Author response on “Comparing turbulent parameters obtained from LITOS and radiosonde measurements” by A. Schneider et al.

Report #1: Marvin Geller

I suggest that the abstract be rewritten. My reason for this is, at the present time, it has too much of a negative tone. A quick reading of it would indicate that Thorpe analysis of radiosonde data leads to spurious results, and should be discarded. This is quite different from the closing paragraph of this paper. My suggested rewrite would make the point that the Thorpe and LITOS analyses lead to different results on individual turbulent layers. I would not expect anything different given the instantaneous nature of the measurement, the intermittency of atmospheric turbulence, and the variety of sources of atmospheric turbulence. On the other hand, this paper itself does suggest that the Thorpe analysis might give useful information in the statistical mean. In my opinion, presenting only the negative implication, as is done in the present abstract, without indicating areas where the Thorpe analysis likely gives useful information gives a misleading impression.

We thank the referee for pointing out potential misunderstandings. We have rephrased the second half of the abstract as follows:

In our measurements no such proportionality can be seen, although the mean of the ratio $L_O/L_T$ is close to what is assumed in radiosonde analyses. Dissipation rates for individual layers obtained from radiosondes deviate up to a factor of $\sim 3000$ to those obtained by spectral analysis. Some turbulent layers measured by LITOS are not observed by the radiosonde at all, and vice versa. However, statements about the statistical mean seem to be possible by Thorpe analysis.

Furthermore, I think that the first sentence in the second paragraph of the Introduction should also be rewritten. I think that Clayson and Kantha (2008) indicated that their methods might give unique information on atmospheric turbulence, exploiting the fact that such information might be derived from operational observations that are available over large geographical areas and are made throughout the year for many years.

To prevent misunderstandings, we have changed our phrasing as follows:

In order to enlarge the knowledge of turbulence by exploiting existing measurements available for large geographical areas and several years, it has been proposed to extract turbulence parameters such as $\varepsilon$ from standard radiosonde data (vertical resolution 5 m) (Clayson and Kantha, 2008).

Report #2: Richard Wilson

I am rather satisfied with most answers of the authors to my (numerous) questions. Thank you to the authors for specifying many details. Even if I have always doubts about several aspects of the data analysis and about the interpretation of the results, I found the paper substantially improved. These remaining issues (see comments below) will hopefully feed future stimulating debates about turbulence detection and measurements in the atmosphere. I recommend publication.
We thank the reviewer for this positive feedback. Indeed, for the future we expect many stimulating discussions about turbulence detection in the stratosphere, and the evaluation of agreements and disagreements of the different methods will hopefully provide further insight into the geophysical nature of turbulence.

(The numbering refers to the one of the reviewer#1-questions/authors-responses)

2) I am very surprised with the results obtained by including the effects of moisture on the vertical stratification. To my experience in that matter, the effect is dramatic if clouds exist (see the figure 4 in Wilson et al., AMT, 2013).

We use a generally weaker criterion for significance (see below), but even with the rigorous criterion the difference remains small (no change for BEXUS 8, and 22 instead of 18 significant layers for BEXUS 12). In the cold arctic atmosphere, moisture seems to play less a role.

3) I do not understand the reported TNR: according to my experience, the TNR is substantially larger in the stratosphere than in the troposphere due to larger \( \frac{d\Theta}{dz} \). The authors obtained an inverse results. Also a value TNR = 12 in the troposphere (for BEXUS 12) implies a noise level \( \sigma \sim 3\text{mK} \) (by taking \( \frac{d\Theta}{dz} \sim 3 \times 10^{-3}\text{K/m} \) and \( \Delta z = 10\text{m} \). Such a low noise level for radiosonde measurements is very unfamiliar for me. From Vaisala radio sonde, I estimated the noise level to be few \( 10^{-2}\text{K} \) (see figure 3 of Wilson et al., 2011).

About the fact that 2 bins layers passed the significance test: I think that a statistics from a sample of 2 elements is for the less highly doubtful.

