Author’s responses to reviewer comments and changes in the manuscript are provided here. Additional changes made by the author’s are also outlined. A marked up manuscript, showing the changes main to the main text and updated tables and figures, is provided at the end of this document.

Response to Anonymous Referee #2:

General comments

- CI2 is constrained to measurements but bromine is not. This makes it difficult to interpret the model results. I would prefer to either constrain all halogens or none.
  o We originally did not constrain the model to Br2 due to a period of missing data during 29 and 30 March. However, we agree that constraining to the Br2 measurements, as is done for CI2, strengthens this analysis, therefore we adjusted the model to read-in the Br2 measurements, as well. For the missing period, we used an average diurnal Br2 cycle from previous days, and then adjusted the Br2 slightly so that modeled BrO is in line with the observations. An explanation of this has been added to the text on page 15 of the revised manuscript.

- The authors say they could not reproduce the day-to-day variability in Br2 from only the heterogeneous chemistry. An additional prescribed bromine flux was necessary to estimate Br2 and BrO observations. Why then is heterogeneous chemistry included in the model at all? Wouldn’t it be more straightforward to prescribe gas-phase bromine concentrations directly? What additional value has the heterogeneous chemistry in the model?

  The model was constructed to include heterogeneous reactions to investigate whether or not we could achieve the amount of bromine required in the gas phase to agree with observations given known aqueous phase reaction rates and measurements of halide ions in Barrow snow. Since we are constraining the model to Br2 and CI2, the flux of these species from this chemistry is irrelevant. The heterogeneous chemistry does impact the deposition of soluble species (e.g. HOBr, HBr, HCl), and thus their loss from the gas phase through the mass transfer reactions. BrCl is also not prescribed in the model, and the aqueous phase chemistry does contribute to the production of this molecule.

- It is mentioned that the variability seen in the ambient NOx data is not represented or tested. I wonder if the model results are still useful then. NOx has a large impact on halogen chemistry.
  o We definitely agree that NOx has a large impact on the chemistry we are simulating here. Therefore, we have chosen to constrain the model to NO and NO2 observations, as well, using 10-minute averages of the data. We believe that this change greatly strengthens the analysis as it reflects the NOx variability. We have left the discussion regarding the NOx sensitivity of the halogen chemistry limited in this manuscript, however, as this topic is addressed in detail in another paper currently in ACPD: Custard et al., The NOx dependence of bromine chemistry in the Arctic atmospheric boundary layer, Atmos. Chem. Phys. Discuss., 15, 8329-8360, 2015.
To increase iodine, the model switches from 1 ppt IO to 0.5 ppt I2. Why is a different molecule chosen now? I think simply increasing IO by a certain factor would be more useful.

We used 1 ppt IO and 0.5 ppt I2 because these correspond to two of the very few iodine observations in the Arctic (1 ppt IO by DOAS by Honninger and 0.5 ppt I2 by CIMS by the Shepson group recently). To clarify this, we have changed the terminology to “Low Iodine” and “High Iodine” to distinguish the different modeling scenarios. Figure 3 has now been changed to show the IO levels for the Low Iodine and High Iodine scenarios, and the corresponding I2 levels (0.025 pptv and 0.5 pptv, respectively) are discussed in the text on Page 21 of the revised manuscript.

Specific comments

• Page 28687: “We simulated a 7 day period during late March that included a full ozone depletion event lasting 3 days and subsequent ozone recovery”. The recovery of ozone is mentioned here in the abstract but I cannot find any information in the text how it was modeled.
  o The model was constrained to O3 observations across the 7-day period. This is stated on Page 28694, Lines 9-14 of the original manuscript: "It is important to note that, because our objective was to investigate the halogen chemistry occurring during this time period rather than to attempt to simulate an ozone depletion event, we have constrained our model with the observed ozone mole ratios in order to fully study the fast chemical interactions occurring under these observed conditions, which are a strong function of O3.”

• Page 28691: “Most recently, I2 at levels ≤ 0.5 pptv have been observed by our research group at Barrow, Alaska”. Can you please add a reference to this statement?
  o This reference is currently in submission with the Journal of Geophysical Research (A. R. W. Raso et al., Active Molecular Iodine Snowpack Photochemistry in the Arctic), and we have added this to the manuscript.

• Page 28691: “Halogen atoms can react with formaldehyde” This statement is certainly true for Cl and Br but is the reaction of iodine atoms with formaldehyde significant?
  o Thank you for pointing this out. Reaction with I is not in the model, therefore, we have clarified this statement to read “Bromine and chlorine atoms can react with formaldehyde.”

