Dear Dr. Stier,

we added the changes as requested (minor revision).

- We added a more detailed description of AOD calculation and water uptake by the aerosols (Sect.2, page 3).
- We added a discussion on the temporal sampling of the satellite, mentioning the issue of subsampling of the level 3 satellite data (Sect.5.1, page 5).
- We added a discussion of the different sampling (model and satellite) for cloud-free and all-sky conditions in Sect.5.1, page 7.
- We corrected the conclusion, clearly stating that the meteorology does play a role, but this could be enhance or dampened if interactive/online dust emissions were calculated (Sect. Conclusions, page 12).

In the following pages the manuscript is presented with highlighted the changes from the previous version.

Best regards,
Andrea Pozzer (on behalf of all co-authors)
AOD trends during 2001–2010 from observations and model simulations

Abstract. The aerosol Optical Depth (AOD) trend between 2001–2010 is estimated globally and regionally from observations and results from simulations with the EMAC (ECHAM5/MESSy Atmospheric Chemistry) model. Although interannual variability is apply only to the anthropogenic and biomass burning emissions, the model is able to reproduce quantitatively the AOD trends as observed by MODIS satellite sensor, while some discrepancies are found when compared to MISR and SeaWIFS observations. Thanks to an additional simulation without any change in the emissions, it is shown that decreasing AOD trends over the US and Europe are due to decrease in the emissions, while over the Sahara Desert and the Middle East region the meteorological changes do play a major role. Over South East Asia, both meteorology and emissions changes are equally important in defining AOD trends. Additionally, decomposing the regional AOD trends into individual aerosol components reveals that the soluble components are the most dominant contributors to the total AOD, as their influence on the total AOD is enhanced by the aerosol water content.

1 Introduction

The atmosphere is a mixture of various gases and aerosols. The increase of greenhouse gases causing climate change is partially countered or enhanced by aerosol radiation modifications (the aerosol direct effect; Andreae et al., 2005). Additionally, aerosols can modify cloud properties (indirect effects; Ramanathan et al., 2001a, b). Kaufman et al. (2002) have shown that these indirect effects can also affect climate. Furthermore, depending on their composition aerosols affect the ecosystems, quality of life (cardiovascular and respiratory diseases; Lelieveld et al., 2013) and visibility. Since the late 1980s the decline in solar radiation at the Earth’s surface due to aerosol pollution (dimming) has reversed over the Northern Hemisphere (Wild et al., 2005, Wild, 2010). This change from dimming to brightening has important consequences for climate change, affecting the hydrological cycle, cloud formation processes and surface temperatures, possibly intensifying the warming trend caused by carbon dioxide (CO₂) and other greenhouse gases. Remote sensing instruments and Atmospheric Chemistry Transport Models (ACTMs) provide possibilities for improved qualitative and quantitative analysis of the global burden of atmospheric trace gases and aerosol particles. ACTMs and chemistry climate models (CCMs) are additionally used to assess the effects of future changes in aerosol (+ precursor) emissions on climate by making use of physical and chemical process descriptions in dependency of emission inventories. These emission inventories are constructed from estimates for population and economic growth to determine present gas phase and aerosol emissions as well as future emission scenarios. The emission inventories include natural and anthropogenic emissions relevant for aerosol formation, such as sulphur dioxide (SO₂), nitrogen oxides (NOₓ), black (BC) and organic (OC) carbon, ammonia (NH₃) and many more compounds.

SO₂ and BC are mainly emitted from fossil fuel (coal and petroleum) combustion. Primary sources for NOₓ are road transport and fossil fuel combustion for energy production,
and NH$_3$ is mainly emitted from agricultural activities (waste burning and fertilizers) and to a small extent by the combustion of biofuels for energy use. The amount of NH$_3$ emitted by agricultural activities is related to the type of fertilizer, meteorological conditions (wet/dry) and soil properties.

Since 1990 in Europe and in North America the emissions of aerosol precursors have dropped in response to the implementation of air quality legislation (Clean Air Act Amendments), which aims to reduce the emissions of sulfur dioxide (SO$_2$) and nitrogen oxides (NO$_x$). Despite the implementation of the 11th Five Year Plan (2006–2010) of State Environment Protection Administration (SEPA) in China, which requires power plants to implement new air pollution reduction technologies after 2006, air pollution remains a major concern in this region (Cao et al. 2009). Half of China’s SO$_2$ emissions are attributed to the burning of coal, mostly by power plants, which are to a large degree located in the eastern part of the country where the large cities are situated. Between 2001 and 2005, SO$_2$ emissions still increased by 27% (11th Five Year Plan, SEPA, March 2006). Lu et al. (2010) found an increase in SO$_2$ of 53% between 2000 and 2006 (with annual growth rate of 7.3%), with 85% in the North and 28% in the South of the country. The increase has been reduced after 2006, due to the implementation of new emission reduction technologies (i.e. desulfurization) in power plants. SO$_2$ emissions in China do not show a strong seasonal cycle (Zhang et al. 2009), because of the continual energy production for industry and domestic usage.

