Abstract

Located in the dust belt, the Arabian Peninsula is a major source of atmospheric dust. Frequent dust outbreaks and some 15 to 20 dust storms per year have profound effects on all aspects of human activity and natural processes in this region. To quantify the effect of severe dust events on radiation fluxes and regional climate characteristics, we simulated the storm that occurred on 18–20 March 2012 using a regional weather research forecast model fully coupled with the chemistry/aerosol module (WRF-Chem). This storm swept over a remarkably large area affecting the entire Middle East, North-Eastern Africa, Afghanistan and Pakistan. It was caused by a southward propagating cold front and associated winds activated the dust production in river valleys of the lower Tigris and Euphrates in Iraq, the coastal areas in Kuwait, Iran, and the United Arab Emirates, Rub al Khali, An Nafud and Ad Dahna deserts, and along the Red Sea coast on the west side of the Arabian Peninsula. Our simulation results compare well with available ground-based and satellite observations. The total amount of dust generated by the storm reached 93.76 Mt. About 80 % of this amount deposited within the calculation domain. The Arabian Sea and Persian Gulf received 5.3 Mt, and the Red Sea 1.2 Mt. Dust particles bring nutrients to marine ecosystems, which is especially important for the oligothrophic Northern Red Sea. However, their contribution to the nutrient balance in the Red Sea remains largely unknown. By scaling the effect of one storm to the number of dust storms observed annually over the Red Sea, we roughly estimate the annual dust deposition to the Red Sea to be 6 Mt.

1 Introduction

Mineral dust is the dominant atmospheric aerosol (Buseck and Posfai, 1999). It plays an important role in the Earth’s climate system, although the magnitude and even the sign of its radiative effect at the Top-of-the-Atmosphere (TOA) remain uncertain.
airborne dust is generated in desert and semi-desert areas and transported across local-to-global scales.

Dust storms lift millions of tons of dust into the atmospheric boundary layer. Such large quantities of dust cause severe air pollution, reduce visibility, cause airport shutdowns, and increase traffic and aircraft accidents (Morales, 1979; Hagen and Woodruff, 1973; Middleton and Chaudhary, 1988; Dayan et al., 1991; Yong-Seung and Ma-Beong, 1996). Other environmental impacts of dust include reduced soil fertility and crop damage, reduced solar radiation on the surface and, as a consequence, decreased efficiency of solar devices, damaged telecommunications and mechanical systems, increased occurrence of respiratory diseases and other impacts on human health (Hagen and Woodruff, 1973; Mitchell, 1971; Fryrear, 1981; Squires, 2007; Jauregui, 1989; Liu and Ou, 1990; Yong-Seung and Ma-Beong, 1996; Nihlen and Lund, 1995; Longstreth et al., 1995; Bennett et al., 2006; Bennion et al., 2007). Dust deposition to oceans, however, provides nutrients to ocean surface waters and the seabed (Talbot et al., 1986; Swap et al., 1996 and Zhu et al., 1997).

Despite continuous attempts to improve modeling of dust generation processes and accumulation of empirical data, the amount of atmospheric dust aerosols, their optical properties, and their radiative impact remain uncertain. In the 1970s, the total Aeolian dust emissions from deserts were estimated at approximately 500 Mtyr⁻¹ level (Persson and Junge, 1971). Junge (1979), Ganor and Mamane (1982), and Morales (1979) found that the Sahara desert generates 200 to 330 Mtyr⁻¹ or about 50% of the total annual dust flux. These studies appear to underestimate dust emissions, however recent calculations (Andrea, 1995; Duce, 1995) show that dust emissions to the atmosphere on a global scale are typically in the range of 1000 to 3000 Mtyr⁻¹. Tanaka and Chiba (2006) calculated that the annual dust emission from North Africa is 1087 Mt and from Asia (including the Arabian Peninsula, Central Asia and China) 575 Mt. Inter-governmental Panel on Climate Change (IPCC, 2001) reported the mineral dust mass flux from Asia to be about 100 to 200 Mtyr⁻¹, which is approximately 10% of total annual global dust emissions. IPCC (2007) later reported that Asian dust emissions
increased to about 800 Mt yr\(^{-1}\) with the Taklamakan and Gobi Deserts being the two major sources of Asian dust emissions (Uno et al., 2005) dispersing dust on the global scale (Clarke et al., 2001; Grousset et al., 2003).

Direct and indirect atmospheric radiative impact by dust has implications on global climate change and presently is one of the largest unknowns in climate model predictions. The African and Asian low-latitude deserts, the so-called dust belt, are the major sources of dust for the entire world (Pye, 1987; Prospero et al., 1987, Arimoto et al., 1989; Laurent et al., 2008; Uno et al., 2005). The dust belt includes the Sahara desert, arid and semiarid regions in Arabia and Central Asia, and the Taklamakan and Gobi deserts in East Asia. Littmann (1991), Wang et al. (1996), Xu and Hu (1997), Zhou (2001), Qiu et al. (2001) and Qian et al. (2002) studied spatial and temporal dust variability, source areas and moving paths of dust storms in China. During severe dust storms, dust from East Asia can reach far beyond the continent, drifting over the Pacific Ocean to the west coast of North America (Husar et al., 2001; Tratt et al., 2001; Mc Kendry et al., 2001). Similarly, Saharan dust crosses the Atlantic and affects both Americas (Prospero et al., 1987; Reid and Maring, 2003; Haywood et al., 2003).

The Sahara is the world's largest dust source (Washington et al., 2003; Shao et al., 2011). The characteristics of Saharan dust were studied experimentally since the 1990s (Jayaraman et al., 1998; Satheesh and Ramanathan, 2000; Haywood and Boucher, 2000). The Puerto Rico Dust Experiment (PRIDE) (Reid and Maring, 2003) and the Saharan Dust Experiment (SHADE) (Haywood et al., 2003) focused on Saharan dust during long-range transport. Two comprehensive field campaigns were conducted in 2006 (Heintzenberg, 2009) and 2008 (Ansmann et al., 2011) under the framework of the Saharan Mineral Dust Experiment (SAMUM) to quantify the optical properties and the radiative impact of Saharan dust near source regions and in the aged mixed plume from Saharan dust and biomass burning aerosols transported off the West African continent. The Fennec 2011 campaign (Washington et al., 2012) made significant advances by providing new measurements close to dust sources over the remote Sahara.
Miller and Tegen (1998) conducted one of the first studies of the radiative effects of dust using a Global General Circulation Model (GCM) coupled with a mixed ocean module to show that dust aerosols reduce the global average surface net radiation by nearly 3 W m\(^{-2}\) during summer in the Northern Hemisphere. Tegen et al. (1996) showed that dust from disturbed soils causes a decrease in the net surface radiation by about 1 W m\(^{-2}\). Recently, Balkanski et al. (2007) confirmed that the global average dust-related surface net radiative flux change is in the range of \(-1.11 \text{ to } 0.92 \text{ W m}^{-2}\). However, the radiative effect of dust in desert regions during dust outbreaks could be two orders of magnitude stronger (Kalenderski et al., 2013).

Radiative effect of dust is quite sensitive to aerosol composition and the refractive index, surface reflectivity, aerosol size distribution and the vertical profile of dust particles. Early studies of the aerosol effects of dust focused on the refractive index. Sokolik and Toon (1999) and Claquin et al. (1999) showed that dust mineralogy is comprised of six main minerals: illite, montmorillonite, kaolinite, quartz, calcite and hematite. Absorption by dust in the shortwave spectrum is mostly determined by the presence of iron oxides in the form of hematite. Balkanski et al. (2007) proposed that uncertainties be constrained based on the hematite concentration. By considering three hematite concentrations (0.9, 1.5 and 2.7 %), they were able to achieve good agreement with Aerosol Robotic Network (AERONET) retrieved refractive indices and show that dust is less absorbing than was previously thought.