• Page 28692: “Halogen chemistry also generally increases the Leighton ratio ([NO2]/[NO])”. It should also be discussed here that XO reacts with NO2 and forms XNO3. This decreases the Leighton ratio.
  o Yes, thank you for pointing this out. We have added a sentence, on pages 7-8 of the revised manuscript, pointing out this reaction, as well as X + NO2, and have included these reactions as R17 and R18. However, the net effect of halogen chemistry is an increase in the Leighton ratio.

• Page 28695: What is the difference between J coefficients and J values? If they are identical, why are two different names used?
  o The terms “J coefficient” and “J value” were used interchangeably in the text. We have changed all instances to “J coefficient” to be consistent throughout.
• Page 28698/99: “Because the I2 flux is constant during the ODE, while Br2, and especially Cl2 are decreased, iodine becomes more dominant for reaction with O3 and IO increases.” I understand that the relative importance of iodine increases under these conditions but why should the absolute values of IO increase when ozone is depleted?
  o IO is being produced in the process of ozone depletion, and even though O3 is low, most I atoms produced react with O3.

• Page 28702: “it is generally accepted that bromine is the dominant reactant leading to ozone destruction. However, this has not been quantified, nor has this been investigated for varying chemical conditions.” I find this statement too bold. There are many studies which look at this question. I agree, though, that there are still many open questions left.
  o The intent behind this statement was to say that this chemistry has not been examined in detail during very specific chemical conditions, because, prior to OASIS, high time resolution measurements of this large of a suite of species had not been done simultaneously. It was not our intention to imply that no studies have investigated bromine chemistry. We have reworded this statement on page 20 of the revision to read: “However, this has not been quantified over highly variable chemical conditions, since prior to OASIS, simultaneous high-time resolution measurements of such a large suite of chemical species had not been performed.”

• Page 28716: “From our analyses it is clear that the interactions between bromine, chlorine, and iodine are very complex” I think this was already clear before this study started.
  o That is definitely correct, and this was merely used as a transitional statement. We have removed “From our analyses” from this sentence.

• Page 28717: “While chlorine is clearly not necessary to cause ozone depletion, it can significantly impact the rate of ozone depletion.” According to Table 8, chlorine increases the ozone depletion rate from 5.2 to 5.3 ppb/h. I would not call this significant.
  o Thank you, we agree with this assessment. However, after implementing the other changes to the model (e.g., prescribing Br2 and NOx), the increase in the ozone depletion caused by Cl is now from 1.85 to 2.94 ppb/hr. Nevertheless, we have changed this text to read: “While chlorine is clearly not necessary to cause ozone depletion, it can impact the rate of ozone depletion through synergistic effects of cross-reactions that enhance Br atom recycling. Moreover, the presence of elevated chlorine levels can impact important Arctic chemical budgets, including HOx, NOx, and VOCs, with implications for the oxidative capacity of the PBL.” Thus, we have removed the comparative word “significantly”, and added that Cl chem impacts VOCs, HOx, and NOx chemistry.

• Page 287: “In light of these new data, it is crucial that future Arctic modeling studies take into account the activity of chlorine.” Indeed, it is crucial to include chlorine chemistry in the models. However, it is important for hydrocarbons, not for ozone.
  o This is an important point. Given the new numbers for Cl contribution to the O3 depletion rate (noted above), and the additional sentence we added pointing out that Cl chemistry is important for VOCs, HOx, and NOx (also noted above), we have opted to leave this sentence as is.

• Page 28731: The reference Vogt 1999 is incomplete.
  o This has been repaired.
• Page 28740: Why are the heterogeneous reactions of XNO3 not considered here?
  o We recognize that the heterogeneous reaction scheme for nitrogen oxide compounds is not complete in this manuscript (again this is the subject of Custard et al. ACPD, 2015), however, the heterogeneous reactions of BrNO3 to produce Br2 are not a factor here as the model is now constrained to Br2. This chemistry may have some degree of impact on BrCl, however, the modeled BrCl is within the range of our sparse observations from the campaign, which indicated that BrCl is a relatively unimportant source of Br or Cl. Because our focus here is on the relative impacts of the different halogen radicals, it was important, and a new opportunity, to have accurate relative production rates, as constrained by observations of Br2.