We thank the referee for his comments. Indeed, we use a slightly modified version of the significance test compared to Wilson et al. (2011). Particularly, instead of the standard deviation of the first differences divided by \( \sqrt{2} \), we use the square of that value as measurement noise standard deviation. This results in more significant layers. We agree that some of the identified layers are questionable, but the overall agreement with LITOS is much better, if the lower noise level is assumed. Nevertheless, the main results of our paper are unchanged if the rigorous test is applied, only the statistical basis is smaller. Those main results are (a) no proportionality between \( L_O \) and \( L_T \), (b) a broad distribution of values for the ratio \( \left(\frac{L_O}{L_T}\right)^2 \), and (c) nevertheless comparatively good agreement on average between our results and published values. In other words, our main conclusion is valid independently of the noise treatment. The question of detection sensitivities of the Thorpe method using standard radiosondes and the LITOS method is outside the scope of this paper and should not be answered on the limited data set of two balloon soundings from a single (polar) location.

The tnr is not substantially larger in the stratosphere than in the troposphere even for the rigorous test because the increase in noise exceeds the increase in trend. Particularly, for BEXUS 8 the mean tnr is slightly less in the stratosphere compared to the troposphere while for BEXUS 12 it is slightly larger.

We have adapted our manuscript accordingly.
Comparing turbulent parameters obtained from LITOS and radiosonde measurements

Abstract. Stratospheric turbulence is important for the mixing of trace species and the energy balance, but direct measurements are sparse due to the required resolution and accuracy. Recently, turbulence parameters such as the energy dissipation rate $\varepsilon$ were inferred from standard radiosonde data by means of a Thorpe analysis. To this end, layers with vertically decreasing potential temperature are analysed, which is expected to indicate turbulence. Such an application assumes a proportionality between the Thorpe length $L_T$ and the Ozmidov scale $L_O$. While this relation is accepted for the ocean, experimental evidence for such proportionality in the stratosphere is sparse. We have developed a high-resolution (8 kHz) turbulence measurement system called LITOS, which for the first time resolves the inner scale of turbulence in the stratosphere. Therewith the energy dissipation rate $\varepsilon$ can be determined by spectral analysis. This independent value for $\varepsilon$ enables us to check the relation $L_O \propto L_T$.

In our measurements no such proportionality can be seen, although the mean of the ratio $L_O / L_T$ is close to what is assumed in radiosonde analyses. Furthermore, dissipation rates for individual layers obtained from radiosondes deviate up to a factor of $\sim 3000$ to those obtained by spectral analysis. Some turbulent layers measured by LITOS are not observed by the radiosonde at all, and vice versa. However, statements about the statistical mean seem to be possible by Thorpe analysis.

1 Introduction

Although the stratosphere is mostly stably stratified, breaking of gravity waves and instabilities cause turbulence and energy dissipation. This modifies the energy transport from the troposphere to the mesosphere. The amount of energy converted into heat is described by the turbulent energy dissipation rate $\varepsilon$. Moreover, turbulence is an important parameter for the vertical mixing of trace species. As in the stratosphere turbulent dissipation occurs on small scales of centimetres and below, measurements are technically challenging and therefore sparse (e.g., Barat, 1982; Theuerkauf et al., 2011).

In order to enlarge the knowledge of turbulence by exploiting existing measurements available for large geographical areas and several years, it has been proposed to extract turbulence parameters such as $\varepsilon$ from standard radiosonde data (vertical resolution 5 m), as radiosoundings are performed daily from a worldwide net of stations (Clayson and Kantha, 2008). The evaluation uses the method developed by Thorpe (1977, 2005) to detect static instabilities as a proxy for turbulence. Note that such a measurement is somewhat different from measuring the turbulent motions directly, as done by LITOS. For example, within an instability turbulence may have not yet been developed, or on the other hand, turbulence might be still active while the instability has already ceased. Additionally, turbulence may not be related to static instabilities at all.

The Thorpe analysis of unstable layers is done by comparing a measured potential temperature profile to an equivalent (statically) stable one obtained by sorting. This means that the order of the data points is changed upwards and downwards to yield a statically stable profile with monotonously increasing potential temperature. Precisely, the Thorpe displacement $D_T$ is defined by the vertical displacements needed for the sorting, i.e. if an air parcel at altitude $z_j$ is sorted to $z_k$, then the Thorpe displacement at $z_j$ is $D_T(z_j) = z_j - z_k$. The Thorpe length is the root mean square of the Thorpe displacements taken over an unstable layer,

$$L_T := \text{rms}(D_T).$$

It describes the distance on which heavier air parcels are carried above lighter ones. Wilson et al. (2011, 2010) use...
the Thorpe method for statistical analysis without computing dissipation rates.