Zhang et al. (2013) showed that the radiative impact of dust vary for the different dust vertical profiles over the African and Asian dust source regions in solar spectrum by about 0.2 to 0.25 W m\(^{-2}\) and in Infrared by about 0.1 to 0.2 W m\(^{-2}\). To quantify the vertical distribution, transport, generation, and deposition of dust, global off-line dust models were developed by Zender et al. (2003), Chin et al. (2002), Ginoux et al. (2004), and Tanaka and Chiba (2006). Model studies showed that about 30 % of emitted dust is deposited very near the dust sources and 70 % is subject to regional and long-range transport. Prospero (1996) estimated that dust deposition in the Atlantic is about 170 Mt yr\(^{-1}\), 25 Mt yr\(^{-1}\) in the Mediterranean, and 5 Mt yr\(^{-1}\) in the Caribbean.
It has long been recognized that radiative effects of mineral aerosols are an important driver of the climate (Tegen and Fung, 1994, 1995; Tegen et al., 1996; Lie et al., 1996; Andreas, 1996). Early attempts at dust modeling using global models were made by Westphal et al. (1987, 1988), Gillette and Hanson (1989), Joussaume (1990), Tegen and Fung (1994, 1995). The presence of dust affects atmospheric heating rates and thus atmospheric stability and circulation, which together with changes in the surface energy balance affect the hydrologic cycle (Miller and Tegen, 1998; Miller et al., 2004b). The climate is altered by the presence of dust and the altered climate can in turn influence the emission, transport, and deposition of aerosols (Miller et al., 2004b; Yue et al., 2010). These dust effects on a global scale generally cause a reduction in the atmospheric dust load (Perlwitz et al., 2001). A comprehensive analysis of simulated dust distributions and their radiative effects was recently conducted under the scope of the Aerosol Inter-comparison (AeroCom) project (Textor et al., 2006; Stier et al., 2007).

Regional-scale dust effects were addressed using fine-resolution limited area models (e.g., Nickovic et al., 2001; Uno et al., 2001; Lu and Shao, 2001; Kaskaoutis et al., 2008; Tegen et al., 2013). A regional modeling system was developed for simulations of Saharan dust emissions, transport and radiative effects (Heinold et al., 2008, 2009; Laurent et al., 2010; Tegen et al., 2010) during SAMUM-1. A regional model was also used to simulate the spatio-temporal evolution of the mixed plume of Saharan dust and biomass burning aerosols (Heinold et al., 2011a), the radiative effect, and the dynamic response of the atmosphere due to Saharan dust and biomass burning (Heinold et al., 2011b) during SAMUM-2.

The studies mentioned thus far mostly focused on western and central North Africa, the Sahel, and Sahara regions. There are relatively fewer measurement and modeling studies focusing on eastern North Africa and the Arabian Peninsula. This region has been severely under-sampled; there are few available in-situ observations, and very few international research campaigns have been conducted in this area compared with the Sahara. In the Arabian Peninsula, dust storms and blowing dust are frequent events during most of the year. The major dust sources in the Arabian Peninsula include the
Tigris and Euphrates Rivers, the alluvial plain in Iraq and Kuwait, the low-lying flat lands in the east of the peninsula along the Persian Gulf and the Ad Dahna and the Rub Al Khali deserts (Kutiel and Furman, 2003; Shao, 2008). Goudie and Middleton (2006) provided an extensive discussion of the causes of dust storms in the Middle East. Eastern Syria, northern Jordan and western Iraq are the source for most of the fine dust particles (less than 50 µm in diameter) found in Arabian dust storms (NOAA, 2002). This dust is transported far into southern Arabia where it may have contributed to loess deposits on parts of the Arabian Shield and even in the Asir Plateau. Sandstorms containing larger particles (150 to 300 µm in diameter) are also frequent throughout Arabia, but rarely reach above 15 m altitude. Most sand grains move by saltation and some by surface creep; they rarely move in suspension by storm winds, haboobs, or dust devils.

Dust storms in the southern Arabian Peninsula are more frequent in summer. In the northern Arabian Peninsula they occur mainly in spring. The peak of dust storm activity occurs usually during the day time, when intense solar heating of the ground generates turbulence and local pressure gradients (Middleton, 1986a, 1986b). Across the Arabian Peninsula, remotely sensed aerosol and dust activity peaks during May to August (Prospero et al., 2002; Washington et al., 2003; Barkan et al., 2004; Goudie and Middleton, 2006). The United Arab Emirates Unified Aerosol Experiment (UAE²) focused on dust in the southern Arabian Gulf region in August to September 2004 to evaluate the properties of dust particles that converge in the UAE region from numerous sources and their impact on the radiation budget (Reid et al., 2008). Mohalfi et al. (1998) studied the effect of dust aerosols on the synoptic system and showed that dust aerosol radiative heating strengthens Saudi Arabian heat low. Kalenderski et al. (2013) simulated a winter dust event that occurred in January 2009 over the Arabian Peninsula and the Red Sea to study various dust phenomena. Notaro et al. (2013) investigated the temporal and spatial characteristics of Saudi Arabian dust storms using trajectory analysis. Using MODIS data, they found that the highest aerosol optical
depth (AOD) is achieved during dust storms that originate from the Rub Al Khali and Iraqi Deserts.

This study aims to quantify the impact of dust on the Arabian Peninsula and Red Sea focusing on the severe dust storm observed during 18–19 March 2012. This storm likely drew at least some of its dust from Iraq, Iran, Kuwait and the Arabian Peninsula’s Empty Quarter or Rub’ al Khali desert, sprawling over parts of Saudi Arabia, Yemen, Oman and United Arab Emirates. The simulation period was from 00:00 UTC (Universal Time Coordinate) on 5 March to 00:00 UTC on 25 March 2012 with the model spin-up during first six days. Using model output and observations, we provide an improved estimate of the storm’s impact on the terrestrial and oceanic environment.

The remainder of this paper is organized as follows. Section 2 discusses the model’s configuration and methodology. Section 3 examines the environmental conditions that led to development of the dust storm, estimates the dust emissions, load and deposition, discusses the structure of the dust storm, compares model results with available Aerosol Robotic Network (AERONET) and satellite observations, presents the vertical structure of atmosphere and dust distribution, and calculates radiative effect of dust. We offer a summary of the results in Sect. 4.

2 Methodology

In this study, we combine advanced high-resolution modeling of meteorological and dust processes with analysis of ground-based and satellite observations of aerosols and meteorological fields.

2.1 Modeling

The Weather Research Forecast (WRF) system is a mesoscale forecast model with an incorporated data assimilation capability that advances both the understanding and prediction of weather (Skamarock et al., 2008). WRF has been utilized in a variety of
research and operational projects, from the scale of convective storms to the scale of continental weather patterns (Michalakes et al., 2005). WRF-Chem extends WRF by incorporating a chemistry module that interactively simulates emissions of aerosols and gases, their transport, turbulent and convective mixing, and chemical and microphysical transformations of trace gases and aerosols (Grell et al., 2005).

