology and meteorological conditions are provided by Kanakidou et al., (2011; and references therein), while internal transport patterns in the urban complex are described by Melas et al. (1998). The station is considered as an urban background site, established and operated by the Institute of Environmental Research and Sustainable Development.
2.2 Samples collection
This study covers five years from May 2008 to April 2013, resulting in the collection of 1510 samples on a daily basis. PM$_{2.5}$ aerosol samples were collected using a Dichotomous Partisol sampler (R&P Co) during most of the period (90% of the sampling time) and a Partisol FRM Model 2000 air sampler (R&P Co) (10% of the sampling time), operating at 15.0 and 16.7 L/min, respectively. Sampling duration was 24h starting at 14:00 LT.

Samples were collected on quartz fiber filters (4.7cm, Whatman QMA). Filters were prebaked at 550°C for 4h to remove any absorbed organic material and were stored and transported to and from the field into petrislides. After sampling they were stored until analysis. Filter blanks and blank field samples were also prepared and analyzed. For the estimation and correction of the amount of adsorbed organic vapor on the sampling filter, a tandem filter collection method was applied (e.g. Turpin et al., 2000; Kirchstetter et al., 2001; Yttri et al., 2007). Two quartz fiber filters from the same lot were used in series, the front filter collects essentially 100% of the particulate matter (and some gas-phase material) and the backup filter is exposed only to gas-phase compounds. The measured carbon content of the backup filter can be subtracted from that of the front filter to give an estimate of the particulate phase OC (Turpin et al., 2000; Novakov et al., 2005; Sillanpaa et al., 2005). Nevertheless, it has been reported that the back-to-back filter configuration does not allow enough time for equilibration of gases on the second filter, and therefore this approach could underestimate the positive OC artefact. Tandem filters were collected for a selected number of samples, using the aforementioned Partisol samplers. In our analyses, the backup filters indicated a positive OC artifact which was always smaller than 5%, thus no correction was applied.

2.3 Mass and chemical analyses

2.3.1 Aerosol Mass
PM mass was determined by weighing the filters before and after sampling according to the U.S. EPA RFPS-1298-126 method, using a Mettler Toledo MX5 microbalance
(1 μg sensitivity). The filters (samples and blanks) remained for 48 h under controlled
conditions (RH 40 ±5%, T 20 ±3°C), prior to each weighing.

2.3.2 OC – EC analysis
All quartz filters (samples and blanks) were analyzed by a thermal optical
transmission technique, using a Sunset Laboratory Inc. (Oregon) carbon analyzer. A
punch of 1 cm² was removed from the filter and loaded into the analyzer as described
by Bougiatioti et al. (2013) and Novakov et al. (2005). OC and EC were determined
using the EUSAAR-2 protocol (Cavalli et al., 2010). Briefly, the first phase subsumes
4 stages of heating at 200, 300, 450 and 650°C at He atmosphere, while, during the
second 4-step temperature program, the sample is heated at 500, 550, 700 and 850°C
at He/O₂ atmosphere. The detection limit of the analysis was 0.26 and 0.05 μg C cm⁻²
for OC and EC, respectively. The reported results were blank-corrected.

2.3.3 WSOC analysis
For the determination of the Water Soluble Organic Carbon (WSOC) concentrations,
punches of 2 cm² were removed from the filter and placed in an ultrasonic bath for 45
minutes using 15mL of nanopure water. The sample extract was filtered using syringe
filters (PALL IC Acrodisc (PES), 0.45 μm, 13 mm). The solutions obtained after the
filtration were analyzed for total organic carbon (TOC) using a Shimadzu TOC-V
CSH Total Organic Carbon Analyzer. In short, the sample is injected into a
combustion cell equipped with oxidation catalyst (Pt) and is heated at 680°C. TC
(Total Carbon) is converted to carbon dioxide and it is cooled, dehumidified and
transferred through the carrier gas (synthetic air) to the NDIR (Non-Dispersive Infra-
Red) gas analyzer. For the IC (Inorganic Carbon) analysis, the sample is injected to
the IC reaction vessel where it is acidified, to convert IC to carbon dioxide, and it is
volatilized by a sparging process. Then the sample is transferred by the carrier gas to
NDIR in order to be detected. Total water soluble organic carbon is calculated by
extracting inorganic water soluble carbon from total water soluble carbon (TOC=TC–
IC) and is labeled as WSOC. The analytical detection limit for WSOC was 80ppb. All
data were corrected for the obtained blank levels.
23.4 Ion chromatography