• Page 28750: In Fig. 4, it seems that the values for Br, Cl, and I add up to 100 %. This is different from the data in Table 7 which is calculated based on equation (4). Why is equation (4) not used for Fig. 4?
  o The reason for the discrepancy is two-fold: one is that the figure is averaged over 3 days, whereas the table is calculated for just midday of one particular day (previously 25 March, now 29 March). Secondly, you are correct that figure is calculated as the fraction by Br, Cl, or I over the sum of the O3 loss terms, whereas the table used the entire modeled delta O3 (not just the sum of the terms). To make these consistent, and because O3 production terms also factor into the delta O3 (which impact this calculation), we have changed the table to also use the sum of the O3 loss terms, and have updated equation 4 to reflect this change.

• Page 28750: Another question I have are about the nighttime values in Fig. 4. What is their meaning? At night, the concentrations of ozone-destroying Cl and Br atoms are close to zero.
  o In Figure 4 (now Figure 5), we plot only hours 6 through 21 of the day (from when the sun first rises to when it last sets) and exclude the nighttime values. Even so, you are correct that the absolute values of halogen atoms are very low, however, here we are plotting the relative importance rather than absolute levels.

Response to Anonymous Referee #3

• The paper examines interactions and contributions of halogens (bromine, chlorine, and iodine) to ozone depletion at Barrow using a 0D photochemical model. The model is run during an ODE event during which observations of O3, VOCs and OVOCs, CO, Cl2, Br2, HOBr, BrO, ClO, NO2, OH and HO2 were available. In general the paper is well written and organized. I report some comments and suggestions.

• It takes me a certain time to realize which species was measured and how they were used with respect to model simulations. I think since the paper mainly deals with model simulations it would be great to first present in a short section the measurements (Fig. 1 and 2, and Table 5) and better explain why the model is constrained by measurements for Cl2 but not for Br species.
Thank you for this suggestion and we agree that it would be useful to better explain the measurements done during the campaign. We have added now Section 2.1 Field Campaign and Measurements Description, that gives a brief overview of the OASIS campaign itself, the measurement site, and a brief description of the in situ measurements that went into driving the model. Also, and following the suggestions of Referee #2, we have adjusted the model to now be constrained to Br$_2$, and have updated the text to reflect this change.

Also, page 28698, it is stated that “The fluxes of HONO, NO2 and I2 were scaled to JNO2 since HONO and NOx (and likely I2) are photochemically produced (Honrath et al., 1999; Zhou et al., 2001; Saiz-Lopez et al., 2011). All fluxes, with the exception of I2, were adjusted in order to agree with observed gas-phase concentrations of the respective species. However HONO is not listed in Table 5? I was unable to get typical values of the encountered mixing ratio of HONO in the paper? Also concerning HONO, you only consider a flux of HONO and not the recently pointed out production of HONO from reaction of the HO2 (H2O) complex with NO2 (Lin et al., 2014) ? Li, X. et al.: Missing Gas-Phase Source of HONO Inferred from Zeppelin Measurements in the Troposphere, Science, 344, 292–296, 2014.

Thank you for bringing this recent paper to our attention. While it may certainly be the case that this proposed mechanism can be important for gas phase HONO formation, it appears from reading this paper that more work is needed before it can be added to a model mechanism. Currently, the rate constant for reaction and the product yield are both unknown. Because of this, we have not added this reaction to the model, but we have added an acknowledgement and reference to this paper in the text, and have added new Figure 3, which shows the modeled vs. observed HONO for simulations performed with and without the additional flux.

On Figure 1 and 2, a double scale showing both concentrations and mixing ratio would be useful (for readers more familiar to compare values of mixing ratios).

This is good suggestion, thank you. We have left Figure 1 just with mixing ratios, as this is how the data was reported and is the more common metric used, however, in Figure 2 and all other figures that used molecule·cm$^{-3}$, we have included a second axis for mixing ratio.

Page 28697, second paragraph: I am not sure if the discussion of estimated Br2 emission from the snow is very useful here since it is very clear that the estimations are based on numerous assumptions including the values assumed for the quasi liquid layer. If you decide to report this discussion it would be important for the reader to report assumed bulk concentrations of Cl- and Br- in snow since even after 30 minutes of reading the paper from Krnavek et al. (2011) I was unable to guess the values that you have used.

We have added in the text that we use the snow over multi-year ice values for the model, on page 15 of the revised manuscript.
Response to Comment/Suggestion from Anatoli Bogdan

It is believed that PSCs are formed by freezing aqueous aerosol drops which contain acids up to 30 wt %. Since ice is highly intolerant to impurities, after freezing mixed phase particles are formed: an ice core enveloped with a freeze-concentrated solution (FCS). Since the rate of heterogeneous reactions depends on the surface phase state of PSC particles, there will be difference whether solid pure ice or mixed-phase PSC particles are considered in model(s). If the current models cannot take into account this important physical process (phase separation during freezing), it would be a good thing to mention it in introduction of the paper. Also it would be a good thing to give some reasoning why it is not considered in the model used by the authors. About mixed-phase PSC particles the authors can find in a paper Bogdan, A., Molina, M. J., Tenhu, H., Mayer, E. & Loerting, T. 2010.“Formation of mixed-phase particles during the freezing of polar stratospheric ice clouds” Nature Chem., 2, 197-201.