The Ozmidov length scale

\[ L_O := \alpha \sqrt{\frac{\varepsilon}{N^2}}, \]  

where \( \varepsilon \) is the (kinetic) energy dissipation rate, \( N \) the Brunt–Väisälä frequency and \( \alpha \) a numerical constant near unity, represents the vertical scales of the largest turbulent eddies (Ozmidov, 1965). For the determination of the dissipation rate from a Thorpe analysis, the key assumption is a proportionality between Thorpe and Ozmidov lengths, \( L_O \propto L_T \).

This relation has been extensively studied in the ocean, and the assumption is fulfilled to a good extent (Thorpe, 2005; Dillon, 1982; Wesson and Gregg, 1994). But for the atmosphere there are only few examinations of the proportionality (e.g. Gavrilov et al., 2005; Kantha and Hocking, 2011; Wilson et al., 2014). With our new high-resolved instrument LITOS (Leibniz-Institute Turbulence Observations in the Stratosphere) (Theuerkauf et al., 2011), the energy dissipation rate \( \varepsilon \) is obtained independent of \( L_T \) by means of spectral analysis of wind fluctuations. Thus it is possible to check the relation \( L_O \propto L_T \).

Please note that our comparison involves two parameters: (a) evaluation method (Thorpe or spectral analysis) and (b) vertical resolution (low or high). We concentrate on results from high-resolved spectral analysis (as very precise method of \( \varepsilon \) determination) and low-resolved Thorpe analysis. Such a Thorpe evaluation of radiosonde data has been proposed for extensive use (Clayson and Kantha, 2008; Love and Geller, 2012). Note that Love and Geller (2012) call 1 Hz (5 m) high resolution, while we call it low resolution (compared to LITOS with 8 kHz). In principle, the Thorpe analysis can also be performed on data with higher resolution, as done, e.g., by Luce et al. (2002) for temperature data with 50 Hz sampling rate; however, these data are rarely available compared to standard radiosonde. Besides, a kind of spectral analysis can be used to determine dissipation rates from low-resolution wind data (Barat, 1982), but this method depends on the absolute value of the wind velocity which is not available for our measurements (see next section).

In Sect. 2, the measurement principle of LITOS and the determination of the energy dissipation rates with both methods are shortly reviewed. The independent measurements of \( L_O \) and \( L_T \) are compared in Sect. 3. Section 4 shows results for the energy dissipation rate \( \varepsilon \) from both a Thorpe analysis and our high-resolved spectral analysis. Conclusions are drawn in Sect. 5.

2 Instrumentation and methods

As described in Theuerkauf et al. (2011), LITOS is a balloon-borne instrument which measures winds with high vertical resolution of millimetres. The wind sensor is a constant temperature anemometer (CTA), which facilitates the cooling effect on a heated wire of 5 \( \mu \)m diameter. To infer wind velocities from the anemometer voltage, a calibration in the same ambient conditions (pressure, temperature) is required. This is not possible for a balloon flight, as the pressure varies within several orders of magnitude during the flight. Nevertheless, we are only interested in the spectral form, and the absolute values are not important (see below); therefore we use the anemometer voltage for the analysis. The vertical resolution is obtained by applying a sample rate of 8 kHz with a balloon ascent rate of 5 m s\(^{-1}\). Up to date, three flights on large (~10,000 m\(^3\)) balloons were performed, namely BEXUS 6, 8 and 12 in 2008, 2009 and 2011, respectively. They were launched at Kiruna (68° N, 21° E) in autumn. For BEXUS 6, the radiosonde data are partly disturbed so that it is not considered in this article.

The left panel in Fig. 1 shows an example of a time series of the anemometer voltage of the BEXUS 12 flight. Large-scale motions have already been removed by subtracting a spline. At altitudes with small variations (\( \lesssim 1 \) mV, e.g., from 10.28 to 10.3 km), the signal mainly shows instrumental noise; this corresponds to a calm region. Large fluctuations, as in the height range of 10.18 to 10.28 km, correspond to turbulence. Note that there is a sub-structure which divides the turbulent region into different patches. For the patch from 10.27 to 10.28 km (shaded in the graph), the power spectral density (PSD) is plotted in the right panel of Fig. 1 (blue curve). An inertial regime with a \(-5/3\) slope and the transition to the viscous subrange with a \(-7\) slope is identified. The part below \( \sim 10^{-2} \) m spatial scale with approximately constant PSD corresponds to the instrumental noise level. As the transition to the inertial range is resolved, a fit of the Heisenberg (1948) model in the form given by Lübben (1992) is applied to the experimental data (red curve). This gives the inner scale \( l_0 \), i.e. the transition from the inertial to the viscous subrange. In the example, \( l_0 = 1.9 \times 10^{-2} \) m ± 4.5 \( \times 10^{-3} \) m (fit error). Note that \( l_0 \) does not depend on the absolute value of the PSD, only on identifying the bend in the spectrum. From the inner scale, the energy dissipation rate is obtained by