Punches of 2 cm² from the quartz filters were extracted in ultrasonic bath with 10 ml of nanopure water, for 45 minutes, and were then filtered using syringe filters (PALL IC Acrodisc (PES), 0.45 μm, 13 mm) to remove any insoluble species. The acquired filtered solutions were analyzed by ion chromatography (IC) for the determination of the main ionic species concentrations (anions: Cl⁻, Br⁻, NO₃⁻, SO₄²⁻, PO₄³⁻, C₂O₄²⁻ and cations: NH₄⁺, K⁺, Na⁺, Mg²⁺, Ca²⁺). Anions were determined using a Dionex-500 ion chromatograph equipped with an Ion Pac AS4A-SC column and an AG4A-SC pre-column, with an ASRS-300 suppressor. Anions’ separation was conducted with isocratic elution of NaHCO₃ (3.4 mM) / Na₂CO₃ (3.6 mM) as an eluent and a flow of 1.5 mL min⁻¹. For the determination of cations an Ion Pac CS12A column and a CG12A guard column was used, with a CSRS-300 suppressor, under isocratic elution of 20 mM MSA (Methanesulphonic acid) at a flow rate of 1.0 mL min⁻¹. The detection limit of the analysis was 20, 12, 40, 12 and 40 ppb for NH₄⁺, K⁺, Na⁺, Mg²⁺ and Ca²⁺, respectively, while the corresponding detection limit for all anions (Cl⁻, Br⁻, NO₃⁻, SO₄²⁻, PO₄³⁻, C₂O₄²⁻) was 20 ppb. The reported concentrations were corrected for blanks.

3 Results and discussion

3.1 Mass concentrations of OC – EC and observed seasonal trends

The daily concentration levels of OC range from 0.1 to 8.5 μg m⁻³ (average: 2.1 ±1.3 μg m⁻³), contributing on average about 11±3% to the total PM₂.₅ mass. Accordingly, the mass concentration of EC ranges from 0.01 to 3.33 μg m⁻³ (average: 0.54±0.39 μg m⁻³), contributing 3±1% to the total PM₂.₅. OC and EC values from previous studies in Athens and other European sites are presented in Table 1. It should be noted that most of these studies refer to shorter time periods (4 – 11 months), and for different site types. Compared to OC and EC concentrations in Athens back in 2003, this study reveals levels 3-4 times lower, while later studies revealed similar levels (or slightly higher depending on the site type) in the range of 1.5-4 μg m⁻³ for OC and 0.4-1.8 μg m⁻³ for EC. OC concentrations from several studies in southern Europe cities (mainly western Mediterranean) during the period 2002-2006 are in the range 3-9 μg m⁻³ while EC values are in the range 0.7-1.7 μg m⁻³. Concentrations in an urban site in Istanbul
during the period 2008-2009 appear much higher compared to the values of this study.

Regional background concentration levels at the Finokalia site (Crete Island, 2004-2006) are on average 1.8 and 0.27 μg m⁻³, for OC and EC, respectively.

Total carbon is calculated as the sum of OC and EC (TC=OC+EC), with OC accounting for 79±4% of the total carbon, constituting the predominant carbon contributor, in accordance with findings in other European sites (e.g. (Lonati et al., 2007; Sanchez de la Campa et al., 2009). However, the contribution of TC to PM in this study (14±3%) is lower than what is reported in the literature for other urban/urban background locations (e.g. 25-46% in Viana et al. (2006); 27-28% in Lonati et al. (2007); about 19% in Sanchez de la Campa et al. (2009); 29% in Perrone et al. (2011); Querol et al. (2013)).