Here, we configured WRF-Chem with the RADM2 (Regional Acid Deposition Model 2) photochemical mechanism (Stockwell et al., 1990), the Fast-j photolysis scheme (Wild et al., 2000), the Modal Aerosol Dynamics Model for Europe (MADE) and the Secondary Organic Aerosol Model (SORGAM) aerosol model (Ackermann et al., 1998; Schell et al., 2001). MADE/SORGAM uses the modal approach with three log-normally distributed modes (Aitken, accumulation, and coarse modes) to represent the aerosol size distribution. The aerosol species treated in MADE/SORGAM are mainly composed of sulfate, nitrate, ammonium, organic matter (OM), black carbon (BC), water, sea salt and mineral dust. We also employed the Goddard Global Ozone Chemistry Aerosol Radiation and Transport (GOCART) dust emission scheme (Ginoux et al., 2001) to calculate the influx of dust into the atmosphere. GOCART simulates dust emissions as a function of surface wind speed, surface erodibility, and surface wetness (Chin et al., 2002). Emission flux, $F_p$, for a specific aerosol size group, $p$, is expressed as

$$F_p = C S s_p U_{10m}^2 (U_{10m} - U_t) \quad \text{if} \quad U_{10m} > U_t$$

where $C$ is a dimensional constant coefficient of proportionality; $S$ is the space-dependent dimensionless erodibility field taken from Ginoux et al. (2001) and has a spatial resolution of 0.25° × 0.25°; $U_{10m}$ is the wind speed 10 m above the ground; $U_t$ is the threshold velocity of wind erosion, which depends on particle size and surface wetness; $s_p$ is a particular particle size mass fraction within the soil. Dust is a primary aerosol and does not have a very fine Aitken mode. $s_p$ is set to be 0, 0.07 and 0.93 for Aitken, accumulation and coarse modes, respectively.
The dust generation process is very complex. Eq. (1) is a simplified empirical approximation of this process and has to be adjusted using available observations to account for different model resolution and meteorological conditions. For example, coefficient $C$ in Eq. (1) was originally estimated to be equal to $1 \text{mg s}^{-2} \text{m}^{-5}$ based on regional datasets (Ginoux et al., 2001). Zhao et al. (2010) proposed to tune this parameter and used $C = 0.65 \text{mg s}^{-2} \text{m}^{-5}$ in their calculations to replicate consistency of calculated optical depth with AERONET observations. In our simulations, we used $C = 0.8 \text{mg s}^{-2} \text{m}^{-5}$ to achieve consistency between the simulated and AERONET aerosol optical thickness (AOD) observed from 11 to 24 March 2012.

To cover the entire area affected by the storm and to account for processes that were responsible for the storm’s development, we ran the WRF-Chem model in the spatial domain from 4 to 40° N in longitude and 25 to 80° E in latitude with 10 km horizontal resolution. In our calculations, we therefore used 495 grid points in the west-east direction and 396 grid points in the south-north direction, as well as 40 vertical levels with the top of the model domain at the 10 hPa level. The following physical parameterizations (Skamarock et al., 2008) were used to configure the model simulations: the Lin microphysics scheme; the Rapid Radiative Transfer Model (RRTMG) for both longwave (LW) and shortwave (SW) radiation; the Mellor-Yamada-Janjic (MYJ) boundary layer scheme; the Noah land surface model; the Grell cumulus parameterization. Lateral boundary and initial conditions for meteorological fields were provided by the National Centers for Environmental Prediction’s (NCEP) global analysis (FNL). We used NCEP’s daily global sea surface temperature (SST) analysis (RTG_SST_HR) to update SST every six hours. The various model domain configurations and physics options are summarized in Table 1.

2.2 Observations

To test and constrain the model simulations, we used reanalysis fields as well as meteorological and aerosol observations available in the Middle East and surrounding areas.
2.2.1 Space-borne aerosol instrumental observations

Aerosol Optical Depth (AOD) data from MODIS (Moderate Resolution Imaging Spectroradiometer) sensors on board the Terra and Aqua satellites are widely used in aerosol studies (Salomonson et al., 1989). The MODIS instrument provides high radiometric sensitivity (12 bit) in 36 spectral bands ranging in wavelength from 0.4 µm to 14.4 µm. Two bands are imaged at a nominal resolution of 0.25 km at nadir, with five bands at 0.5 km, and the remaining 29 bands at 1 km. A ±55° scanning pattern of the Earth Observing Satellite (EOS) orbit at 705 km altitude achieves a 2330 km swath and provides global coverage every one to two days. The MODIS daily Level 2 AOD data are produced at the spatial resolution of a 10 km × 10 km (at nadir). There are two MODIS aerosol data products, one containing data collected from the Terra platform and the other containing data collected from the Aqua platform. To maximize the observation coverage, we used AOD retrievals over land and sea derived from the dark target product (Remer et al., 2005, 2008) and the “deep blue” product over bright land surfaces (Hsu et al., 2004, 2006). The dark target ocean and land AOD products were available from both Terra and Aqua, but the deep blue retrievals were only available from Aqua. In this study, we have used daily deep blue (level 2) data in combination with the standard ocean algorithm for comparison with the simulated aerosol optical properties.

Spinning Enhanced Visible Infrared Radiometer (SEVIRI) (Aminou et al., 2002) is a line scanning radiometer currently located on board the European geostationary meteorological satellite, Meteosat-9; it was previously on Meteosat-8. This instrument provides data in four visible and near infrared channels and 8 infrared channels with a resolution of 3 km at nadir. In this study, we used the 0.6 µm channel. An advantageous feature of SEVIRI is its ability to image the study area with high temporal resolution of 15 min. This allows SEVIRI to track aerosol events, which offers a great advantage over polar orbiting instruments, like MODIS, that usually sees the particular seen once a day. The SEVIRI’s spatial resolution is, however, coarser than that of MODIS but the
aerosol gridded products for the Arabian Peninsula from both instruments are roughly on the 10 km × 10 km grid.

2.2.2 Ground-based aerosol observations

The Aerosol Robotic Network (AERONET) uses CIMEL Robotic Sun Photometers and provides observations of AOD on up to 8 wavelength channels between 0.340 and 1.640 µm (Holben et al., 1998) and angular distribution of sky radiance at four wavelengths (0.440, 0.675, 0.870, and 1.020 µm). In addition to the direct measurement of AOD, the inversion algorithm retrieves physical and optical properties of aerosols that comprise the aerosol refractive index, column average size distribution, single scattering albedo, and asymmetry parameter. The maximum AERONET uncertainty in AOD retrieval is estimated to be 0.02 with the highest error in the ultraviolet wavelength (Holben et al., 1998; Eck et al., 1999) and the calibrated sky radiance measurements typically have an uncertainty of less than 5% (Holben et al., 1998). CIMel Sun Photometers are calibrated annually by comparison with an AERONET master instrument.

The AERONET data are at high time resolution but have limited spatial coverage. During the study period, AOD observations were available at Kuwait University (29.32° N, 47.97° E), at Mezaira (23.14° N, 53.77° E), and at our own site established in February 2012 on the KAUST campus (22.30° N, 39.10° E). We chose cloud screened (Level 1.5) AERONET AOD for our model validation since level 2 data (cloud screened and quality assured data) were not available during the simulation period. The Angstrom power law was used for comparing the simulated optical properties output at 0.60 µm with the AERONET measurements as follows:

\[ \text{AOD}(0.600) = \text{AOD}(0.675) \times \left( \frac{0.600}{0.675} \right)^{-\alpha} , \]  

(2)
where $\alpha$ is the Angstrom exponent calculated from the AERONET measurement as:

$$\alpha = \frac{\ln \left( \frac{\text{AOD}(0.440)}{\text{AOD}(0.675)} \right)}{\ln \left( \frac{0.675}{0.440} \right)}$$  \hspace{1cm} (3)

2.2.3 Weather station meteorological observations

There are meteorological data from 108 surface weather stations and 12 upper air stations available in the area of interest. For the purposes of this study, we focus on the upper air radiosonde data. The radiosonde (RS) is a balloon-borne instrument platform with radio transmitting capabilities. Data from the radiosonde is interpreted at the launching station and entered into a worldwide communications network. The time sampling of RS data is usually twice daily at 00:00 UTC (midnight) and 12:00 UTC (noon). RS profiles contain pressure, temperature, relative humidity, wind speed, and wind direction. Depending on the sensor and balloon used at each location, the vertical resolution of RS data typically have 40 levels between 1000 and 50 hPa. We used temperature profiles from three RS stations for a comparison with modeled heating rates at 12:00 UTC on 19 March 2012. Stations are identified by their World Meteorological Organization (WMO) five digit codes. The three stations over the Arabian Peninsula selected for this study include Jeddah (41024), Abu Dhabi (41217) and Kuwait (40582). The vertical temperature RS profiles were retrieved from the upper air archive at the University of Wyoming (http://weather.uwyo.edu/upperair/sounding.html).