Previous studies by Ohmura (2009), Long et al. (2009), Norris and Wild (2009) have investigated the global and regional solar radiation budget by using observations of the Global Energy Balance Archive (Geba). Other studies have used various satellite products to investigate the impact of air pollution on the incoming solar radiation at the Earth’s surface (dimming and brightening phenomena), such as Wild et al. (2005), Wild (2010) special issue J. Geophys. Res., and references therein), Pinker et al. (2005), Hinkelman et al. (2009), Mishchenko and Geogdzhayev (2007), Remer et al. (2008), Chylek et al. (2007), Lu et al. (2010), Zhang and Reid (2010) and Kishcha et al. (2009). These studies have shown elevated AODs (decreasing incoming solar radiation at Earth’s surface) over India, East Asia, Bay of Bengal, Arabian Sea and reduced AODs (increasing incoming solar radiation) over North America and Europe.

A recent work of Hsu et al. (2012) with the SeaWIFS instrument has shown high precision in trend derivation while reporting decreasing trends over the eastern USA and Europe and increasing trends over China and India. Hsu et al. (2012) additionally have investigated the impacts of other uncertainty factors in trend estimates, e.g. retrieval algorithm deficiency and sampling bias, by comparing their results with AERONET and MODIS-Terra products. In particular the correlation analysis between large-scale meteorological events (such as El Niño Southern Oscillation and North Atlantic Oscillation) and SeaWiFS-retrieved AOD indicated strong influences of the climatic indices on Saharan dust outflow and biomass-burning activity in the tropics.

In de Meij et al. (2012a) the trends in AODs by remote sensing instruments have been investigated and linked to the changes of the aerosol (precursors) emissions in different emission inventories. They have found significant decreasing trends in observed AODs by MODIS, MISR and AERONET over Western Europe and North-East America between 2000–2009, associated with the reported negative trends in SO$_2$, NH$_3$ and NO$_x$ emissions. Positive AOD trends have been found over parts of Asia. Seasonal trends were also investigated in the same study. However, no model simulations have been performed to quantify the changes in the aerosol (precursors) emissions on aerosol and AOD trends. In the present study we relate the chemical reactions of the gas and aerosol species on the trends in the simulated AODs and compare them with observations. A recent study by Chin et al. (2014) assessed the aerosol variations and trends over a period of 30 years. They used the GOCART model on 2.5° × 2.5° horizontal resolution, with ACCMIP and RCP8.5 emissions. Two simulations were performed, one with all natural and anthropogenic emissions and the second one with no anthropogenic emissions. They have found that changes in calculated AODs are consistent with the changes in the emissions. They also have reported that for global averaged AOD values no significant trend could be identified and that analysis on regional scale is required. However, one must be careful in the conclusions as the annihilation method (i.e. removing all the anthropogenic emissions, in this case) could lead to strong effects due to the non-linearities (e.g. chemistry, aerosol microphysics) inherent in the climate system.

The objective of this work is to investigate the causes of AOD trends over different regions of the world, especially linking the trends to changes of natural/anthropogenic emissions or changes in atmospheric dynamics. To achieve this objective, two different simulations were performed: (a) anthropogenic and biomass burning emissions change realistically during the decade 2001–2010 and (b) anthropogenic and biomass burning emissions are kept constant and are equivalent to the year 2000 (i.e. with no inter-annual emission variability).

To our knowledge no work has been reported comparing the AOD trends from satellite measurements with model simulation with and without changing emissions for the decade 2001–2010 on global scale. This work clearly defines the causes of significant AOD trends for some regions.

In the next section the model used in this study is presented (Sect. 3), followed by the description of the analyzed observational dataset. In Sect. 4 the model results are compared with observations to evaluate its capability to reproduce AOD and AOD trends. The AOD trends in global and regional scale are analyzed in Sect. 5 and the causes of AOD trends for specific regions are discussed in details in Sect. 6. The conclusions are summarized in Sect. 7.
2 Model description and setup

The ECHAM/MESSy Atmospheric Chemistry (EMAC) model is a numerical chemistry and climate simulation system that includes sub-models describing tropospheric and middle atmosphere processes and their interaction with oceans, land and human influences. It uses the second version of the Modular Earth Sub-model System (MESSy2) to link multi-institutional computer codes. The core atmospheric model is the 5th generation European Centre Hamburg general circulation model (ECHAM5, Roeckner et al., 2006). For the present study we use ECHAM5 version 5.3.02 and MESSy version 2.42.