\[ \varepsilon = \frac{c^4 \nu^3}{l_0^4}, \]

where \( \nu \) is the kinematic viscosity (derived from the radiosonde measurement of temperature and pressure on the same gondola), and \( c = 5.7 \) (Theuerkauf et al., 2011; Haack et al., 2014). For the example in Fig. 1, \( \varepsilon = 3.2 \times 10^{-4} \) W kg\(^{-1}\) \( \pm 3.0 \times 10^{-4} \) W kg\(^{-1}\).

In order to obtain a vertical profile of energy dissipation rate, a sliding window of 5 s (roughly 25 m altitude) is used. For each window, \( \varepsilon \) is computed according to the procedure described above. For non-turbulent spectra, \( \varepsilon \) is set to zero. A spectrum is regarded as non-turbulent if the noise-level detection fails, if the inner scale \( l_0 \) is not within the fit range,
if \( \varepsilon \) has implausible values (less than zero or greater than 100 W/kg), or if the mean distance between the fit and the data is larger than a fixed threshold. That means the decision is made automatically based on a set of objective criteria. The resulting \( \varepsilon \) profile has a vertical resolution of \( \sim 10 \) m due to the selected overlap.

The Thorpe analysis is performed similar to the procedure described in Wilson et al. (2011) on data from a Vaisala RS92 radiosonde, which was on the same gondola as the CTA sensors. Moisture is cared for using the routine given by Wilson et al. (2013). To this end, saturated regions are detected, and a composite potential temperature profile \( \Theta_{ct} \), is computed by integration of \( \partial \Theta / \partial z \) using the moist buoyancy frequency within those saturated regions and the dry buoyancy frequency otherwise. The left panel of Fig. 2 shows the potential temperature profile for the BEXUS 12 flight. In the inset, the part from 15.48 to 15.80 km is magnified for better visibility of instabilities, which manifest as negative gradients of potential temperature. The Thorpe displacement is shown in the right panel of Fig. 2. Large displacements correspond to large vertical extents of unstable layers. To identify unstable layers and their vertical extension, the cumulative sum of the Thorpe displacement (which is negative within an unstable region and zero within a stable one) is used. To select real overturns and discard negative potential temperature gradients originating from measurement noise, a statistical test is applied. To this end, the range of the potential temperatures within an inversion is compared with the range of a pure noise sample of the same length (Wilson et al., 2010). We assume here that the instrument noise standard deviation in segments of 200 m is described by the half the square root of the standard deviation of first differences of the potential temperature after trend removal. For each detected unstable layer, the Thorpe length is computed according to Eq. (1).

Only significant overturns with a 99% percentile are used, discarding \( \sim 45 \% \) (BEXUS 8) and \( \sim 30 \% \) (BEXUS 12), respectively, of the inversions as noise-induced. The mean trend-to-noise ratio (TNR) is \( \xi = 1.7 \) for the BEXUS 8 flight and \( \xi = 4.1 \) for the BEXUS 12 flight.

Several thin layers of only 10 m or 20 m passed the significance test. We are aware that this is on the edge of radiosonde capability. These thin layers would to a large extent be suppressed if the instrument noise would be set to the standard deviation of first differences divided by \( \sqrt{2} \) as done by Wilson et al. (2011). However, LITOS also shows many thin layers. Hence, this procedure would result in much less coincident layers especially in the stratosphere and, by this, bias the comparison. Nevertheless, as we will describe below, our main results are independent from the procedure of noise calculation.

### 3 Comparison of Thorpe and Ozmidov scales

A plot of the Thorpe length for the BEXUS 12 flight is shown in the left panel of Fig. 3. Unstable layers take up 50% of the altitude and can be found in the whole range. Large Thorpe lengths stand out, e.g., at 5 km, between 5 and 10 km and near 25 km altitude, corresponding to the large values of \( D_T \) in the right panel of Fig. 2. Mean values of \( L_T \) are 29 m in the troposphere and 22 m in the stratosphere, i.e. the Thorpe length is slightly larger in the less stable troposphere.