2.2.4 Reanalysis output

To compare meteorological fields and spatial patterns, we use output from the ERA-Interim reanalysis (Dee et al., 2011). It is the latest global atmospheric reanalysis produced by the European Centre for Medium-Range Weather Forecast (ECMWF) as a transition between ERA-40 and a future reanalysis project. It provides information on a large variety of surface parameters (3 hourly), describing weather as
well as ocean-wave and land-surface conditions and 6 hourly upper-air parameters (37 pressure levels up to 1 hPa), on a 0.7° x 0.7° grid. ERA-Interim uses improved an atmospheric model and a more sophisticated data assimilation method (4-D-Var) for atmospheric analysis compared with ERA-40. Information about the current status of ERA-Interim production and availability of online data can be found at (http://apps.ecmwf.int/datasets/data/interim_full_daily/). In this paper, 10 m wind field ($U_{10}$) from WRF-Chem high resolution (10 km) simulation results are compared with ERA-Interim reanalysis. The $U_{10}$ field from ERA-Interim was interpolated to WRF projections for comparison.

3 Results

The dust storm on 18–22 March 2012 covered an extremely large area and disrupted human activities in Iraq, Iran, Kuwait, Syria, Jordan, Israel, Lebanon, UAE, Qatar, Bahrain, Saudi Arabia, Oman, Yemen, Sudan, Egypt, Afghanistan, and Pakistan. Many airports in these countries were shut down because of dust impact on visibility and machinery.

3.1 Meteorological conditions and storm spatial-temporal development

Figure 1 shows geopotential height from WRF-Chem simulations and ERA-Interim reanalysis at 500 hPa at 00:00 UTC on 17–19 March 2012. Sea-level pressure for the same days at 00:00 UTC is shown in Fig. 2. The model results compare well with the reanalysis fields in both Figures. On 17 March there was a trough in mid-troposphere at 500 hPa stretching over eastern Mediterranean Sea, Syria, Iraq, western Iran and northern Saudi Arabia. This upper air disturbance caused a significant pressure decrease in the lower atmosphere and a low-pressure system consequently developed in eastern Iraq and northwestern Iran with a central sea-level pressure of 1008 hPa. A high pressure is seen over northeastern Afghanistan and Tajikistan. The spatial
distribution of 10 m wind bars at 09:00 UTC from 17 to 19 March is shown in Fig. 3. Strong surface winds of 15 m s$^{-1}$ are observed over northwestern Iraq on 17 March at 09:00 UTC (Fig. 3a).

On 18 March the high level trough deepened and moved southeastward into the northern Arabian Peninsula covering Iraq and western Iran. A surface high pressure builds up over the eastern Mediterranean Sea. The presence of a low pressure in southern Saudi Arabia, the Gulf of Oman and central Iran in combination with a high in the eastern Mediterranean Sea enhanced a strong pressure gradient along the Arabian Peninsula. As a result, a strong surface wind of 15 m s$^{-1}$ developed to the west of the low near the Persian Gulf in southeastern Saudi Arabia and Qatar and to the northeast of UAE (Fig. 3b). This is well above the generally assumed threshold wind speed (5 to 6 m s$^{-1}$) for dust suspension (Gillette, 1978). These strong winds forced the dust emission and transported dust to the south and southwest of the Arabian Peninsula.

On 19 March the high level trough moved towards eastern Iran and western Afghanistan. The low-pressure system in the southern Arabian Peninsula was overtaken by the high-pressure system. But if a surface high developed in the northern Arabian Peninsula, it could cause further dust transport towards the south and southwest of the Arabian Peninsula. A low-pressure system that developed in central Pakistan in combination with the high pressure in the northern Arabian Peninsula increased the strong winds in southern Iran with a strong surface wind speed of 20 m s$^{-1}$ (Fig. 3c). One of the most identifiable synoptic features in the Arabian Peninsula during the simulation is the low-pressure system that moved southeastward through the Peninsula on 19 March 2012 suggesting that the dust storm was closely related to the south and southwestward propagation of a cold front. Figure 4 shows the simulated near-surface wind field and dust concentration at 08:00 UTC and 15:00 UTC on 18 March 2012. Comparisons with synoptic observations confirm that the flow field is well simulated. The cold front is a line-shaped narrow region stretching from the western coast of Saudi Arabia to Eastern UAE, as can be seen from the dense temperature contours (Fig. 4a). Strong northeasterly wind (maximum 15 m s$^{-1}$) prevailed behind the
cold front, resulting in strong dust emissions and high dust concentrations. The dust was carried southwestward by the northeasterly wind to converge on the frontal area, resulting in high dust concentrations near the front. The dust was then transported westward over the red sea along the front and towards the southern Arabian Peninsula. The dust storm affected a large area, although the area of dust emissions was much smaller. In southern Saudi Arabia, the dust front rapidly advanced to the south and southwest. Figure 4 shows that within a time period of seven hours, the dust front advanced more than 150 km. At 15:00 UTC 18 March (Fig. 4b), dust was wide spread, with the same maximum dust concentration as that at 08:00 UTC.

Dust and sand lift both ahead of and behind cold fronts; winds tend to be even stronger behind the front than ahead of it (Sissakian et al., 2013). Behind an advancing cold front, southern Iraq and northern Saudi Arabia experienced blowing dust or shamal-like conditions (Hamidi et al., 2013). The summer shamal results from a characteristic synoptic pattern in which the most prominent features are (a) a semi-permanent high-pressure cell extending from the eastern Mediterranean to northern Saudi Arabia; (b) a low-pressure cell over Afghanistan; and (c) a thermal low pressure belt associated with the monsoon trough extending into southern Arabian peninsula. A high pressure in the eastern Mediterranean and a low pressure over the Afghanistan are clearly seen.

3.2 The vertically integrated mass balance and optical depth of the dust

Dust emissions are calculated in the model interactively from Eq. (1) using soil properties and simulated surface winds that drive dust emissions and are extremely important to storm development. Therefore, to ensure that the model could adequately generate dust, we compare the simulated 10 m wind field \( U_{10m} \) with the output from the ECMWF (European Center for Medium Range Weather Forecast) Interim global re-analysis, ERA-I. The \( U_{10m} \) is extracted from ERA-I and interpolated to WRF projections for comparison. The simulated and reanalysis fields are well correlated (not shown) with a time-averaged correlation coefficient of 0.79. Figure 5a shows the erodibility field \( S \) used in the GOCART emission scheme (Eq. 1). Figure 5b–d shows simulated dust
emissions averaged over 24 h periods for 17, 18 and 19 March 2012, respectively. On
17 March (Fig. 5b) the most intense simulated emissions were located in the lower
Tigris and Euphrates river valleys and in newly dry lakebeds, which are filled with loose
fine-grain soils and have high susceptibility. These are known major sources of dust in
Iraq. The maximum dust emission rate exceeded 300 µg m\(^{-2}\) s\(^{-1}\). On 18 March (Fig. 5c)
dust was generated in the wide Arabian Desert area (The Rub’ al Khali, An Nafud and
Ad Dahna) with almost same maximum intensity as on the previous day. A dust source
belt about 50 km wide along the west coast (22° N to 25° N) of the Arabian Peninsula
was also active on 18 March. On 19 March (Fig. 5d), the dust source regions were
along the eastern coast of the Persian Gulf, coastal areas of the Arabian Sea near Iran
and Pakistan, and on the southern flanks of the mountain chain along the Arabian Sea
coast. The active dust source in this region was a small intermountain valley centered
at 27.5° N, 59° E. At the center of this valley, there is a large, 1087 km\(^2\), dry salt lake,
Hamum-e-JazMurian. The majority of dust at the eastern coast of the Persian Gulf was
generated from this lake. Dust source regions along the western coast of the Arabian
Peninsula were also active. The area of dust generation was relatively compact but
maximum dust emissions exceeded 500 µg m\(^{-2}\) s\(^{-1}\) due to strong winds (Fig. 3).