The EMAC model has been extensively evaluated for gas tracers (e.g. Pozzer et al., 2007) and for aerosols (e.g. Pringle et al., 2010; Pozzer et al., 2012; Astitha et al., 2012). The modeled AOD is calculated at 550 nm using concentrations of dust and sea salt particles, biomass burning products (black carbon and organic carbon) and anthropogenic aerosols (sulphates, nitrates, etc). The aerosol optical properties are calculated with the EMAC submodel AEROPT, which is based on the scheme by Jöckel et al. (2010) and makes use of predefined lognormal modes (i.e. the mode width σ and the mode mean radius have to be taken into account). Look-up tables with the extinction coefficient, the single scattering albedo and the asymmetry factor for the shortwave and extinction coefficient for the longwave part of the spectrum are pre-calculated with explicit radiative transfer calculations (see Pozzer et al., 2012). The considered compounds are organic carbon, black carbon, dust, sea salt, water-soluble compounds (WASO, i.e. all other water soluble inorganic ions, e.g.: NH$_4^+$, SO$_4^{2-}$, HSO$_3^-$, NO$_3^-$) and aerosol water (H$_2$O).

Aerosol water is determined by the aerosol partitioning model ISORROPIA II (Fountoukis and Nenes, 2007), which is based on a ZSR relation (Stokes and Robinson, 1966) of the simulated aerosol compounds. Furthermore, additional compounds such as organic carbon further contribute to aerosol water following the ε-approach (Petters and Kreidenweis, 2007). Aerosol water uptake is limited by a relative humidity of 95% of grid box mean relative humidity. The extinction, single scattering albedo and asymmetry factor are determined with the help of the volume weighted complex refractive index of the particles assuming an internal mixture of the individual components. This assumption partially influences the absolute values of the calculated AOD (see e.g. Klingmüller et al., 2014 and references therein). Potential impacts can be amplified absorption by soot due to multiple reflection as seen from a detailed core-shell treatment. However, as all simulations use the same assumption of internal mixing potential trends in AOD should be affected only to a minor degree.

Previous studies using the EMAC model have proven that the simulated AOD is able to capture the overall global pattern although a general underestimation is present (de Meij et al., 2012b; Pozzer et al., 2012). The seasonal cycle of AOD is in general well represented in the EMAC model simulations in most parts of the globe, especially over dust influenced regions. In heavily anthropogenic polluted regions, the modeled AOD is slightly overestimating the observations.

In this study, the Chemistry Climate Model (CCM) EMAC has been used with a T63L31 resolution, corresponding to a horizontal resolution of $\approx 1.875^\circ \times 1.875^\circ$ of the quadratic Gaussian model grid, and with 31 level vertical levels up to 10 hPa in the lower stratosphere. The model set-up used in this work was presented by Pozzer et al. (2012), and here only the differences and the central features are described.

The atmospheric chemistry is simulated with the MECCA (Module Efficiently Calculating the Chemistry of the Atmosphere) submodel by Sander et al. (2005, 2011), while the aerosol microphysics and gas-aerosol partitioning are calculated by the Global Modal-aerosol eXtension (GMXe) aerosol module (Pringle et al., 2010a). For descriptions of the emission and deposition routines we refer to Kerkweg et al. (2006a, b); Pozzer et al. (2006) and Tost et al. (2007).

As in Pozzer et al. (2012) and Pringle et al. (2010a), both dust and sea-salt emissions are offline prescribed using offline monthly emission files based on AEROCOM and do not depend on the model meteorology, hence having no multi-annual variability. However, the desert dust and sea salt aerosol concentrations that influence the AOD calculation exhibit multi-annual variability as the model description of the aerosol microphysical process (coagulation, condensation, ageing) as well as transport (advection, convection) and deposition processes are subject to meteorological variability.

The biomass burning contribution was added using the Global Fire Emissions Database (GFED version 3, van der Werf et al., 2010) with a monthly temporal resolution.

In this work we used the emissions scenarios recently developed for the ACCMIP (Atmospheric Chemistry and Climate Model Intercomparison Project, www.giss.nasa.gov/projects/accmip/) initiative, which focuses on emissions scenarios based on the Representative Concentration Pathways (RCP) (Lamarque et al., 2011; Meinshausen et al., 2011; van Vuuren et al., 2011b a, and references therein). The RCPs consist of four emission scenarios, also called RCP 2.6, 4.5, 6.0, and 8.5 representing the radiative forcing of anthropogenic activity from 2.6 to 8.5 W m$^{-2}$ in 2100, which depend on the mitigation or emission scenarios. Among them, the emission scenario RCP 8.5 is used in this study as Granier et al. (2011) showed that it is a “reasonable” choice for anthropogenic emissions after the year 2000 and for the recent past.

In this work two simulations were performed covering the year 2000–2010:

- a simulation named BASE, where the anthropogenic emissions were based on the RCP 8.5 scenario and the
biomass burning were based on the GFED emissions (e.g., with annual variability of the emissions).