While we thank you for this suggestion, and we recognize the importance of this process for the chemistry of PSCs, this analysis deals exclusively with near surface boundary layer chemistry and primarily gas-phase reactions. Polar stratospheric clouds are not relevant to the aim and scope of this work.

Additional Comments from Authors:

In addition to the changes suggested by the reviewers that have much improved this manuscript, we have also implemented the follow changes:

1. Since we have now constrained the model to observed Br2 and NOx, original Table 6 has been removed.
2. Original Table 7 is now new Table 6. New Table 6 has been expanded to include the sum of O3 production terms and the sum of O3 loss terms for each simulation.
3. New Table 7 has been added to show the fractional depletion of O3 by Br and Cl for a series of simulations with varying Cl2.
4. Table 10 has been added to show the partitioning of the HO2/OH, BrO/Br, ClO/Cl, and IO/I ratios for a variety of different modeling scenarios to aid in the discussion presented in Section 3.4.
5. A pie chart inset has been added to original Figure 6, now new Figure 7, for better visualization of the fractional importance of each reaction partner.
6. New Figure 8 has been added to expand the discussion of the importance of VOCs as reaction partners for Cl atoms, which was pointed out by Anonymous Referee #2.
7. Original Figure 7 and Original Figure 9 were combined into one figure, new Figure 9.
8. Original Figure 8 was moved to new Figure 10, and pie chart insets were added for better visualization of the fractional importance of HOx source for both depleted and background ozone days.
Interactions of bromine, chlorine, and iodine photochemistry during ozone depletions in Barrow, Alaska

Abstract. The springtime depletion of tropospheric ozone in the Arctic is known to be caused by active halogen photochemistry resulting from halogen atom precursors emitted from snow, ice, or aerosol surfaces. The role of bromine in driving ozone depletion events (ODEs) has been
generally accepted, but much less is known about the role of chlorine radicals in ozone depletion chemistry. While the potential impact of iodine in the High Arctic is more uncertain, there have been indications of active iodine chemistry through observed enhancements in filterable iodide, probable detection of tropospheric IO, and recently, observation of snowpack photochemical production of I₂. Despite decades of research, significant uncertainty remains regarding the chemical mechanisms associated with the bromine-catalyzed depletion of ozone, as well as the complex interactions that occur in the polar boundary layer due to halogen chemistry. To investigate this, we developed a zero-dimensional photochemical model, constrained with measurements from the 2009 OASIS field campaign in Barrow, Alaska. We simulated a 7-day period during late March that included a full ozone depletion event lasting 3 days and subsequent ozone recovery to study the interactions of halogen radicals under these different conditions. In addition, the effects of iodine added to our base model were investigated. While bromine atoms were primarily responsible for ODEs, chlorine and iodine were found to enhance the depletion rates and iodine was found to be more efficient per atom at depleting ozone than Br. The interaction between chlorine and bromine is complex, as the presence of chlorine can increase the recycling and production of Br atoms, while also increasing reactive bromine sinks under certain conditions. Chlorine chemistry was also found to have significant impacts on both HO₂ and RO₂, with organic compounds serving as the primary reaction partner for Cl atoms. The results of this work highlight the need for future studies on the production mechanisms of Br₂ and Cl₂, as well as on the potential impact of iodine in the High Arctic.
1 Introduction

The importance of halogen chemistry in Polar Regions has been well established over the past few decades since the observation of near-surface boundary layer ozone depletion in the 1980’s (Oltmans and Komhyr, 1986; Barrie et al., 1988; Bottenheim et al., 1990). Since that time, ozone depletion events (ODEs) have been observed at numerous Arctic and Antarctic locations (e.g., (Bottenheim et al., 2002; Saiz-Lopez et al., 2007b; Simpson et al., 2007; Oltmans et al., 2012)). ODEs are characterized by episodic depletions of tropospheric ozone from background mole ratios of approximately 35 parts per billion by volume (ppbv) to less than 2 ppbv over periods of hours to days. These events are known to occur following the onset of polar sunrise, and continue through polar spring, when temperatures are low and snow and sea ice are still present, with a stable atmospheric boundary layer (Simpson et al., 2007).