The Ozmidov scale is computed from the energy dissipation rate obtained by LITOS, using Eq. (2) and \( \alpha = 1 \). The Brunt–Väisälä frequency \( N \) is calculated from the radiosonde data as it only slowly varies with altitude. In that computation, the sorted potential temperature profile is used instead of the original data, because a background stratification is needed and an imaginary \( N \) shall be avoided (Dillon, 1982, Sect. 3). The result for the BEXUS 12 flight is plotted in the right panel of Fig. 3 (cyan curve). According to LITOS, 53% of the atmosphere is turbulent, i.e. \( \varepsilon > 0 \) and hence \( L_O > 0 \).

Figure 4 shows the Thorpe length and the Ozmidov scale for the altitude range of 15.48 km to 15.80 km. As LITOS computes \( \varepsilon \) on a constant grid independent of the layers, the substructure of larger turbulent layers can be seen (e.g., from \( \sim 15.5 \) km to 15.62 km), while the Thorpe length is a per-layer value by construction. Some layers are only detected by either LITOS or the radiosonde. For example, from 15.44 km to 15.47 km and from 15.7 km to 15.79 km, only LITOS observes turbulence while the Thorpe method does not. At the first-mentioned altitude region, the potential temperature gradient is positive, so that the Thorpe method is blind for the turbulent motions. At the second one, the decrease of potential temperature is not significant so that the Thorpe method is blind for the turbulent motions. On the other hand, from 15.38 km to 15.41 km and from 15.45 km to 15.47 km, the Thorpe analysis observes instability, while no turbulent motions can be detected by LITOS. Potentially, turbulence has not yet been developed by the static instability detected by the Thorpe method. A final answer cannot be given from our data. The slightly different altitudes of layers observed by both systems might be due to quantisation effects.

In order to do a comparison between both length scales, the layers where both methods detect turbulence are selected. For BEXUS 8 (BEXUS 12), 86% (69%) of the significant unstable layers are also detected by LITOS, and 90% (88%) of the layers detected by LITOS intersect with a significant unstable layer. The energy dissipation rate (obtained from LITOS) is averaged over the layer (as detected by the Thorpe analysis of radiosonde data). Such means over a Thorpe layer will be denoted by averaging brackets \( \langle \cdot \rangle \). For each unstable layer, the resulting \( \langle \varepsilon \rangle \) is plugged into Eq. (2) to infer an Ozmidov scale \( L_O = \sqrt{\langle \varepsilon \rangle / (N^2)} \) for the layer. The blue curve in the right panel of Fig. 3 shows a plot for the BEXUS 12 flight. The layer near 5 km with large \( L_T \), e.g., is
also seen in $L_T$, but less pronounced. In contrast, at $\sim 10\,\text{km}$ altitude the Ozmidov scale is larger than the Thorpe scale. Mean values of $L_O$ are 15 m in the troposphere and 6 m (i.e. only half the value) in the stratosphere. Thus, in qualitative agreement with Eq. (2), the less stable troposphere shows on average a larger Ozmidov scale, i.e. larger eddies. As the Thorpe length shows a similar behaviour (see above), this generally supports the assumption of a relation between $L_T$ and $L_O$.

In Fig. 5 Ozmidov scale $L_O$ and Thorpe length $L_T$ are plotted against each other for those 136 (175) significant unstable layers of the BEXUS 8 (BEXUS 12) flight where turbulence has been detected by LITOS. Both length scales are in the same order of magnitude, but no direct relation between them can be seen in either flight. The correlation coefficient between both is 0.32 for BEXUS 8 and 0.33 for BEXUS 12. Note that $L_T$ is limited by the resolution of the radiosonde ($\sim 10\,\text{m}$). An analogous plot for the simultaneous layers obtained using the more restrictive noise estimation of Wilson et al. (2011) contains similar scatter with no apparent correlation.

The histograms at the top and right axes in Fig. 5 show the distributions for $L_O$ and $L_T$, respectively, for the composite dataset of BEXUS 8 and BEXUS 12. The maximum for the Thorpe length is slightly larger than for the Ozmidov scale. The decrease towards large scales is similar for both lengths. At small scales $L_T$ is limited by the resolution of the radiosonde which produces the cut-off at 10 m, while the histogram for $L_O$ shows a continuous decrease.