Conversion of OC to OM (Organic Matter) is recognized as one of the most critical factors of uncertainty in mass closure calculations (Yttri et al., 2007). Turpin and Lim (2001) suggest the use of different conversion factors per site type: 1.6±0.2 for urban areas, 1.9–2.3 for aged aerosols, and 2.2–2.6 for biomass burning. Taking into account that our site is an urban background station also affected by long range transport (e.g. Sciare et al., 2005; Kanakidou et al., 2011; Pateraki et al., 2012; Remoundaki et al., 2013), we used the value of 2.1 (OM=2.1·OC). On average, OM accounts for 24±6% of PM₂.₅ which is consistent with the value (22%) provided by Remoundaki et al. (2013) for Athens, while lower to those reported in other European sites (e.g. Sillanpaa et al., 2005; Sanchez de la Campa et al., 2009).

In Fig. 1 the daily concentrations of OC and EC are presented for the whole sampling period (May 2008-April 2013). It is observed that OC and EC present significant covariance for most of the period, with maxima mainly during the colder months. The seasonal variability in OC and EC is clearly demonstrated in Fig. 2, which reveals higher concentrations from November to March. This is mainly attributed to emissions from residential heating and low altitude temperature inversions that trap local emissions of particulate OC and EC near the surface (e.g. Yttri et al., 2007). The minimum OC concentrations appears in late spring and early autumn, when there is no domestic heating and photochemistry is slowed down compared to summer. In the case of EC, minimum concentrations are found during the warmest months of the
year, when there is less fuel combustion in Athens (period of summer vacations) and thus lower production of primary EC.

The summer versus winter contrast is further shown in Fig. 3, on an annual basis. Winter refers to Dec.-Feb. period of the December year, while summer to Jun.-Aug. The EC summer levels after 2009 appear slightly reduced compared to 2008, coinciding the economic recession period in Greece, which led to reduction of traffic emissions and industrial activities (Vrekoussis et al., 2013). In winter, there is an increase during the last two years (2011-2012), attributed to the massive turn of Athens residents in wood burning for main domestic heating. Although OC presents a significant number of spikes during the winters of 2011 and 2012 (Fig. 1), mainly attributed to wood burning, the average values of OC do not present a clear interannual trend. Most probably this is because, contrary to EC, OC has additionally a significant secondary origin (see section 3.5) and the influence from primary sources (wood burning) is balanced out in the average values but are shown up as increased standard deviations (episodic nature) observed during winter 2011 and 2012 (a factor 2 higher compared to previous years). The summer to winter ratio of EC mass concentration presents a significant declining trend from 0.99 in 2008 to 0.43 in 2012, illustrating the combined effect of summer and winter changes in EC emissions, as related to the economic crisis (see section 3.4).

3.2 OC/EC concentration ratios

The daily OC/EC ratios range from 0.5 to 29.3, with an average of 4.7±1.3 for the 5-year period. These ratios are generally comparable with results from other Mediterranean sites (see Table 1), however, on a seasonal basis the OC/EC ratios ([OC/EC]_winter=4.6, [OC/EC]_summer=6.3) are higher than those reported for other urban background sites around the world ([OC/EC]_winter=2.4–3.5, [OC/EC]_summer=1.3–3.9) as reviewed by Lonati et al. (2008). Higher ratios can be attributed either to secondary production from gas to particle conversion of VOCs (mainly during long-range transport of polluted air masses; Pio et al., 2007) or to primary sources such as biomass burning, during which high OC/EC ratios are exhibited (Amiridis et al., 2012).
In more detail, the seasonal cycle of OC/EC ratio (Figure 4) presents maximum values during summer (6.3), when photo oxidation reactions lead to the production of secondary aerosol (increase of OC concentrations) (e.g. Viana et al., 2007) and reduction of heating (decrease of EC concentration). On January (the coldest month of the year), the high OC/EC ratio could be attributed to the elevated OC concentrations, mainly due to fuel and/or biomass burning combustion for heating, that coincide with a comparatively smaller increase in the production of EC.