Photochemical reactions involving halogen radicals, notably bromine, are thought to be the primary cause of ODEs (see Simpson et al. (2007) for a review). The chemical destruction of $O_3$ by Br can be described by reactions R1 – R3 (Platt and Hönninger, 2003).

\[ \text{Br}_2 + h\nu \rightarrow 2\text{Br} \quad \text{(R1)} \]
\[ \text{Br} + O_3 \rightarrow \text{BrO} + O_2 \quad \text{(R2)} \]
\[ \text{BrO} + \text{BrO} \rightarrow \text{Br}_2 + O_2 \quad \text{(R3)} \]

The efficiency of Br atoms in destroying ozone is due primarily to its relative lack of atmospheric sinks, and thus its relatively high gas-phase concentration, as well as its ability to recycle and regenerate from temporary sink species. Bromine atoms do not react appreciably with methane or other saturated hydrocarbons; thus, its primary sinks (other than $O_3$) consist of a few oxygenated volatile organic compounds (OVOCs) (e.g., aldehydes) or unsaturated hydrocarbons, which result in production of HBr, and HO$_x$ species. BrO can react to regenerate
a Br atom (via reaction R3, followed by R1), or react with HO₂ to produce HOBr, which can in turn lead to the production of two Br atoms through a heterogeneous reaction mechanism termed the bromine explosion (Tang and McConnell, 1996; Vogt et al., 1996), as shown below.

\[
\begin{align*}
\text{BrO} + \text{HO}_2 & \rightarrow \text{HOBr} + \text{O}_2 \\
\text{HOBr}(g) & \rightarrow \text{HOBr}(aq) \\
\text{HOBr}(aq) + \cdot \text{Br}^−(aq) + \cdot \text{H}^+(aq) & \rightarrow \text{Br}_2(aq) + \text{H}_2\text{O} \\
\text{Br}_2(aq) & \rightarrow \text{Br}_2(g)
\end{align*}
\]

(R4) (R5) (R6) (R7)

The production of Br₂ can thus be sustained on saline snow, ice, and aerosol surfaces, as has been confirmed in laboratory studies that have observed production of Br₂ and BrCl from aqueous and frozen halide surfaces exposed to HOBr (Fickert et al., 1999; Adams et al., 2002; Huff and Abbatt, 2002), as well as in a recent field-based study that observed Br₂ production from sunlit snowpacks in Barrow, Alaska (Pratt et al., 2013).

The presence of chlorine chemistry in the Arctic has been well recognized through indirect measurements of hydrocarbons (Jobson et al., 1994; Ariya et al., 1998; Keil and Shepson, 2006; Tackett et al., 2007) and through detection of photolyzable chlorine species (defined as \([\text{Cl}_2 + \text{HOCl}]\)) (Impey et al., 1997); however, few direct measurements of chlorine species have been reported. The only currently reported measurements of ClO were by Tuckermann et al. (1997), who detected ClO at Spitsbergen. Unlike bromine, chlorine radicals efficiently oxidize a wide-range of pollutants and volatile organic compounds (VOCs), often with faster rate coefficients than analogous reactions by the hydroxyl radical (OH); thus, chlorine has an abundance of atmospheric sinks. Estimates of polar region Cl atom concentrations using hydrocarbon decay methods are typically in the range of \(10^4 – 10^5\) molecules·cm⁻³ (Jobson et al.,
1994; Ariya et al., 1998; Boudries and Bottenheim, 2000), approximately 2-3 orders of magnitude lower than analogous estimates of Br (Cavender et al., 2008).

Like bromine, chlorine can react directly with $O_3$, generating a ClO radical via Reaction R8. The presence of ClO may also promote bromine-induced depletion of $O_3$ through the fast cross-reaction of BrO and ClO that serves to regenerate Br atoms (Reaction R9) (Le Bras and Platt, 1995; Platt and Hönninger, 2003).

$$\text{Cl} + \text{O}_3 \rightarrow \text{ClO} + \text{O}_2 \quad \text{(R8)}$$

$$\text{BrO} + \text{ClO} \rightarrow \text{Br} + \text{OCIO} \text{ (or Cl} + \text{O}_2) \quad \text{(R9)}$$