- a simulation named FIXEMI, where the anthropogenic and biomass burning emissions were kept constant during all the simulation and equivalent to the year 2000 (i.e. with no interannual variability of the emissions).

Additionally, to compare the different simulations, the chemistry and the dynamics have been decoupled, such that there is no direct interaction and feedback between the atmospheric composition of the gas phase and aerosol particles with the dynamics of the atmosphere.

Accordingly, both simulations follow the same (i.e. binary identical) dynamics and meteorology, i.e. the CCM is used as a chemistry-transport model. The model dynamic has been weakly nudged (Jöckel et al., 1996; Jöckel et al., 2006) towards the analysis data of the European Centre for Medium-Range Weather Forecasts (ECMWF) operational model to represent the actual day-to-day meteorology in the troposphere, which allows a direct comparison of the simulations results with observations.

Although the simulations cover the period 2000–2010, the first year is used as spinup time, and the results of this work are based on 10 years of data (2001–2010). Additionally, the submodel SORBIT (Jöckel et al., 2010) was used to sample the AOD at the correct local time of the satellite overpass. Hence, we can neglect any influence of the diurnal cycle in the comparisons performed in the next sections.

3 Remote sensing data

In this work, observations from three different satellite sensors have been analyzed independently. Specifically, the following satellite datasets have been used:

- The Multi-angle Imaging SpectroRadiometer (MISR) instrument (Diner et al., 1998) is located onboard the Terra satellite and has been operational since February 2000. The instrument is designed to measure the solar radiation reflected by the Earth–Atmosphere system by a multiple camera configuration (four forward, one nadir and four backward at viewing angles of 70.5°, 60.0°, 45.6°, 26.1°, and 0°). Each camera measures in four different wavelengths centered at 446 nm (blue), 558 nm (green), 671 nm (red) and 866 nm (near-infrared). MISR data are acquired at 0.275 × 0.275 km² and 1.1 × 1.1 km² and aerosol products are derived at 17.6 × 17.6 km² resolution. There is a time difference of 7.5 minutes between the first and the last camera to view the exact geographic position as the satellite flies over. Each path has a swath width of 360 km with a 16-day repeat cycle. In this study, Level 3 Component Global Aerosol Product version F15 (CGAS-F15) data are used. Specifically the AOD (Aerosol Optical Depth) retrievals at 558 nm from the Level 2 product are averaged on a monthly basis and stored on a geographic grid of 0.5° × 0.5°. The validation of MISR AODs over land and ocean with AERONET (Aerosol ROBotic NETwork) data has shown that MISR retrievals are within ±0.05 or ±20% of that of AERONET (Kahn et al., 2005; 2010).

- The MODerate resolution Imaging Spectroradiometer (MODIS) sensor is also located on the Terra satellite. In contrast to MISR, the MODIS instrument has only one NADIR looking camera which measures radiances in 36 spectral bands, from 0.4µm - 14.5µm, with spatial resolutions of 250m (bands 1 - 2), 500m (bands 3 - 7) and 1000m (bands 8 - 36). Daily level 2 (MOD04) aerosol optical thickness data are produced at the spatial resolution of 10 × 10 km over land, aggregated from the original 1 km × 1 km pixel size. As the swath width is about 2330 km, the instrument has almost a daily global coverage. MODIS aerosol products are provided over land (Kaufman et al., 1997) and water surfaces (Tanré et al., 1997) with uncertainties being ±0.05 ±0.15 × AOD (Chu et al., 2002; Remer et al., 2008; Levy et al., 2010) and ±0.03 ±0.05 × AOD (Remer et al., 2002; 2005), respectively. In this paper, AOD550 data from the MODIS Level 3 (Col. 051) gridded product are used at a spatial resolution of 1° × 1°. In this work the Deep Blue algorithm products was not used, as does not present any coverage after the year 2007 in this MODIS version. Nevertheless, this algorithm allows retrieval from bright surfaces and therefore could allow a full coverage also over desert area (Sayer et al., 2013).

- The Sea-WIFS (Sea-Viewing Wide Field-of-View Sensor) instrument operated on board GeoEye’s OrbView-2 (AKA SeaStar) satellite providing data from September 1997 to December 2010. AODs at different wavelengths have been retrieved over land with the use of the Deep Blue algorithm over land (Hsu et al., 2004; 2006) and ocean using the SeaWiFS Ocean Aerosol Retrieval (SOAR) algorithm (Sayer et al., 2012) at a horizontal resolution of ~ 13.5 km. Here, SeaWiFS v004 Level 3 AOD550 gridded data are used at a spatial resolution of 1° × 1° following (Hsu et al., 2012). Validation studies of Sea-WIFS’s AOD550 with ground-based observations from AERONET and data from other satellite sensors indicate an absolute expected error of ±0.03 ±15% over ocean and ±0.05 ±20% over land at 550 nm (Sayer et al., 2012).