Overall, the high values of OC/EC ratio (>2) year round, indicate the clear impact of additional processes like the production of secondary organic carbon. To estimate the primary and secondary origins of carbonaceous aerosol, the correlation between the OC and EC mass concentrations is investigated (e.g. Turpin and Huntzicker, 1995). In the present study a statistically significant correlation is found between OC and EC for the whole period (not shown, $R^2=0.49$, slope=2.33, n=1365, p<0.001), revealing that OC and EC emission rates are mostly proportional to each other (e.g. Na et al., 2004). A comparable correlation coefficient was reported by Koulouri et al. (2008) for another Eastern Mediterranean, though remote coastal, location (Finokalia, Crete). The above suggest that a large fraction of OC and EC fractions is emitted by common primary sources.

### 3.3 Water Soluble Organic Carbon

Water soluble organic carbon (WSOC) is considered a major component of carbonaceous aerosol as it serves as a proxy for secondary organic aerosols due to its highly oxidized and soluble nature (Park et al., 2013).

The WSOC concentration in PM$_{2.5}$ ranged from 0.03 to 10.6 μg m$^{-3}$, with an average of 1.5±0.9 μg m$^{-3}$, and no significant differences between summer (1.7±0.8 μg m$^{-3}$) and winter (1.6±1.2 μg m$^{-3}$). These levels are similar to those reported for the remote-coastal site of Finokalia, Crete, by Bougiatioti et al. (2011), but lower than those reported for Istanbul by Theodosi et al. (2010) (PM$_{10}$ in urban site, see Table 1). The concentration of WSOC presents a statistically significant correlation with OC (Figure 5) ($R^2=0.87$, n=1000, p<0.001), indicative of their common sources. Moreover, WSOC follows the seasonal trend of OC (Figure 6) throughout the year, showing maximum values during winter and mid-summer, when WSOC is either emitted from
primary combustion sources, such as traffic, and biomass burning or is produced through atmospheric processing of volatile organic species (Park et al., 2013).

WSOC usually consists of organic compounds that derive from the atmospheric oxidation of VOCs and gas particle conversion (secondary OC), while the oxygenation of particulate OC may also occur in the particulate phase or via multiphase chemistry by reaction of strong oxidants such as ozone or hydroxy radicals. As a result, the WSOC/OC ratio decreases in urban locations and near fossil fuel sources (~20%) and increases at more remote sites due to aerosol aging (Pio et al., 2007).

In this study, the WSOC accounts, on average, for about 63±7% of the OC, which is in agreement with the value (67%) reported by Bougiatioti et al. (2011) for Finokalia, Crete, but higher than the value (42%) reported by Lonati et al. (2007) for Milan. The above indicate the dominant role of aerosol aging processes at the regional scale. Finally, the WSOC/OC ratio shows maximum values during summer (Figure 6), when there is intense photo oxidation that leads to the production of secondary organic species.

The water insoluble organic carbon (WIOC) has been calculated through subtraction of WSOC from the total OC concentration. On an annual basis WIOC contributes about 39±7% to OC. Although WIOC shows no significant correlation with EC on a daily basis, their seasonal cycles show covariance (Figure 6), indicating that part of the production of WIOC can be attributed to primary sources such as fossil fuel combustion.

The concentration of non-sea salt sulfate (nss-SO$_4^{2-}$) has been estimated using the equation described in Sciare et al. (2005) and Pio et al. (2007):

\[ \text{sea salt} = [\text{Na}^+] + [\text{Cl}^-] + [\text{Mg}^{2+}] + [\text{ss-K}^+] + [\text{ss-Ca}^{2+}] + [\text{ss-SO}_4^{2-}] \]

Sea salt sulfate (ss-SO$_4^{2-}$) was calculated in accordance with the composition of sea water and was then subtracted from the total sulfate concentration, in order to calculate the quantity of non-sea salt sulfate (nss-SO$_4^{2-}$).