The spatial distribution of daily average simulated dust deposition rates for 17, 18 and
19 March 2012 are shown in Fig. 6. There was no precipitation during the simulation
period and therefore the dominant dust removal mechanism was dry deposition. The
deposition velocity is higher for large particles therefore coarse dust tends to deposit
closer to a source than the fine ones. Figure 6 shows that the maximum dust depo-
sition exceeds 90 µg m\(^{-2}\) s\(^{-1}\), about one third of maximum dust emissions rates. On
17 March (Fig. 6a) a lot of dust was deposited in northeastern Persian Gulf relatively
far from the source regions. On 18 March the strongest dust deposition happened in
wide surroundings of the dust sources, as well as in the Persian Gulf and the Red Sea
(Fig. 6b). On 19 March (Fig. 6c), dust was deposited in the Red Sea, the Gulf of Oman
and the Arabian Sea off the Iran and Pakistan coasts.
Total dust emission/deposition are computed by integrating emission/deposition over the domain area. Figure 7a shows time series of daily total emission and deposition (in Mt day\(^{-1}\)) for the simulation period of 11 to 24 March 2012. The daily emissions \((F_s)\) and depositions \((F_d)\) are of the same order of magnitude. The maximum daily emission, \(F_s = 13.10\) Mt day\(^{-1}\), and maximum daily deposition, \(F_d = 10.06\) Mt day\(^{-1}\), occurred on 18 March because dust was dispersed and deposited over wider areas than those where dust was generated. The maximum total hourly dust emission and deposition rates of 0.85 Mt hr\(^{-1}\) and 0.52 Mt hr\(^{-1}\), respectively, occurred at about 07:00 UTC on 18 March (not shown). This is expected because in the daytime the atmosphere is unstable and the momentum transfer from the free troposphere to the surface, which enhanced the surface winds, is more efficient. Dust emissions are substantially weaker in the night when the boundary layer collapses. Zhao et al. (2010) simulated the total dust emissions using DUSTRAN and GOCART dust schemes over Northern Africa using WRF-Chem and found maximum daily dust emissions of 12 Mt day\(^{-1}\), which is similar in magnitude to the emission flux calculated in this study. Shao et al. (2003) estimated average daily total dust emissions and total dust deposition in a Northeastern Asian Dust storm that occurred in 2002. They reported the average emissions and deposition to be 11.5 and 10.8 Mt day\(^{-1}\), respectively. In our study, the average daily total dust emission and deposition were 6.7 and 5.2 Mt day\(^{-1}\), which is about half of that estimated by Shao et al. (2003). This comparison thus shows that the dust storm of 18–22 March 2012 is in the range of the most powerful dust events considered in the literature.

A portion of the dust deposited in the ocean provides nutrients to marine ecosystems and increases the ocean’s net productivity. Dust emitted from southern Iraq, Iran and the eastern Arabian Peninsula was mainly deposited in the Persian Gulf and the Arabian Sea. Dust emitted from the western coast of the Arabian Peninsula was mostly deposited in Red Sea. Time series of daily total dust deposition over the ocean areas (including the Red Sea, Persian Gulf, and parts of the Arabian Sea that are included in the domain) are plotted in Fig. 7b. Over the ocean areas, the dust load increased
in the course of the dust episode from 17 to 20 March, reaching its maximum on 20 March (not shown). This delay in time is expected, as dust was transported from land to ocean. The maximum dust deposition of 1.5 Mt day\(^{-1}\) over ocean areas also occurred on 20 March. Over the Red Sea, the maximum dust deposition of 0.23 Mt day\(^{-1}\) occurred on 19 March. The dust balance over the entire simulation period is summarized in Table 2. Over the 11 day simulation period, about 93.76 Mt of dust were emitted and about 73.04 Mt of dust were deposited over the entire study domain. The total dust deposited on the land was about 66.48 Mt and over the ocean around 6.56 Mt, out of which 1.20 Mt were deposited on the Red Sea. Shao et al. (2007) estimated the total amount of dust eroded from the Australian continent during the 22–23 October 2002 severe dust storm to be 95.8 Mt, which is comparable with our present value of 93.76 Mt during the March 2012 dust storm over the Arabian Peninsula. Zhao et al. (2006) obtained a similar figure of 120 Mt for the spring dust aerosol emissions into the atmosphere from the Asian source region.

Although the magnitude of dust deposition over the oceans is not accurately known, there is evidence that dust deposition could have a significant impact on chemical and biological processes in the oceans (Martin, 1990; Watson et al., 2000; Fan et al. 2006; Sunda and Huntsman, 1997). In the present study, we have calculated the amount of dust deposited over the ocean and particularly in the Red Sea. Aeolian deposition is especially important for the Red Sea because this sea has very little fresh water discharge from the coastal areas; what little discharge there is mostly associated with flash flood events.

Dust storms occur very frequently in Arabian Peninsula and their intensity could be quite different from year to year. To estimate the number of dust storms happening annually, we analyzed MODIS satellite images for the 2002–2013 period, which were provided under the scope of natural hazard reports in this area by NASA’s rapid response system (http://earthobservatory.nasa.gov/NaturalHazards). For this 12 year period, the number of cases when a dust plume covered more than 20% of the Middle East area reaches 237 or about 20 annually. The number of dust storms affected the Red Sea is
71 or about 5–6 annually. Then the deposition of mineral dust to the Red Sea should be about 6 Mt yr\(^{-1}\). This figure is a rough estimate. An extended analysis of the intensity and variability of the dust storm activity over the Arabian Peninsula is required to make this estimate more certain.

Figure 8a shows the simulated spatial pattern of the dust load at 10:00 UTC on 19 March. Dust plumes were seen spreading over the Gulf of Oman, the Red Sea and the southern coast of the Arabian Peninsula. The highest dust load exceeded 4.5 g m\(^{-2}\) over the Gulf of Oman and southern Saudi Arabia bordering Yemen. The image taken by Aqua/MODIS at 09:50–10:05 UTC (Fig. 8b) shows a significant dust load over the entire southern Arabian Peninsula and its coastline along the Arabian Sea as well as over the Persian Gulf. The simulated and observed dust loads in Fig. 8 are quite consistent at most locations, suggesting that the model correctly predicted the dust event. Both modeled and satellite imagery clearly show dust aerosols covering not only the land but also very large areas of the oceans.

Figure 9a–c shows a spatial distribution of AOD from WRF-Chem, MODIS and SEV-ERI retrievals, respectively. Since the number of passes of the MODIS instrument on board the Aqua satellite over the domain of interest during the time of interest is limited, two 0.55 µm retrievals at 09:50 and 10:05 UTC on 19 March were used for comparisons with the simulated AOD (0.60 µm) at 10:00 UTC. A combination of both standard-ocean and deep blue products was used to get the maximum spatial coverage over the simulated domain. The model captures the spatial distributions of AOD well. Both modeled and observed optical fields indicate a high dust plume over the Persian Gulf, Gulf of Oman, Red Sea and southern Arabian Peninsula.

Figure 9d–f compares hourly simulated and observed AODs at three AERONET sites (KAUST campus, Kuwait University and Mezaira) during the simulation period. The AERONET 15 min observations were averaged hourly to compare with modeled values. The time series match well with each other most of the time. Even though the magnitude of the simulated AOD at the KAUST campus was lower compared with that
of AERONET during 19 March, the simulations were able to reproduce the peak and
the temporal dependence quite well.