Due to analytical challenges, few tropospheric observations of $\text{Cl}_2$ and ClO exist, therefore the role of Cl in ozone depletion events remains uncertain and has been much debated. Typical estimated Cl concentrations are likely too low for chlorine to be a significant direct contributor to ozone depletion. However, elevated levels of $\text{Cl}_2$ (exceeding 100 pptv) were recently observed during the Ocean-Atmosphere-Sea Ice-Snowpack (OASIS) 2009 campaign in Barrow, Alaska using chemical ionization mass spectrometry (CIMS) (Liao et al., 2014). The impact that such high levels of Cl$_2$ could have on ODEs or on the oxidation chemistry of the Arctic troposphere has not been fully investigated. Although Reaction (R9) can act to enhance the rate of ozone depletion by propagating the Br cycle, formaldehyde, propanal, acetaldehyde and $\text{HO}_2$ are all produced as by-products of VOC oxidation by Cl and are efficient sinks for Br or BrO radicals (Shepson et al., 1996; Sumner et al., 2002). Therefore, it is likely that the interaction between chlorine and bromine is complex. Modeling studies simulating ozone depletion events often use BrCl as the primary source of Cl atoms (Calvert and Lindberg, 2003; Piot and Von Glasow, 2008), and thus [Cl] is quite low and often insignificant. Few have added
significant Cl\(_2\) sources (Sander et al., 1997; Piot and von Glasow, 2009). As a result, our understanding of chlorine chemistry in the Arctic is limited.

Iodine may play a significant role in the photochemical reactions leading to ODEs (Sander et al., 1997; Saiz-Lopez et al., 2007b; Saiz-Lopez et al., 2008; Mahajan et al., 2010) based on recent ground-based and satellite observations of IO of up to 20 – 50 pptv over snow and ice-covered surfaces in coastal Antarctica (Saiz-Lopez et al., 2007a, 2007b; Schönhardt et al., 2008; Frieß et al., 2010). Although IO has been routinely detected at high levels in Antarctica, there has been no successful set of IO measurements in the High Arctic to date. However, this is possibly due to limitations of current analytical methods rather than an absolute absence of iodine chemistry. Several studies in the Arctic have indicated the presence of iodine species through measurements of springtime peaks in filterable iodine (Sturges and Barrie, 1988; Barrie et al., 1994; Sirois and Barrie, 1999) and total gaseous iodine (Martinez et al., 1999). Hönninger (2002) was able to detect IO during only one instance above the detection limit at Alert in 2000 using long path DOAS, corresponding to 0.7 pptv of IO if averaged over the 10 km light path. Mahajan et al. (2010) also observed up to 3.4 pptv IO at the sub-Arctic location of Kujjuarapik, Canada. Most recently, I\(_2\) at levels \(\leq 0.5\) pptv have been observed by our research group at Barrow, Alaska by CIMS, lending direct evidence supporting the presence of at least low levels of iodine chemistry in the Arctic (Raso et al., 2015).

Due to the lack of iodine observations in the Arctic, models often omit iodine chemistry when simulating ODEs. However, this may significantly underestimate the rate of ozone depletion because the BrO + IO cross-reaction (Reaction R10), which propagates the Br chain, has a rate constant that is approximately 2 orders of magnitude faster than the BrO self-reaction.

\[ \text{BrO} + \text{IO} \rightarrow \text{Br} + \text{I} + \text{O}_2 \]  

(R10)
Indeed, previous modeling studies have found that significant enhancements in ozone depletion result from even small concentrations of reactive iodine (Calvert and Lindberg, 2004a; Saiz-Lopez et al., 2008; Mahajan et al., 2010).

Besides causing tropospheric ODEs, halogens can also impact HO\textsubscript{x} and NO\textsubscript{x} chemical cycles. The presence of reactive halogen species has the general effect of shifting the [HO\textsubscript{2}]/[OH] ratio towards OH (Platt and Hönninger, 2003; Thomas et al., 2012), primarily through reactions R11 and R12, where X can be Br, Cl, or I.

\[
\begin{align*}
\text{XO} + \text{HO}_2 & \rightarrow \text{HOX} + \text{O}_2 \\
\text{HOX} + h\nu & \rightarrow \text{X} + \text{OH}
\end{align*}
\]

(Bromine and chlorine) atoms can react with formaldehyde (and higher molecular-weight aldehydes), leading to production of hydrogen halides and HO\textsubscript{x}. Alternatively, halogen atom reaction with HO\textsubscript{2} can act as a HO\textsubscript{x} sink. The inclusion of chlorine chemistry further impacts the HO\textsubscript{x} chemistry because RO\textsubscript{2}, HO\textsubscript{2} and carbonyl compounds are produced as side-products of Cl oxidation of VOCs (e.g., Reactions 13 – 15).