In contrast to our measurements, an approximate proportionality between Thorpe and Ozmidov lengths is observed in the ocean (e.g., Dillon, 1982; Wesson and Gregg, 1994; Thorpe, 2005). For example, Wesson and Gregg (1994) find that most of their data fall between $L_O = 4L_T$ and $L_O = (1/4)L_T$ with a range from $10^{-2}$ m to $10^2$ m. This is the basis for applying the Thorpe analysis on atmospheric data. Several authors (e.g., Gavrilov et al., 2005; Clayson and Kantha, 2008; Kantha and Hocking, 2011) inferred energy dissipation rates from the Thorpe analysis. The mean value over all unstable layers detected by the Thorpe analysis, for comparability. On average, the values are in the same order of magnitude, and the profiles have a similar structure. The large dissipation near $\sim 10\,\text{km}$ in the CTA data does not stand out in the Thorpe analysis. The mean value over all significant unstable layers from Thorpe, 1 mW kg$^{-1}$, is larger than the one from LITOS, 0.3 mW kg$^{-1}$. For BEXUS 8 the averages are 3 mW kg$^{-1}$ from Thorpe and 2 mW kg$^{-1}$ from LITOS. That fits to the fact that the used value for $c^2$, 0.3, is larger than the one obtained from our own data, $c^2 = 0.1$ (cf. Fig. 6). If the whole $\varepsilon$ profile (not only the unstable layers detected by Thorpe) is taken into account, the average dissipation rate obtained by LITOS is 0.4 mW kg$^{-1}$ for BEXUS 12 and 2 mW kg$^{-1}$ for BEXUS 8. To get a closer look, the deviation of $\langle \varepsilon \rangle$ from LITOS to $\varepsilon$ inferred from the Thorpe analysis indicated by the ratio $\langle \varepsilon_{\text{LITOS}} \rangle / \varepsilon_{\text{Thorpe}}$ of the blue and green curves in Fig. 7 is plotted in Fig. 8. It reveals a large range of 5 orders of magnitude. Overall, for 71 % (BEXUS 8: 64 %) of the layers, $\varepsilon$ inferred from the Thorpe analysis is larger than the value from the spectral analysis. That the ratio is sometimes larger and sometimes smaller than unity illustrates that the most likely value of $c^2$ does not contain the whole information, but the width of the distribution is important. The correlation coefficient between $\langle \varepsilon_{\text{LITOS}} \rangle$ and $\varepsilon_{\text{Thorpe}}$ is 0.06 (BEXUS 8: 0.39). Due to the influence of the Brunt–Väisälä frequency, pronounced peaks in $L_O$ or $L_T$ (Fig. 3) do not necessarily correspond to large $\varepsilon$ (Fig. 7), e.g., at $\sim 5\,\text{km}$.

4 Energy dissipation rates

The relation between the energy dissipation rate $\varepsilon$ and the length scales discussed above involves the Brunt–Väisälä frequency, see Eqs. (2) and (4). Thus the $\varepsilon$ values computed from LITOS via spectral analysis and the ones from the radiosonde via Thorpe analysis have to be compared separately.

The left panel of Fig. 7 shows an altitude profile of energy dissipation rates obtained from the Thorpe analysis of the radiosonde on BEXUS 12, assuming $L_O = cL_T$ with $c^2 = 0.3$ as in Clayson and Kantha (2008). In the right panel, the altitude profile of energy dissipation obtained from LITOS is plotted in cyan, while the blue curve depicts the mean $\langle \varepsilon \rangle$ over the unstable layers detected by the Thorpe analysis, for comparability. On average, the values are in the same order of magnitude, and the profiles have a similar structure. The large dissipation near $\sim 10\,\text{km}$ in the CTA data does not stand out in the Thorpe analysis. The mean value over all significant unstable layers from Thorpe, 1 mW kg$^{-1}$, is larger than the one from LITOS, 0.3 mW kg$^{-1}$. For BEXUS 8 the averages are 3 mW kg$^{-1}$ from Thorpe and 2 mW kg$^{-1}$ from LITOS. That fits to the fact that the used value for $c^2$, 0.3, is larger than the one obtained from our own data, $c^2 = 0.1$ (cf. Fig. 6). If the whole $\varepsilon$ profile (not only the unstable layers detected by Thorpe) is taken into account, the average dissipation rate obtained by LITOS is 0.4 mW kg$^{-1}$ for BEXUS 12 and 2 mW kg$^{-1}$ for BEXUS 8. To get a closer look, the deviation of $\langle \varepsilon \rangle$ from LITOS to $\varepsilon$ inferred from the Thorpe analysis indicated by the ratio $\langle \varepsilon_{\text{LITOS}} \rangle / \varepsilon_{\text{Thorpe}}$ of the blue and green curves in Fig. 7 is plotted in Fig. 8. It reveals a large range of 5 orders of magnitude. Overall, for 71 % (BEXUS 8: 64 %) of the layers, $\varepsilon$ inferred from the Thorpe analysis is larger than the value from the spectral analysis. That the ratio is sometimes larger and sometimes smaller than unity illustrates that the most likely value of $c^2$ does not contain the whole information, but the width of the distribution is important. The correlation coefficient between $\langle \varepsilon_{\text{LITOS}} \rangle$ and $\varepsilon_{\text{Thorpe}}$ is 0.06 (BEXUS 8: 0.39). Due to the influence of the Brunt–Väisälä frequency, pronounced peaks in $L_O$ or $L_T$ (Fig. 3) do not necessarily correspond to large $\varepsilon$ (Fig. 7), e.g., at $\sim 5\,\text{km}$.