The average value for the whole period is 3.0±2.0 μg m$^{-3}$, which is in agreement with the findings from other studies in Athens (Theodosi et al., 2011; Remoundaki et al., 2013). WSOC is weakly correlated to nss-SO$_4^{2-}$ ($R^2=0.15$, n=1017, p<0.001, during
summer $R^2=0.26$ vs $R^2=0.03$ during winter), suggesting that long-range transport and aerosol ageing could be considered as additional contributors to WSOC. Additionally, the low correlation between WSOC with nss-$K^+$ ($R^2=0.05$, n=1023, $p<0.001$) propounds limited production of WSOC from biomass burning. Finally, the higher correlation coefficient of WSOC with EC ($R^2=0.35$, n=993, $p<0.001$) indicates that there is some contribution to WSOC from primary anthropogenic sources rather than biogenic. The dependence of WSOC to EC is improving in winter (summer: $R^2=0.29$; winter: $R^2=0.44$), indicating production of WSOC from primary sources (e.g. biomass burning).

Based on the above, the primary fossil fuel and wood combustion sources appear to contribute more to the winter WSOC concentrations, whereas during summer, sources like oxidation processes of secondary products are more efficient in generating WSOC.

### 3.4 Sources of carbonaceous aerosol

The independent contribution of biomass burning and fossil fuel combustion emissions to organic matter concentrations could be quantitatively estimated through the potassium-OC and potassium-EC correlations (e.g. Satsangi et al., 2012). In general, biomass burning contributes significantly to the atmospheric concentrations of water soluble potassium ($K^+$) and the latter is applied as an inorganic tracer for aerosol derived from this source (e.g. Currie et al., 1994; Pio et al., 2008; Schmidl et al., 2008), while fossil fuel combustion leads to minor production of potassium (e.g. Yang et al., 2005a; Yang et al., 2005b).

To utilize $K^+$ as a representative tracer of pure biomass burning emissions, we have applied a correction for the contribution from sea salt. Sea salt potassium (ss-$K^+$) was obtained in accordance with the composition of sea water (Sciare et al., 2005; Pio et al., 2007; Bougiatioti et al., 2013) and was then subtracted from the total $K^+$ concentration, to calculate the remaining non-sea salt potassium (nss-$K^+$). The nss-$K^+$ concentrations were up to 1.8 $\mu$g m$^{-3}$, with a 5-year average of 0.17±0.04 $\mu$g m$^{-3}$, comparable to the values reported by Koulouri et al. (2008). It is worth noting that part of the calculated nss-$K^+$ can be due to dust either from Sahara desert or road-dust
re-suspension. In this line, the contribution from these sources in our PM$_{2.5}$ filters cannot be totally ruled out.

In this study, no significant correlations are calculated between nss-K$^+$ with OC and EC (neither do they correlate significantly on a seasonal basis; nss-K$^+$ vs EC: summer $R^2$=0.02, winter $R^2$=0.11; nss-K$^+$ vs OC: summer $R^2$=0.02, winter $R^2$=0.04), indicating that during the whole period, biomass burning does not consist the main source of organic carbon and that the dominant primary source of EC is mainly fossil fuel combustion (such as traffic). On the other hand based on high resolution measurements (30 min) performed in winter 2013 (Mihalopoulos et al., unpublished data) a clear correlation was observed between nss-K$^+$, OC and EC in PM$_1$ during intense episodes of biomass burning. The absence of significant correlation between OC and nss-K$^+$ using the entire data set indicates that the influence of biomass burning during intense wood burning episodes (clearly shown in Fig. 1) is masked when calculating the five year summer and winter square correlation coefficients.