\[
\begin{align*}
\text{Cl} + \text{CH}_4 (+ \text{O}_2) & \rightarrow \text{CH}_3\text{OO}\cdot + \text{HCl} \\
\text{CH}_3\text{OO}\cdot + \text{NO} & \rightarrow \text{CH}_3\text{O} + \text{NO}_2 \\
\text{CH}_3\text{O} + \text{O}_2 & \rightarrow \text{HCHO} + \text{HO}_2
\end{align*}
\]

(Bromine and chlorine) can also react with NO\textsubscript{2} to form XNO\textsubscript{2} or XONO\textsubscript{2}, respectively (R17 – R18), however, the net effect of halogen chemistry is an increase in the [NO\textsubscript{2}]/[NO] ratio.

\[
\begin{align*}
\text{XO} + \text{NO} & \rightarrow \text{X} + \text{NO}_2 \\
\text{X} + \text{NO}_2 & \rightarrow \text{XNO}_2
\end{align*}
\]
In this work, we utilize a zero-dimensional model to further investigate the chemical interactions occurring in the Arctic related to the chemistry of halogen radicals and the interactions between bromine, chlorine, and iodine. The OASIS 2009 campaign, conducted in March and April in Barrow, Alaska, provides a valuable opportunity to perform a unique study of halogen chemistry using direct observations of a variety of atmospheric species, including HO\textsubscript{x} and XO\textsubscript{x} radicals, and molecular halogens, with high time resolution measured concurrently and from a single location. During OASIS, measurements of a large suite of saturated, unsaturated, and oxygenated VOCs, numerous halogenated species (e.g. Br\textsubscript{2}, Cl\textsubscript{2}, BrCl, HOBr, BrO, ClO), OH, HO\textsubscript{2}, NO, NO\textsubscript{2}, HONO, O\textsubscript{3}, and actinic radiation were conducted. We constrain our model with time-resolved data from OASIS, in order to investigate the following questions:

- What is the fraction of ozone depleted by each halogen atom, and how do each of the halogens impact the rate and timescale of ozone depletion?
- How do chlorine and iodine impact bromine chemistry relating to ODEs?
- What is the effect of halogen species on HO\textsubscript{x} and NO\textsubscript{x} chemistry, and, conversely, what is the effect of HO\textsubscript{x} and NO\textsubscript{x} on halogen chemistry?
- What is the importance of chlorine chemistry (e.g., is it only the BrO + ClO cross-reaction that makes chlorine chemistry important)?

Several modeling scenarios were constructed in an effort to address these questions and to dissect the complex chemistry occurring during ODEs. The results of this work have been organized in the following manner:

- Section 3.1: Comparison of modeled versus observed mole ratios for pertinent species
Section 3.2: Contribution of Br, Cl, and I to ozone depletion and the rate and timescale of ozone loss

Section 3.3: Impact of chlorine on bromine chemistry and oxidation capacity

Section 3.4: Impact of iodine and bromine-iodine interactions

2 Methods

2.1 Field Campaign and Measurements Description

The OASIS (Ocean-Atmosphere-Sea Ice-Snowpack) 2009 campaign occurred during the months of February through April as part of the most recent International Polar Year (2007 – 2009). The motivation for OASIS was to investigate the chemical and physical processes leading to ozone and mercury depletion events in polar spring. The OASIS campaign represents the largest suite of simultaneous and co-located atmospheric trace gas measurements conducted in the Arctic to date, and as such, has provided a rich data set for understanding chemical processes in the Arctic troposphere.

The atmospheric measurements employed in this work were conducted from mobile instrument trailers located near the Barrow Arctic Research Consortium (BARC) facility on the Naval Arctic Research Laboratory (NARL) campus. A map of the measurement site is shown in Figure 1. Winds arriving at the measurement site are primarily northeasterly (i.e. from the sea ice), and thus, should represent background conditions with influence from only natural processes and snow/ice interactions. Occasional winds from the west (i.e. from the town of Barrow) are easily identifiable by coincident enhancements in both NO$_x$ and CO.