In addition to the satellite observations, AOD from station observations are also used in this work. The AOD observations have been obtained from the global AERosol ROBotic NETwork (AERONET Holben et al., 1998; Dubovik et al., 2000). The solar extinction measurements are used to calculate the aerosol optical depth with an accuracy of about
As shown in Fig. 1, the model reproduces the AOD observed by AERONET within a factor of two in 73.5% and 72.9% of the cases for BASE and FIXEMI, respectively. When the observed AODs are compared to the simulated AODs, it is interesting to notice that both simulations show similar linear fit: the correlation coefficients (0.57 and 0.52 for BASE and FIXEMI, respectively) and the bias (0.02 and 0.03 for BASE and FIXEMI, respectively) are very similar while the slope is almost equal to 1 for both simulations. This implies that the average global observed and calculated AODs do not vary significantly during 2001 and 2010, which corroborates the study by Chin et al. (2014). It also indicates that both simulations are in general able to reproduce the overall maxima/minima, although BASE shows slightly better agreement for correlation and slope of the linear fit. However, large differences are found in the AOD trends on a regional scale between BASE and FIXEMI and this will be further discussed in the next sections.

5 AOD trends

5.1 AOD trends – geographic patterns

In Fig. 2 the global trends observed by MODIS, MISR and SeaWIFS instruments are shown. A simple linear model has been applied to estimate the trends following the work of Weatherhead et al. (1998): $Y_t = \mu + \omega X_t + S_t + N_t$, where $Y_t$, $\mu$, $\omega$ and $X_t$ denote the monthly time series, the offset, the trend (i.e. AOD yr$^{-1}$), and the years of the time series ($X_t = t/12$ with $t$ as month), respectively. $S_t$ is a seasonal component representing the effect of the seasonal variations in the trend estimates, while $N_t$ is the residual term of the interpolation. The seasonal component we have taken into account is based on the Fourier series as proposed by Weatherhead et al. (1998, Eq. 2). Finally, no trends were calculated for location with less than 6 data points for each year between 2001 and 2010 (grey area in Fig. 2).

It is clear that trends from monthly averages level 3 data should be taken with cautions, as the monthly averages are calculated independently of the representativeness of the data sampled. The sampling of actual retrievals is highly non-uniform in space and time, even at the resolution of the products used in this work (Kahn et al. 2009). Therefore, especially in the case of location with very high frequency of cloud covered sky, the monthly averages could be calculated based on the value of few observations for each month.

As already shown by de Meij et al. (2012a), “significantly negative trends are present over Europe and North America,
Figure 2. Linear trend between 2001-2010 in $10^{-2}$ year$^{-1}$ from different satellite instrument. The grey area means that less than 6 observations for each year were present, while white area means that not retrieval is present. Locations with trend significant at the 95% level are covered with the + symbol.
whereas over South and East Asia they are mostly positive”. More specifically, both MISR and SeaWIFS show a significant decrease over North America and partially Europe, being smaller than what observed by MODIS. Strong significant increase is instead visible over Saudi Arabia for both MISR and SeaWIFS. MODIS presents a much better spatial coverage (due to the almost daily global coverage), showing a strong reduction of the AOD in the decade 2001–2010 especially over East-USA, Europe and biomass burning regions, such as Central Africa and South East Asia. South Arabia shows a significant increasing trend, although this is not shown directly by MODIS, as the standard Dark Target product does not present aerosol information over bright surfaces, such as deserts and ice. Although the Deep Blue algorithm corrected this deficiency, no data is available after the year 2007 in the version of the MODIS data used in this work; therefore no trends can be calculated from the MODIS Deep Blue dataset and this product is not used in this work.

In Fig. 3 the trends are estimated for both simulations (FIXEMI and BASE), using the same method as for the remote sensed observations. For both model simulations AOD data is sampled at the same co-located time of the observations, thanks to the submodel SORBIS (Sample along satellite ORBIT, Jöckel et al. [2010]), following the trajectories of the platform TERRA (on which MODIS and MISR instruments are on board) and OrbView-2 (with the SeaWIFS instrument on board).

The model present some discrepancies on developing region and over regions strongly influenced by biomass burning. On the other side, the sign of the trends is correctly reproduced over Norths America and Europe. The tendencies over North America and East Europe are consistent with the results of various studies based on trend analysis of satellite-retrieved AOD (e.g. Zhang and Reid [2010], Hsu et al. [2012], Yoon et al. [2014]). Since the satellite-retrieved AOD data, which have been used in most of the trend analyses, are only available under cloud-free conditions, the trend estimates based on the cloud-free AOD products can be biased due to insufficient retrievals in cloudy seasons (Yoon et al. [2014]). It must also be underlined that the simulation data is not screened for cloudy conditions, as in the satellite, but represents aerosol optical properties at all times. However, due to the relative humidity limited aerosol water uptake, a large overestimation of AOD due to the high water available for aerosol growth in cloudy conditions is not expected. Nevertheless, the cloudy conditions contribute to AOD values at the upper edge of the extinction probability density function.