### 3.3 Vertical mixing of dust within the boundary layer and free troposphere

The characteristics of the vertical distribution of dust aerosols are important for esti-
mating the radiative effect of dust and its impact on circulation and the climate (Forster
et al., 2007; Claquin et al., 1998; Huang et al., 2009; Zhu et al., 2007). The evolution
and diurnal cycle of the atmospheric boundary layer directly affects the life cycle and
vertical redistribution of dust particles. Cuesta et al. (2009) revealed a variety of new
dynamical mechanisms that control the structure of the Saharan atmospheric boundary
layer and affect the vertical distribution of dust. Here, we will analyze those processes
for the conditions typical to the Middle East.

#### 3.3.1 Vertical structure of a dust layer

Most of dust aerosols resides in the atmospheric boundary layer. The portion of
aerosols that moves above the boundary layer to the free troposphere is subject to long-
range transport and therefore is of particular interest. N’Tchayi Mbourou et al. (1997),
Engelstaedter et al. (2006), and Chaboureau et al. (2007) reported that the diurnal
cycle of dust in the Sahel and Sahara is the result of daytime boundary-layer dry con-
vection removing the nocturnal inversion and affecting the uplift and transport of dust
in the almost 6 km deep boundary layer (Gamo, 1996; Carolina and Martin, 2012).
The Planetary Boundary Layer (PBL) can be influenced by different mechanisms as-
associated with the coastal breezes, terrain and surface properties (Warner and Sheu,
1999). The Arabian Peninsula PBL may be influenced by the breezes originating from
the Persian Gulf and the Red and Arabian Seas. The Asir mountain range in Western
Arabia runs along the Red Sea coast and is the highest in the south where its altitude
reaches 3 km. During the day, the surfaces of the mountains heat the air higher up in
the atmosphere, quicker than the ocean surface can. This leads to enhancing subsi-
The impact of dust storms on the Arabian Peninsula and the Red Sea

P. Jish Prakash et al.

Figure 10 shows the diurnal cycle of simulated vertical profiles of dust concentration, potential temperature, wind vector, and PBL height in the altitude/longitude cross-section at 21.7° N on 19 March 2012. The aerosol concentration reaches 2000 µg m⁻³. The thick dust plume stretches from 28.7° E to 70.2° E. At 06:00 UTC, heating has just started, and the PBL height nearly follows the topography. Over mountain and desert areas, the PBL height increases sharply due to rapid surface warming. The PBL height drops over the Red Sea partly because of the development of the sea breeze at 06:00–12:00 UTC. The inland convection increases and enhanced subsidence over the Red Sea suppresses the growth of PBL. Steedman and Ashour (1976) demonstrated that later in the day, the coastal breeze on the eastern shore of the Red Sea penetrates over 200 km inland over the Arabian desert. Lieman and Alpert (1992) showed that the effect of the Mediterranean sea-breeze in Israel is to suppress PBL growth as a result of a subsidence behind the breeze front. At 12:00 UTC, this process continues but much more slowly as the sea breeze front moves inland and the PBL height grows farther to the east. A well-mixed, deep boundary layer develops during the day up to the height of 3.5 km in the afternoon as seen in Fig. 10c. At night, the PBL collapses, resulting in an elevated dust-laden residual boundary layer above the surface inversion (Fig. 10d).

The temporal PBL variability is characterized by the more rapid PBL growth over the high elevations in the western Arabian Peninsula early in the heating cycle. The high PBL then spreads towards the eastern Peninsula. During the night, the nocturnal jets contribute to the dust mobilization close to the surface, while aerosol particles increasingly sediment from the residual layer after the collapse of the PBL. The peak of dust vertical mixing is observed at about 12:00 UTC (Fig. 10c) over the Asir mountains,
in southwestern Saudi Arabia, where a significant amount of dust penetrates in the free troposphere downwind of the Asir mountain ridge.

To quantify the amount of dust mixed above the boundary layer, we calculate the domain average loading below and above the diurnal maximum PBL height (Fig. 11) that approximates the top of a residual layer. Aerosols remaining in the residual layer will be again entrained in the PBL during the next diurnal cycle therefore we assume that only aerosols above the residual layer are disconnected from the surface. Because the PBL dynamics is different over land and over the sea, we did these calculations separately for the land and ocean areas within the model domain. Figure 11 shows that during the simulation period, about 15% of dust over land is in the free troposphere. Over the sea, it is often more than 50%. The dust storm increased the dust loading over land by about 30% and almost tripled it over the sea.

To assess the simulated vertical structure of the atmosphere we used RS soundings from the Jeddah’s King Abdulaziz Airport (21.7° N, 39.18° E). The model and RS profiles of the water vapor mixing ratio and potential temperature (Fig. 12a) show that the PBL height on 19 March 2012 at 00:00 and 12:00 UTC is captured well by the model. The simulated PBL height was about 3 km in the afternoon as seen in Fig. 10c, which is in a good agreement with the position of the inversion layer from Jeddah’s soundings (Fig. 12a). The potential temperature at 12:00 UTC (Fig. 12a) is almost constant between the ground and 3 km altitude, as a result of strong mixing in the PBL. The RS vapor mixing ratio profile also shows the mixing height to be around 3 km. The vertical profile of the magnitude and direction of the horizontal wind over Jeddah from RS profiles on 19 March (00:00 and 12:00 UTC) is shown in Fig. 12b. The wind direction shows a strong diurnal change in the boundary layer at about 1 km altitude. The wind vector over Jeddah was found to be east/south-east in the lowest 1 km and mostly west/north-west above 3 km. The wind speed exceeds 15 m s\(^{-1}\) near the surface and is more than 50 m s\(^{-1}\) at 12 km. The surface wind at 00:00 UTC might be enhanced by the land breeze. This is a very important factor for the transport and deposition of dust over the Red Sea during the night-time (Fig. 10a and d).

19203
3.4 The direct radiative effect of dust

Aerosols directly influence the Earth’s radiative budget by absorbing and emitting long-wave (LW) radiation (Cautenet et al., 1991; Markowicz et al., 2003; Ackerman and Chung, 1992; Haywood et al., 2005) and scattering and absorbing short-wave (SW) radiation (direct effect) (Tegen et al., 1996; Haywood and Boucher, 2000; Harrison et al., 2001; Haywood et al., 2001; Sokolik et al., 2001), and indirectly by altering cloud droplet size distribution (indirect effect) (Twomey, 1977; Albrecht, 1989). Because there is little cloudiness over deserts, the direct radiative effect of dust is of primary interest in this study, and indirect effect is not accounted for. The surface SW cooling by dust results in large reductions in latent and sensible heat fluxes from the surface to the atmosphere (Miller et al., 2004b; Shell and Somerville, 2007). This reduces the turbulent energy within the PBL and the downward transport of momentum to the surface, which suppresses the surface wind speed and dust generation (Miller et al., 2004a). In the troposphere, the absorption of both incoming and reflected solar radiation, as well as emission of thermal radiation by dust particles affect the air temperature and circulation (Alpert et al., 1998; Miller and Tegen, 1998; Sathesh et al., 2007). Depending on their physical and optical properties as well as their chemical composition, aerosols exert a cooling or warming influence on the climate (e.g., Chylek and Wong, 1995; Sokolik and Toon, 1996; Miller and Tegen, 1998; Ahn et al., 2007; Shell and Somerville, 2007; Balkanski et al., 2007). Large uncertainties in the assessment of the radiative impact of mineral dust on regional and global scales have been pointed out in a number of early and recent studies (Sokolik and Toon 1996; Tegen et al., 1996; Carlson and Benjamin, 1980; Sokolik and Golitsyn, 1993; Ackerman, 1997; Liao and Seinfeld, 1998a; Claquin et al., 1998; Stier at al., 2007).