5 Discussion and conclusions

In this paper, the first extensive examination of the relation between the Thorpe length $L_T$ and Ozmidov scale $L_O$ for
stratospheric conditions was performed, using the new high-resolution instrument LITOS and a radiosonde on the same gondola. Therewith, the assumption for computing energy dissipation rates \( \varepsilon \) from a Thorpe analysis of standard radiosondes, namely the proportionality \( L_O \propto L_T \), was checked. In our data no obvious relation between \( \overline{L_O} \) and \( L_T \) can be seen, particularly no proportionality. The proportionality “constant” used in radiosonde analyses, \( c^2 = (\overline{L_O}/L_T)^2 \), shows a very broad distribution with a width of \( \sim 2 \) orders of magnitude. This is also reflected in the large deviation of \( \varepsilon \) values up to a factor of \( \sim 3000 \) obtained with both methods. Nevertheless, although the values for stratospheric layers are highly variable, the mean of \( c^2 \) is 0.1 for both BEXUS 12 and BEXUS 8, which is close to 0.3 used by Clayson and Kantha (2008), who reviewed oceanic measurements to obtain that value. Kantha and Hocking (2011) obtained \( c^2 = 1.0 \) by a comparison of radiosonde data to radar measurements. Gavrilov et al. (2005) used \( c^2 = 1.32 \) (\( c = 1.15 \)) referring to a French thesis; this value was obtained from selected thick stratospheric layers (> 200 m) with statistically homogeneous turbulence. However, in those publications no data basis, distribution width or error is given. Recently, Wilson et al. (2014) reported a few case studies of turbulent layers in the troposphere detected simultaneously by radar and balloon; using their reported estimates of \( L_T \) and \( L_O \) leads to values of \( c^2 \) between 0.1 and 1.6.

One reason for discrepancies from the proportionality \( L_O \propto L_T \) may be that large overturns might change significantly during the time the sensor needs to fly through the layer, so that the sorting procedure makes no sense anymore. Furthermore, direct numerical simulations by Smyth and Mouch (2000) indicate that \( L_O/L_T \) is not constant, but depends on the age of turbulence.

Some turbulent layers are not detected at all by the Thorpe analysis. Those are not associated with a (significant) negative gradient of potential temperature, which is necessary for detection by the Thorpe method. Not all turbulence is related to static instabilities. Even if initially a negative potential temperature gradient may have occurred, it is removed by the turbulent motions which outlive the instability; such fossil turbulence cannot be detected by the Thorpe method. Apart from that, turbulent layers may be too thin to be observed with the relatively coarse vertical resolution of the radiosonde. On the other hand, some unstable layers detected by the Thorpe analysis are not observed by LITOS. An explanation is that the static instability may not yet have lead to turbulent motions. In these cases, a correspondence between both measurements is not expected.

Not all layers are detected by both systems. Of the significant layers detected by the Thorpe analysis, 86 % (BEXUS 8) and 69 % (BEXUS 12) are also detected by LITOS. For BEXUS 12, the mean thickness of significant unstable layers as detected by the Thorpe analysis is 53 m. The mean thickness of those significant layers also detected by LITOS is 63 m, that of significant layers not detected by LITOS only 31 m. That means that the simultaneous detection depends on the size of the layer; mainly thin layers are detected by only one method. But as this only applies to \( \lesssim 30 \% \) of the layers, and those layers were taken out of the comparison, the bias for our results should be small.