Furthermore, in the model results a significant increase of AOD both in simulations BASE and FIXEMI can be observed also over the Saudi Arabian peninsula, confirmed by the observations. In addition, a strong significant increase during the decade 2001–2010 is observed over East Asia, which is however not fully corroborated by the observations. The strong decreasing trend over the Tropical/Southern Africa is not well reproduced by the model.

The model results from simulation data FIXEMI (see Fig. 3 left plots) do not show significant trends both in Europe and Northern USA, while they still do present significant trends both in Northern Africa (Sahara Desert) and South East Asia.

Discrepancies between simulation BASE and MODIS observations are clearly observed in Central Africa and South America. Nevertheless this is not corroborated by other satellite observations. On contrary, both MISR and SeaWiFS present in this region not enough observations to estimate a trend. This points out the large effect that clouds have on these regions and the possible influence on the remote sensed data. Therefore these regions will not be analyzed in detail, as observational datasets could be contaminated (Yoon et al. [2012]).

5.2 AOD regional trends

The global analysis of the AOD trends discussed in the previous section revealed regions of interest where the trends from either satellite instruments or model simulation BASE are significant and require further investigation. The 7 selected regions are Eastern United States (EUS), Western Europe (WE), Sahara desert (SD), Middle East (ME), South Asia (SA), East China (EC), and South East Asia (SEA) illustrated in Fig. 4. In addition, three more regions have been included for completeness, i.e. the North Hemisphere (NH), South Hemisphere (SH) and the whole Globe (GL).

The regional trend analysis is illustrated with scatter plots that show the comparison between the model and the satellite AOD trends (Fig. 5), each point representing the regional mean trend for the respective regions. Additionally, temporal time series both for observations and model results are included in the electronic supplement of this manuscript (doi:10.5194/acp-0-1-2015-supplement), together with trends estimated for different meteorological parameter particularly relevant.

The two model simulations (FIXEMI, BASE) are equally important to investigate the effect of decadal emission changes during 2001–2010. By comparing the two model simulations, we obtain useful information about the contribution of the emissions to the positive or negative AOD trends. The first evident conclusion is that the trends calculated from the BASE simulation (varying emissions) compare well with the satellite trends in contrast with the FIXEMI simulation (constant emissions). The correlation coefficients for the BASE-satellite trends range between 0.73 and 0.87, whereas for the FIXEMI the values are significantly lower (0.32–0.41). This result alone gives a first insight on the importance of the emissions variation of the AOD within the time period under analysis.

Focusing on the target regions, over Western Europe (WE), the AOD trends are negative by the model simulations
Figure 3. Linear trend between 2001-2010 in $10^{-2}\text{year}^{-1}$ for simulations FIXEMI and BASE (left and right column respectively) estimated using the output of the sumodel SORBIT, i.e. at the correct overpass time of the TERRA and OrbView-2 platform.

Figure 4. Regions used in this work.

and the satellite retrievals, with BASE being closer to the satellite-based trend. This is related to the influence of the anthropogenic emissions regulation imposed in Western Europe that resulted in a decrease of the atmospheric aerosol load during the decade 2001–2010 (Vestreng et al. 2007). The same applies to Eastern US (EUS) with results by simulation BASE and observed AOD having a negative trend. Nevertheless, the model overestimates the negative trend by MISR and SeaWIFS and correlates better with the MODIS retrievals.
A common pattern appears in the AOD trends for the climatically sensitive region of Middle East (ME) by the model simulations and satellite data. The positive trends calculated from the observations (the three satellite products agree) are somewhat higher than predicted by the model, which shows a slightly positive trends in both simulations (BASE and FIXEMI). This means that the variation in the anthropogenic and biomass burning emissions did not affect the AOD trend in this region, (see FIXEMI results) which is mostly affected by desert dust emissions and the dynamic factors that control dust transport and deposition. Moreover, the dust emissions were prescribed off-line in the model, i.e. independent on the wind fields and therefore independent on the meteorological conditions and without any interannual variability. Therefore, the positive trends in this region can be attributed to the decrease in the precipitation and the consequent reduc-
tion of wet scavenging of dust particles, phenomena already observed by several authors for the decade 2001–2010 (e.g. Shehadeh and Ananbeh [2013]; Philandras et al., 2011).