To assess the direct radiative effect (DRE) of dust aerosols we calculate the change of total clear-sky radiative flux $\Delta F$, at the top of the atmosphere (TOA) and at the bottom of the atmosphere (BOA), in a simulation, when aerosols are present ($F_A$) and in a simulation where aerosols are absent ($F_C$). Then the DRE can be defined at BOA
and TOA as follows

\[ \Delta F_{\text{BOA}} = F_{\downarrow\text{A}}^{\downarrow\text{A}}_{\text{BOA}} - F_{\uparrow\text{A}}^{\uparrow\text{C}}_{\text{BOA}} - F_{\downarrow\text{C}}^{\downarrow\text{C}}_{\text{BOA}} + F_{\uparrow\text{A}}^{\uparrow\text{C}}_{\text{BOA}} \]  

(4)

\[ \Delta F_{\text{TOA}} = F_{\uparrow\text{C}}^{\uparrow\text{A}}_{\text{TOA}} - F_{\uparrow\text{A}}^{\uparrow\text{A}}_{\text{TOA}} \]  

(5)

where the arrows indicate the direction of the fluxes: \( \downarrow \) denotes a downward flux and \( \uparrow \) an upward flux. This convention is used for both LW and SW radiation. Definitions (Eqs. 4 and 5) imply that negative values of \( \Delta F \) at the BOA and TOA are associated with an aerosol cooling effect, while positive \( \Delta F \) is associated with warming. The DRE, as defined here, is different from a conventional instantaneous direct radiative forcing (DRF) because it includes model responses (see, e.g., Stenchikov et al., 1998). However, the clear-sky SW DRE, discussed below, should be a fairly good approximation of the clear-sky SW DRF.

3.4.1 The shortwave radiative effect

The spatial distributions of daily average clear sky SW, LW and net (SW+LW) dust DRE at BOA and TOA on 19 March are shown in Fig. 13. The SW DRE is mostly negative at the surface, reaching \(-134 \text{ W m}^{-2}\) (Fig. 13a). The domain-averaged SW DRE at BOA equals to \(-16 \text{ W m}^{-2}\) and tends to cool the surface. The daily averaged SW DRE at TOA is about \(10 \text{ W m}^{-2}\) and tends to warm the surface-atmosphere system (Fig. 13b). The warming effect of dust aerosols over land is largely explained by two factors: absorption of solar radiation by dust and high reflectance of the underlying surface. Dust absorbs and scatters the SW radiation. Both these effects reduce the downward flux at BOA but tend to compensate for each other at TOA. Therefore, the BOA cooling effect is robust, but the TOA warming is very sensitive to the dust’s single scattering albedo and surface reflectivity. Over the ocean, the SW DRE at TOA is negative due to the smaller ocean albedo. Over the ocean, the dust increases the outgoing shortwave radiation since it is a much better reflector than is the underlying dark water. This difference in reflectivity dominates the solar absorption by the dust. The negative values of SW...
DRE at TOA over the ocean were consistent with the results from Perez et al. (2006) on Mediterranean dust. Daily averaged SW BOA aerosol effect up to $-21.1 \text{ W m}^{-2}$ was reported by McFarlane et al. (2009) during the atmospheric radiation measurement mobile facility deployment in Niamey and Niger. During the winter monsoon season, Satheesh et al. (2006) reported daily averaged surface SW radiative effect from $-23.6$ to $12 \text{ W m}^{-2}$ over the Arabian Sea for 8 years from 1995 to 2002 with a maximum instantaneous value of $-51 \text{ W m}^{-2}$. During the summer monsoon season, the daily averaged surface SW radiative effect was in the range of $-24.2$ to $-13.1 \text{ W m}^{-2}$ with a “maximum” instantaneous value of $-45 \text{ W m}^{-2}$. At TOA, the SW radiative effect of dust was in the range of $-16.5$ to $-9.1 \text{ W m}^{-2}$ during the summer monsoon and $-7.3$ to $-6.0 \text{ W m}^{-2}$ during the winter monsoon. Pandithurai et al. (2008) reported the SW aerosol radiative effect at BOA to be $-39$, $-64$, $-106$ and $-99 \text{ W m}^{-2}$ for March, April, May and June 2006, respectively. The radiative effect at TOA equaled $-12$, $-4$, $+5$ and $+24 \text{ W m}^{-2}$ during dust events over New Delhi, India. Wang et al. (2010) reported instantaneous SW radiative effect at TOA in the range of $-120$ to $-140 \text{ W m}^{-2}$ during east Asian dust storms. Haywood et al. (2003) revealed an instantaneous direct SW radiative effect at BOA from a large Saharan dust plume advected off the coast of western Africa to be approximately $-130 \text{ W m}^{-2}$. The maximum instantaneous SW DRE at surface in this study was $-449 \text{ W m}^{-2}$ on 19 March 2012.

### 3.4.2 The longwave radiative effect

Figure 13c and d shows that the daily averaged LW DRE is mostly positive at TOA and BOA and is larger at the surface. Dust absorbs terrestrial radiation coming from the surface and from the atmosphere and generally reemits it at lower temperatures than the underlying surface. The presence of dust reduces the outgoing LW radiation and increases the downward TOA LW flux. The maximum daily average LW DRE at the surface is $43 \text{ W m}^{-2}$ with a domain average value of $6 \text{ W m}^{-2}$. At TOA, the maximum daily average value of LW DRE is $8.4 \text{ W m}^{-2}$ with a domain average value of $0.25 \text{ W m}^{-2}$. The LW warming can offset the SW cooling effect of dust at TOA. Zhang
and Christopher (2003) estimated the dust aerosol LW DRE over the Saharan desert from instruments onboard a satellite and showed that there is a strong warming effect of 7 W m\(^{-2}\) over the cloud-free Sahara desert regions for September 2000 and when averaged over six regions from the study area, the LW DRE ranges from −1 to 15 W m\(^{-2}\). Liao and Seinfeld (1998a) reported LW DRT ranging from 0.9 to 1.4 W m\(^{-2}\) for the dust layer using a one-dimensional column radiation model. From low dust loading under dry tropics atmospheric conditions, Sokolik et al. (1998) calculated the LW DRT at BOA in the range of 7 to 14 W m\(^{-2}\) and the LW DRT at TOA in the range of 2 to 7 W m\(^{-2}\). We found that under dust storm conditions, the LW DRE at the surface vary between 50 and 80 W m\(^{-2}\) and the LW DRE at TOA varies between 15 and 25 W m\(^{-2}\).

### 3.4.3 Net DRE

Figure 13e and f show the net (SW+LW) DRE at BOA and TOA, respectively. At the surface, the net DRE is negative in most of the region with an extreme value of −94 W m\(^{-2}\). Strong negative net DRE at BOA is seen over the region where the model and satellites show the highest dust atmospheric loading (Fig. 8). In Fig. 13 the domain average value of net DRE is −10 W m\(^{-2}\) and −4 W m\(^{-2}\) at BOA and TOA, respectively. The SW DRE exceeds the LW DRE at both BOA and TOA. Figure 13e and f shows that net DRE is cooling at the surface, while at the TOA it is warming over the land but cooling over the oceans. This pattern in net DRE agrees with that found by Yue et al. (2010), Ackerman and Chung (1992), Woodward (2001), Liao et al. (2004). Huang et al. (2009) investigated the impact of dust aerosols on the radiative energy budget over the Taklimakan desert during dust episodes in July 2006 and found that daily mean dust net DRE averaged over the case study domain to be 44.4, −41.9 and 86.3 W m\(^{-2}\) at TOA, BOA, and in the atmosphere, respectively. The sign of the net DRE at TOA could be either positive (warming) or negative (cooling), depending on several key variables, such as the surface albedo, particle size, vertical distribution of dust, its optical depth, and the imaginary part of the dust refractive index (Tegen and Lacis, 1996; Liao and
Seinfeld, 1998a, b). In this study, the imaginary part of the dust refractive index is set to 0.003 for the entire SW spectrum.