For LITOS, the detection limit for \( L_O \) on small scales (i.e. high frequencies or large \( \varepsilon \)) is given by the sampling rate. This limit has been encountered in a few cases for small regions where the inertial range extends further than the Nyquist limit of 4 kHz. For large scales (i.e. low frequencies or small \( \varepsilon \)), the detection limit is determined by the trend removal and the window length. As a reasonable part of the inertial range has to be resolved to enable a fit, the limit is estimated to \( \sim 1 \) m. The maximal identified \( L_O \) values of 10 cm and 8.7 cm for BEXUS 8 and BEXUS 12, respectively, were far below this limit. That means that these limitations do not affect the results.

Up to date, we have only two flights with data usable for the analysis presented in this paper, namely BEXUS 8 and BEXUS 12, which both took place at polar latitudes near autumn equinox. Of course they cannot represent the whole variability of the stratosphere. Nevertheless, although there are differences between both flights, such as dissipation rates being on average one order of magnitude higher for BEXUS 8, these are not relevant for the results discussed above. More flights with our new high-resolution instrument are planned to broaden the data basis.

Our results question the applicability of the Thorpe analysis for the extraction of energy dissipation rates for individual turbulent layers. Nevertheless, statements in the statistical mean seem to be possible. Further research on the relation between Thorpe and Ozmidov lengths and the temporal evolution of turbulence is necessary.

Acknowledgements. The data from the BEXUS 8 flight were kindly provided by Anne Haack. The BEXUS programme was financed by the German Aerospace Center (DLR) and the Swedish National Space Board (SNSB). We are grateful for the support by the “International Leibniz Graduate School for Gravity Waves and Turbulence in the Atmosphere and Ocean” (ILWAO) funded by the Leibniz Association (WGL). Furthermore, we would like to thank Lars Umlauf for helpful discussions. We thank the reviewers Richard Wilson and Marvin Geller for their helpful comments.

Figure 1. Example of raw data (left) and associated power spectrum (right) computed for the shaded area in the raw data plot. In the raw data, an amplitude of $\lesssim 1$ mV corresponds to instrumental noise. In the spectrum, the blue curve shows the measurement, the grey dashed lines the 95 % confidence interval and the red curve the fit of the Heisenberg model to the measured spectrum, the red vertical line indicates the inner scale $l_0$. The green dashed lines visualise slopes of $-\frac{5}{3}$ and $-7$. The errors given are fit errors.

Figure 2. Potential temperature profile (left) and Thorpe displacement (right) for the BEXUS 12 flight. The inset in the left panel shows a magnification from 15.48 to 15.80 km for better visibility of instabilities (manifested as negative gradients of potential temperature).

Figure 3. Thorpe length (left) and Ozmidov scale (right) vs. altitude for the detected inversions of the BEXUS 12 flight. The cyan curve shows the Ozmidov scale $L_O$ in the full resolution of the LITOS profile, the blue one averages over the inversions detected by the radiosonde ($L_O$).
Figure 4. Detail plot of Thorpe (green) and Ozmidov (cyan) scales for the BEXUS 12 flight. The potential temperature is plotted in red.

Figure 5. Thorpe scale $L_T$ vs. Ozmidov scale $L_O$ for the BEXUS 8 (green) and 12 (magenta) flights. The black diagonal line represents $L_O = L_T$. The histograms show the distributions of $L_O$ and $L_T$, respectively, of the composite data set of BEXUS 8 and BEXUS 12, i.e. of all data points in the graph. The occurrence axes have a linear scale and are omitted due to readability. Note that $L_T$ is limited by the resolution of the radiosonde ($\sim 10$ m).

Figure 6. Statistics for the ratio $\left(\frac{L_O}{L_T}\right)^2$ for the BEXUS 8 (top) and BEXUS 12 (bottom) flights. The red curves show the most likely normal distributions for the logarithmic data.
Figure 7. Energy dissipation rates from Thorpe analysis of the radiosonde (left) and spectral analysis of the high-resolved wind measurement (right) for the BEXUS 12 flight. The cyan curve shows $\varepsilon$ in the full resolution, the blue one averages over the unstable layers detected by the Thorpe analysis ($\langle \varepsilon \rangle$).