The latest is confirmed by the precipitation trends calculated from the model results, which is shown in Fig. 6. Clearly the region over the North Africa present a negative precipitation trends, which influences the dust deposition and its transport. Further confirmation is by the Global Precipitation Climatology Project (GPCP), which shows a strong decrease in precipitation over the Middle East during the period 2007–2010 (not shown). Finally, despite the increasing AOD trend in the region simulated by the model, this is still lower than what is estimated by the observations, due to (i) the constant emissions which do not include enough variability in the source areas (Astitha et al., 2012), and (ii) lower precipitations decrease in the model simulations than the observed one for the period 2007–2010.

The same behavior is found for the Sahara Desert (SD) region where the AOD trends remain unchanged between the two model simulations (i.e. implying a meteorological driven trend), which can be attributed to the decrease precipitation over North Africa (see Fig. 6). The trends observed by the satellites exhibit a small variation (for MODIS is slightly negative; for MISR and SeaWIFS is slightly positive) which can be attributed to the different algorithm assumptions (Kahn et al., 2007; 2009), calibration methods, and differences in the aerosol models used to construct the lookup tables in the retrieval algorithms (Abdou et al., 2005). Nevertheless, the difference in the trends is very small considering the high total AOD values in this region.

For South Asia (SA) and Eastern China (EC), the improved temporal correlation coefficients by the BASE simulations with the satellite trends shows the importance of the variability in the emissions compared to the constant emission assumption. The sign of the trend changes from negative (FIXEMI) to positive (BASE) in the two simulations, which is due to the increase emissions of the fast developing countries like China and India. The high positive trends modeled by simulation BASE over EC deviate from the satellite trends and this can be explained by the influence of desert dust aerosols that is not accurately represented by the model simulations. In fact, the MODIS trends for the entire EC region are slightly negative whereas the sign is positive by both MISR and SeaWIFS (see Fig. 5). This could be attributed to uncertainties in the AOD retrieval, e.g. sensor calibration status, retrieval accuracy, and cloud contamination. In addition, insufficient sampling not reflecting actual data population due to different sampling times, limited orbital periods, and cloud occurrence, which can be serious over polluted and cloudy areas, could be another reason for differences between the trends estimated from satellite observational datasets (see Yoon et al., 2012; 2014). Finally, the model present a significant negative trend in the in the North Hemisphere (NH) and globally (GL). These trends are also calculated for MODIS and MISR instruments for the same regions, although they results non significant. Interesting in simulation FIXEMI, no significant trend is detected for the NH, which is emissions driven, while a significant decrease is estimated for the Souther Hemisphere (SH) and globally (GL).

### 6 Effects of aerosol components in modeled AOD trends

In this section the main causes of positive/negative trends in the regions of interest are analyzed. The trends for each of the regions defined in Sect. 5.2 are decomposed by estimating the AOD trends for the different aerosol components (see Fig. 7 and Table 1): black carbon (BC), organic carbon (OC), dust (DU), aerosol water (H₂O), sea salt (SS) and water soluble compounds (WASO, i.e. all water soluble inorganic ions). Additionally, in this section, the full model output was used, so that the results are based on the full 10 years model results.

In general, aerosol water content has the largest contribution to the total AOD with the notable exception of desert area where dust dominates and therefore must be considered as the most effective extinction component in the aerosol polluted atmosphere (Gao, 1996; de Meij et al., 2012b) found that over Europe and North America the associated aerosol water contributes around 40–45% to the total AOD.

In the Eastern part of the US and in the Western part of Europe, a decrease in the WASO components (i.e. ammonium, nitrate and sulphate) is found during the decade 2001–
95% of confidence levels.

Additionally, since the aerosol water uptake efficiency and consequently the aerosol water content is decreased by the decrease presence of the WASO components, the negative AOD trends are further amplified. This highlights the fact that the observed AOD trends depend on the reduction in the emissions [van Vuuren et al., 2007; Vestreng et al., 2007, 2009], but also on the nature of the aerosols. The WASO-H$_2$O relationship was analyzed by [de Meij et al., 2012b], both for the EMAC model and the observations for different regions. They showed that, in Europe, the WASO aerosol contributes about 37% to the yearly mean and the associated aerosol water 45%, respectively. In North America the inorganic part contributes 30 to 40% to the total AOD and the associated aerosol water 40%.

Over SD and the ME the positive AOD trends are mainly caused by an increase of the natural dust. The WASO components reduce the total AOD trends in these regions due to the lower anthropogenic aerosol transport from Europe into this
region. This results in a lower aerosol water content which also reduces the total AOD trends. The increase of the natural dust component to the total AOD does not only compensate for this reduction but also exceeds it, causing, as mentioned before, an overall positive trend over the desert-covered regions. The decrease of WASO components in these regions, potentially increases the aerosol lifetime due to the missing coating effect (e.g. sulphate particles over dust) which makes the particles less susceptible for wet removal. This effect plays only a minor role here, as the AOD trends in the FIXEMI and BASE simulations are similar, implying that the trends are strongly dominated by meteorological factors, i.e. the decrease in precipitation as described in Sect. 5.2 and shown in Fig. 6.