The annual means of nss-K$^+$/OC and nss-K$^+$/EC ratios (not shown) exhibit an increasing trend through the studied period which, in the case of nss-K$^+$/EC, can be mostly attributed to the notable increase of nss-K$^+$ concentration compared to that of EC, supporting the influence of wood burning during the last years. In Fig. 7, EC and nss-K$^+$ concentrations are presented on a seasonal basis from 2008 to 2013, showing an anti-correlation in summers indicating limited role of biomass burning during that season. This behavior of EC during summers is indicative of accumulative EC from regional sources (such as fossil fuel combustion from traffic), combined with limited atmospheric washout due to precipitation. During winter, frequent rainfalls remove the regional EC, and thus, the covariance between EC and nss-K$^+$ reflects mainly local sources like domestic heating.

### 3.5 Estimation of Secondary Organic Carbon

Greece is significantly affected by long-range transport of African dust and other aerosol types from distant anthropogenic pollution sources (e.g. Gerasopoulos et al., 2011; Kanakidou et al., 2011). Thus, the comparison between an urban background site and a remote site within the same geographical region would be a useful tool for exploring long range transport vs local sources in conjunction with aerosol ageing.
processes. In this line, OC and EC data from Finokalia (35°32’N, 25°67’N; http://finokalia.chemistry.uoc.gr) were used to represent remote conditions where the aged nature of aerosol has been previously established (Bougiatioti et al., 2009; Bougiatioti et al., 2011; Bougiatioti et al., 2013). Simultaneous measurements of OC and EC at the two sites were conducted for the period from May 2008 to March 2013, and the comparison of the measured levels and their covariance over the different seasons was used to infer the origins and processes responsible for the carbonaceous aerosol loading.

In order to estimate the secondary organic carbon (SOC), we applied the EC tracer method (Turpin and Huntzicker, 1995; Cabada et al., 2002), using the equations:

\[
(OC)_{tot} = (OC)_{pri} + (OC)_{sec} \quad (1) \text{ or }
\]

\[
(OC)_{tot} = \left( \frac{OC}{EC} \right)_{pri} \cdot (EC)_{pri} + (OC)_{sec} \quad (2)
\]

where \((OC/EC)_{pri}\) is the ratio for the local primary sources affecting the measured concentrations. A qualitative estimation of SOC using \(OC/EC\) ratios is valid only after careful inspection of local sources of OC and EC on a seasonal basis (e.g. Na et al., 2004).

In Fig. 8 the seasonal cycles of OC and EC at Penteli-Athens and Finokalia-Crete are shown. The levels of OC and EC in Athens are constantly higher than those at Finokalia, by 55% in the warm season up to 200% in the cold season. By considering Finokalia station as a reference, it is estimated that in Athens during the warm season 67±7% of measured OC and 53±12% of EC is regional, while during cold months, the regional contribution for OC is only 33±7% and for EC 29±8%. It is observed that from April to October there is an almost a constant difference between the two sites that increases notably during the coldest period of the year, from November to March.

During the warm period, due to the limited rain in the area which favors the aging of polluted air masses (e.g. Perrone et al., 2011), a standard background is formed at the regional context. The increased values in Athens compared to Finokalia, can be attributed to an additional EC fraction due to traffic and a constant fractional input of OC added to the fossil fuel road transport emitted aerosol, in agreement with Theodosi et al. (2011). According to Pio et al. (2007) and Theodosi et al. (2011) the
simple use of the same primary OC/EC factor to estimate secondary carbon aerosol in rural and remote European areas in the warm season, is adequate. Thus, from April to October in Athens, we estimated the contribution of primary and secondary organic aerosols in the organic carbon concentrations using Eq. (2) and applying an OC/EC\textsubscript{pri} ratio equal to 1, since traffic is the main active source during this time period (e.g. Lonati et al.; 2008).