### 3.4.4 Atmospheric heating rates

The rate of change of temperature in an atmospheric layer (K day$^{-1}$) due to radiative heating/cooling is called the radiative heating/cooling rate. The simulated instantaneous dust induced perturbations (similar to definitions Eqs. (4) and (5)) of SW heating rates over Jeddah, Abu Dhabi, and Kuwait at 12:00 UTC on 19 March are shown in Fig. 14. The available temperature profiles at 12:00 UTC from RS are also shown. The heating rates vary with the altitude following the vertical distribution of the aerosols. The maximum heating rates over Kuwait (∼4.4 K day$^{-1}$) and Abu Dhabi (∼4 K day$^{-1}$) are at about 1 km altitude. The heating rates reach their maximum value at about 3 km over Jeddah (∼4.9 K day$^{-1}$). Over Mezaira (not shown), the dust-generated heating rates in the lower troposphere reach 9 K day$^{-1}$. The maximum heating over Kuwait and Abu Dhabi is at lower levels compared with that over Jeddah. This is because Kuwait and Abu Dhabi are closer to the dust source regions and hence there is more dust in the lower levels of the atmosphere.

The RS temperature profiles help to clarify the effect of aerosols on the vertical structure of the atmosphere in the PBL under storm conditions. All RS temperature profiles show strong inversions above the layers with maximum heating rates. These inversions are formed by absorption of SW radiation at the top of a dense shallow aerosol layer and further mixing above this layer. The temperature inversion is quite strong, e.g., over Jeddah at about 2.5 km altitude, it reaches 4.4 K and significantly affects the atmospheric and dust dynamics by preserving a dense aerosol layer near the surface. Reported heating rates from the Arabian dust storm are consistent with the figures in the literature for other locations. Lemaître et al. (2010) reported average dust heating rates to be between 1.5 and 4 K day$^{-1}$, depending on the altitude and location of a dust event observed over Benin and Niger, which is comparable with the maximum heating rate over Kuwait (∼4.5 K day$^{-1}$) in our study. The instantaneous heating rates they ob-
The impact of dust storms on the Arabian Peninsula and the Red Sea

P. Jish Prakash et al.

3.5 Meteorological responses to the dust DRE

A number of previous studies demonstrated the impact of dust on surface temperatures in different locations. Zhang et al. (2009) conducted a 10 year model simulation from 1997 to 2006 for the spring season to show that the net radiative impact by East Asian dust causes the surface air temperature to decrease in the range −0.5 to −1.0 K. Han et al. (2013) investigated the effect of dust on meteorology during the 19–22 March 2010 severe dust storm originating from the Gobi desert and showed significant reduct-

Figure 15 presents our simulated spatial distributions of instantaneous changes in surface air temperature and latent and sensible heat fluxes caused by the dust over land at 12:00 UTC on 19 March 2012. The surface air temperature over the majority of the study domain cools in response to the net dust radiative effect. The temperature drops up to $-6.7$ K. The change in the surface latent heat flux is quite similar to the prediction by Miller et al. (2004b). The instantaneous latent heat flux decreases over the study region with a domain average value of $-1$ W m$^{-2}$ in the presence of dust aerosols over land. Figure 15c shows the decrease in the instantaneous sensible heat flux over land due to dust aerosols with a domain average value of $-23.6$ W m$^{-2}$. The daytime cooling at the surface leads to reductions in the upward transport of heat from the surface to the atmosphere. The decreases in global and annual mean surface latent heat and sensible heat fluxes by dust aerosols have been reported previously by Yue et al. (2010), Miller et al. (2004b), Shell and Somerville (2007).

4 Summary and conclusions

A severe dust storm on 18–22 March 2012 was simulated using WRF-Chem to account for interactive dust generation and radiative effects. The model is able to simulate the major distribution features of meteorological fields in the study domain reasonably well. The synoptic systems that generated these dust events were associated with a fast-moving cold front accompanied by a high level trough. Strong wind (velocities exceeding 15 m s$^{-1}$) occurred behind the cold front, which entrained large quantities of dust particles into the atmosphere. The meteorological conditions that led to the strong winds capable of producing the severe dust event have been identified. There were several rich dust source areas in the region, activated by the passage of the front, where the major plumes of dust storm originated. The simulation suggests that the main dust
sources during the dust storm include river valleys of the lower Tigris and Euphrates in Iraq, areas from Kuwait, Iran, UAE and within the basin of the Arabian desert (which includes the Rub’ al Khali, An Nafud and Ad Dahna). Dust sources were also identified along the western coast of the Arabian Peninsula. Our simulation during the 11 day period shows that around 93.79 Mt of dust were emitted into the atmosphere, of which 73.04 Mt of the dust were deposited back to the study domain and around 22 % (i.e., 20.72 Mt) were transported outside the model domain. About 6.56 Mt of dust was deposited to the oceans within the model domain. The Red Sea received about 1.2 Mt of dust during this event. Dust particles bring nutrients to marine ecosystems; by scaling the effect of one storm to the number of dust storms observed annually over the Red Sea, we roughly estimate the annual dust deposition to be 6 Mt.

The variation in terrain elevation and surface properties produces large variability in the PBL depth over the Arabian Peninsula. The deepest PBLs developed over the higher elevations of the western Arabian Peninsula and over desert areas. The model predicted a well-mixed, deep boundary layer up to a height about 3.5 km in the afternoon. Over land, about 15 % of dust were entrained in the free troposphere, while over the seas, it might be more than 50 %. This is extremely important for understanding of dynamics and long-range transport of dust plumes.

The modeled AOD compares well with AERONET at the three sites and with satellite data. The simulation shows that mineral dust heats the lower atmosphere (1–3 km) by SW absorption with a maximum rate up to around 9 K day$^{-1}$ over Abu Dhabi at 12:00 UTC on 19 March. The lower atmosphere heating is also reflected by the temperature inversions observed in the RS temperature profiles. The meteorological responses to the dust radiative effects indicate a cooling at the surface due to the dust aerosols over the high dust concentration regions. The daily domain average values of net dust DRE at the surface and TOA under clear sky conditions at the time of the dust storm on 19 March are $-10$ W m$^{-2}$ and $-4$ W m$^{-2}$, respectively. The shortwave direct radiative effect is negative at the surface over the domain with a maximum daily average value of $-134$ W m$^{-2}$ and a domain-averaged value of $-16$ W m$^{-2}$. The daily average
shortwave radiative effect at TOA is positive ($\sim 10 \text{W m}^{-2}$) over high albedo deserts and negative over oceans due to the smaller surface albedo. The maximum daily averaged LW DRE at the surface is $43 \text{W m}^{-2}$ with a domain average value of $6 \text{W m}^{-2}$. At TOA, the maximum daily average value of LW RE is $8.4 \text{W m}^{-2}$ with a domain-averaged value of $0.25 \text{W m}^{-2}$. At the surface, the SW DRE always leads to cooling and LW DRE to heating. The dust radiative effects cause decreases in the surface air temperature with maximum up to $-6.7 \text{K}$ and a domain-averaged value of $-0.26 \text{K}$ at 12:00 UTC on 19 March. The changes in the surface air temperature are a combined effect of SW and LW dust radiative forcing. The indirect effect of mineral dust is not implemented in the model for the present study. The decrease in domain average values of latent and sensible heat flux are $-1$ and $-23.6 \text{W m}^{-2}$, respectively.

Acknowledgements. The authors would like to thank A. Al Suwailem for help in establishing a permanent AERONET site at the King Abdullah University of Science and Technology, as well as Hala Al-Jassar, a Principal Investigators of the AERONET sites at Kuwait University and Brent Holben, who maintains the Mezaira site, along with organizing the entire AERONET operations, for providing data used in this study.