The simulation with the BASE scenario for SA and EC (see Fig. 7) reveals a reverse situation. The highly soluble WASO components and the water content exhibit a positive AOD trend while the dust component exhibits a negative trend with the overall AOD trend being positive in these two regions. The trends of the WASO components are very similar for the two regions while the aerosol water content trend over East China is nearly three times that of South Asia. This is due to the higher relative humidity over East China with respect to South Asia (∼73% and ∼59%, respectively, for the 2001-2010 average) which causes a more effective water uptake due to the exponential relationship between water uptake and relative humidity.

Finally, over SEA, the negative AOD trends are due to the decrease of all aerosol components (see Table 1). Dust and sea salt, however, show a significant decrease, implying trends driven by meteorological conditions. In particular, this trend is enhanced by the decrease of the aerosol water content (also significant), which is mostly due to the decrease of the highly soluble sea salt. Nevertheless, the BC/OC decrease (due to biomass burning decrease in the region during the 2001–2010 decade) enhances the negative trends by ≈0.4 × 10⁻³ yr⁻¹. Therefore the total trend in this region (∼2.75 × 10⁻³ yr⁻¹) is a combination of a meteorological effect and a decrease of the biomass burning emissions. However, it is unclear what meteorological parameter is driving such trend in the region. In fact, the only significant detectable trends in the simulation is a decrease of wind speed at the surface (see [doi:10.5194/acp-0-1-2015-supplement]), which could possibly decreases the transport of Sea Salt from the open ocean to this region and consequently the water contribution to the AOD, being Sea Salt highly hydrophilic.

Finally, the NH presents a decreasing significant trend (−0.798 ± 0.247 10⁻³ yr⁻¹) 70% of which caused by the water uptake decrease. Interesting, on a global scale (GL, see Fig. 7 and Table 1) the same proportion is kept, with water contributing by 73% to the total (significant) AOD decrease.

7 Conclusions

In this work, the AOD was simulated for a period of 10 years (2001–2010) with the EMAC Chemistry General Circulation Model. AODs from AERONET stations were used to evaluate the model results prior to the calculation of the global and regional AOD trends. Satellite retrievals from MODIS, SeaWiFS and MISR have subsequently been used to estimate the AOD trends and compare them with the simulated results. The trends in the aerosol extinction are qualitatively reproduced over North America, East Europe North Africa and Middle East, while some discrepancies are found over other regions. Seven regions of interest are selected to conduct a regional analysis, based on the strength of the signal from both model and satellite AOD trends.

The main objective of this work is to identify the causes of the decadal AOD trends for the designated regions of interest by decomposing the AOD trends into its aerosol components trends. Therefore, two simulations have been performed to address the research objective; one with changing and one with constant emissions, using identical same atmospheric dynamics. The differences between the two simulations show that the observed AOD increases in the model over Middle East and North Africa are caused mostly due to meteorological effects. A strong increase in the dust component of the AOD is found in both simulations for those regions. However, these results are obtained without any online dust emissions calculation, but rather with fixed prescribed monthly emissions. Therefore this AOD increase could be enhanced or dampened if interactive dust emissions were calculated. Over Eastern US and Western Europe, significant decreasing trends are deduced from the model simulation only when realistic, decreasing emissions in the decade 2001–2010 are included. This indicates the strong influence of anthropogenic emissions on aerosol load and the related AOD. Consequently, it can be confirmed that in Eastern US and Western Europe, the AOD decrease is purely driven by emissions reduction policies.

For South Asia and East China, the AOD trend is positive both from model results and satellite observations. The differences between the two model simulations identify that the AOD is increasing due to a combination of changes in the anthropogenic emissions and the meteorological conditions in the denoted areas. Finally, for South-East Asia, the decreasing trends are due to the decrease in the biomass burning emissions and the meteorological conditions, where the purely meteorological trend contributes approximately 50% of the total AOD trend. The role of natural aerosols (i.e. desert dust) has proven to be significant for Middle East and North Africa and non-negligible for China and South Asia. Future work in this area would include the online production of dust and sea salt emissions during the simulation time in order to identify the changes in the aerosol water content due to meteorology in the dust component AOD by introducing emission variability for both sea salt and dust in the model. Even though the existing param-
eterizations for emissions of natural species hide a number of uncertainties, the comparison with the AOD trends that results from off-line prescribed inventories will identify the relative importance of the two methods (e.g. if the AOD trend from dust changes significantly). Finally, the use of newly developed dataset of remote sensed observations (such as the MODIS collection 6), could improve the reliability and agreements of these dataset and decrease artificial trends due to calibration (Lyapustin et al., 2014).