During this period, SOC ranges from 0.06 to 5.2 μg m\(^{-3}\), with an average of 1.5±0.9 μg m\(^{-3}\), constituting about 75±6% of organic carbon in Athens. It is shown that SOC is a major contributor to OC during the warm season in the area, as also indicated by Bougiatioti et al. (2013) and Lonati et al. (2007), underlying the secondary nature of fine particles (Pateraki et al., 2012). In absolute values, the average in Athens is lower than the one (2.7 μg m\(^{-3}\)) reported by Sanchez de la Campa et al. (2009) in an urban background station in Spain. The monthly means of SOC (Figure 9) in the warm period present maximum in summer (Jul-Aug), when there is intense photochemical activity that leads to the production of secondary organic carbon. WSOC, which is considered to be predominantly a secondary atmospheric product, also follows the seasonal variability of SOC (Figure 9), a conclusion strengthened by the significant correlation between daily SOC and WSOC values (R\(^2\)=0.53, slope=0.69, n=591, p<0.001). Contrary, the correlation between SOC and nss-SO\(_4^{2-}\) was much weaker (R\(^2\)=0.22, slope=1.00, n=785, p<0.001), indicating less common sources between SOC and nss-SO\(_4^{2-}\). Finally, it is worth noting the decreasing trend of SOC during the five year period of this study (not shown), accompanied by a decrease in WSOC (22% reduction from 2008 to 2013) and nss-SO\(_4^{2-}\) (58% reduction from 2008 to 2013). This downward tendency of the aforementioned concentrations can be attributed to the decrease in fuel consumption, as a result of the economic crisis in Greece.

In the cold season, for the estimation of SOC and the relevant primary OC/EC ratio, fossil fuel and wood burning combustion from domestic heating should be also taken into account (Gelencsér et al., 2007; Lonati et al., 2007; Lonati et al., 2008). Since this ratio can vary largely depending on the site and the different sources, it was not feasible to estimate SOC during the cold period. In Fig. 8, the difference between OC and EC levels at Finokalia (Crete) and Penteli (Athens), increases during the cold season compared to warm, reflecting the contribution of additional local sources in Athens. Assuming that the vehicular traffic is stable throughout the year (Grivas et al.,
and long range transport and meteorology is similar over both sites, the increase in OC and EC during the cold season, can be attributed to an additional primary source, most probably heating. In addition by examining the difference of OC and EC levels between Athens and Finokalia during the winter months for the whole studied period a notable increase during the 2011-2013 period compared to 2008-2010 is also observed (30% in ΔOC and 80% in ΔEC), mainly driven by wood burning activities maximized during the last two winters (2011-2013) in most Greek cities (Saffari et al., 2013).

Unfortunately, statistical information or inventories for the use of wood in domestic heating in Athens are totally missing. Moreover, the only study addressing the increasing role of biomass burning on air quality in Greek cities is from Safari et al., (2013), who reported an increase in wood burning tracers at the same time with a decrease in fossil fuel tracers, at Thessaloniki (the second most important Greek city) and during the first winter with a significant increase in fuel price.

### 4 Conclusions

Continuous sampling of the PM$_{2.5}$ aerosol fraction on a daily basis was conducted in Athens (Penteli station, urban background) during a five year period (2008-2013). Subsequent chemical analyses allowed the determination of organic carbon (OC), elemental carbon (EC) and water soluble organic carbon (WSOC) concentrations and the estimation of secondary organic carbon (SOC). A comparison with parallel measurements from a remote site on Crete Island (reference ACTRIS site for Eastern Mediterranean) enabled the identification and quantification of urban sources contribution on regional background. The results of this study, coinciding with the beginning of the economic crisis in Greece, reflect the combinational effect of limited vehicular circulation and increased wood combustion for domestic heating. This first long term measurement of OC, EC, WSOC and the estimation of SOC provide a unique opportunity to qualify and quantify the rapidly changing air pollution characteristics in the studied area, which is a mandate for future air quality policies.

The main conclusions arising from this study are summarized below:

- OC and EC concentrations in Athens back in 2003, were 3-4 times higher compared to this study, while later studies revealed similar or slightly higher values depending on the site type. Average OC and EC concentration is
2.1±1.3 μg m⁻³ and 0.54±0.39 μg m⁻³, respectively. OC and EC present covariance for most of the sampling period while maximum values are observed during the coldest months of the year, when there is increased fuel combustion. The aforementioned outputs reveal that OC and EC emission rates are mostly proportional to each other, suggesting hence that OC and EC fractions are mainly emitted by common primary sources at a regional scale.

- On a seasonal basis, summer EC is formed by predominant regional sources (53±12% of EC), such as fossil fuel combustion (traffic), whereas during winter, the prevailing result of local sources such as fuel combustion is highlighted (71±8% of EC). EC during summertime is decreasing through the years, since there is a simultaneous reduction in traffic and industrial activity, due to the economic crisis in Greece. On the contrary, EC concentration during winter presents a significant increase since 2011, which can be attributed to the selection of wood as the major fuel source for domestic heating. OC concentration does not present a clear inter-annual pattern, probably because of the episodic nature of biomass burning, as depicted from the increased calculated standard deviations that may have balanced out the aforementioned trend.

- Total carbon for the whole sampling period (sum of OC and EC) constitutes a significant part of PM_{2.5} aerosol fraction (TC/PM= ~14%), while OC accounts for 79±4% of total carbon, constituting the predominant carbon contributor. Additionally, the estimated POM accounts for 24±6% of the collected fine aerosol.

- The total of five-year samples provides an average OC/EC ratio of 4.7±1.3, while on a seasonal basis the OC/EC ratios are higher than those reported for other urban background sites around the world. The elevated measured values of OC/EC ratio highlight the secondary nature of secondary organic carbon in the area especially during summertime. Additionally, the calculated correlation between OC and EC suggests that OC and EC fractions are emitted by common primary sources while, simultaneously there is impact of additional sources like production of secondary organic carbon. More specifically, in regards to primary emissions, it appears that the dominant
primary source of EC is mainly fossil fuel combustion (such as traffic) while, biomass emission sources contributes mainly during the cold period.

- The calculated WSOC average concentration is 1.5±0.9 μg m⁻³, and it presents significant dependence on OC concentration, revealing their common sources and subsequently the predominant secondary nature of OC in the studied area. Furthermore, the estimated WSOC/OC ratio is 63±7%, illustrating the presence of aged aerosol in the site. In addition, this work indicates that emissions, from primary non-biomass burning sources of water-soluble organic carbon and from secondary organic products, can contribute to some extent to the variability of organic carbon observed in the studied location.

- SOC presents maximum values during summer, when there is intense photochemical activity, while the intra-annual variability of SOC is similar to that of WSOC, highlighting significant aging processes as characteristic at the regional scale. SOC estimation was not feasible in the cold period (November to March).

- The comparison of OC and EC levels between the urban background and the remote-coastal sites indicated an 80% increase of EC, due to local sources in Athens, during the cold season of the last two years (wintertime 2011-2012 and 2012-2013), when economic hardship massively led residents to wood burning for heating purposes.

\[ R^2 = 0.87 \]
Figure 6. Average seasonal cycle of OC, EC, WSOC, WIOC concentrations and the WSOC/OC ratio calculated from daily values, for the period May 2008 - April 2013.
Figure 7. Average summer and winter nss-K$^+$ and EC concentrations calculated from daily values, for the period May 2008 - April 2013. nss-K$^+$ concentrations were multiplied by 2 for visualization purposes.
Figure 8. Average seasonal cycles of OC and EC concentrations at Penteli, Athens and Finokalia, Crete Island, calculated from daily values, for the period May 2008 - April 2013.
Figure 9. Average monthly variability (from April to October) of WSOC and estimated SOC concentrations, calculated from daily values, for the period May 2008 - April 2013.