Table 5 lists the measurements conducted at OASIS that were used in this modeling study. This is not an exhaustive list of all measurements performed during the campaign. As the
methods have all been described previously, they will only be described very briefly here. Ozone, NO, and NO\textsubscript{2} were measured using the well-established chemiluminescence technique as described in Ridley et al. (1992) and Ryerson et al. (2000). O\textsubscript{3} and NO\textsubscript{x} were measured at 3 heights (2, 6, and 18 ft) from a fixed tower. The data from the 6 ft height were used in this analysis. Carbon monoxide (CO) concentrations were measured using a standard commercial CO analyzer (Thermo Scientific) with infrared absorption detection. The inorganic halogen species Br\textsubscript{2}, Cl\textsubscript{2}, BrO, and HOBr were measured in situ at a height of \textasciitilde1.5 m above the snowpack with a chemical ionization mass spectrometer (CIMS) employing I\textsuperscript{−} ion chemistry. This method, as used in Barrow, and observations have been published in Liao et al. (2011, 2012, 2014). ClO was measured at a height of \textasciitilde3 m above the snowpack via chemical conversion to a stable, halogenated product followed by online separation and detection by gas chromatography with electron capture detection (Stephens et al., 2012). Formaldehyde (HCHO) concentrations were measured at 1 Hz frequency from the fixed tower using a tunable diode laser absorption spectrometer as described in Fried et al. (1997) and Lancaster et al. (2000). As with the O\textsubscript{3} and NO\textsubscript{x} measurements, only data at 6 ft were used in this analysis. HONO was measured using the Long-Path Absorption Photometer (LOPAP) technique described in Villena et al. (2011) with a reported 10% measurement uncertainty. Finally, a large suite of organic compounds were measured both in situ by fast GC-MS (Apel et al. 2010) and via whole air canister samples with offline GC-MS (Russo et al. 2010). Those species that were directly used in this analysis are listed in Table 5.

2.3 Model Description
The model used for this study is a zero-dimensional, photochemical model solved using the commercial software FACSIMILE. It incorporates much of the known gas-phase chemistry that occurs in the Arctic in 220 gas-phase reactions and 42 photolysis reactions (Tables 1 and 2). The model also includes deposition/uptake to snow/aerosol surfaces for certain species, aqueous phase halide reactions, (Tables 3 and 4), and a simple dilution rate for long-lived species (e.g., PAN).

The model was developed to investigate, as a particularly useful example case study, the period 25 through 31 March, 2009, which included a 3-day ozone depletion event during which \( \text{O}_3 \) remained below 1 ppbv. This time period was chosen to investigate the changes in halogen interactions under different ozone regimes, i.e. background ozone (~30 – 35 ppbv), ozone depleting periods, full ozone depletion (\( \text{O}_3 < 5 \) ppbv), and ozone recovery, during which winds were consistently (with the exception of the first half of 25 March) arriving at the measurement site directly from the frozen Arctic Ocean. To enable focused pursuit of specific questions about gas phase free radical chemistry, the model was constrained to observed values of \( \text{O}_3 \), \( \text{C}_2\text{H}_2 \), \( \text{C}_2\text{H}_4 \), \( \text{C}_3\text{H}_8 \), \( \text{C}_3\text{H}_6 \), \( n-\text{C}_4\text{H}_{10} \), \( i-\text{C}_4\text{H}_{10} \), HCHO, \( \text{CH}_3\text{CHO} \), \( \text{CH}_3\text{COCH}_3 \), methyl ethyl ketone, \( \text{Cl}_2 \), \( \text{Br}_2 \), NO, \( \text{NO}_2 \) and CO, as well as calculated time-varying photolysis rate coefficients (\( J \)) for \( \text{O}_3 \) and \( \text{NO}_2 \). The in situ measurements that were used to constrain the model are presented in Figure 1. \( \text{NO}_2 \) mole ratios in Barrow are often quite variable and relatively high compared to other polar measurement locations (Beine et al., 2002). At times, winds travel from the southwest direction, bringing air influenced by Barrow emissions over the measurement site. This is the case for the high \( \text{NO}_2 \) observed at the beginning of 25 March, which correlates to enhanced \( \text{CO} \). Observed values were incorporated at 10-minute time steps, calculated as 10-minute averages of the reported data, over the entire 7-day period. Constraining the model with
these time-varying observations precludes the need for parameterization of atmospheric transport due to advection, and thus justifies the use of a zero dimensional model for this study. It is important to note that, because our objective was to investigate the halogen chemistry occurring during this time period rather than to attempt to simulate an ozone depletion event, we have constrained our model with the observed ozone mole ratios in order to fully study the fast chemical interactions occurring under these observed conditions, which are strong functions of O₃.

Mole ratios of CH₄ were held constant at an average value for this time of 1.89 ppmv as reported by the NOAA-ESRL Barrow Observatory. [H₂O] was calculated for 25 March from observed meteorological conditions of 78% relative humidity and an ambient temperature of -19.5ºC (NOAA; Barrow airport data), corresponding to a water vapor concentration of 2.23x10¹⁶ molecules·cm⁻³. This was held constant throughout the simulation. Temperature was not varied in the model.

The gas-phase chemical reactions and corresponding rate constants used in the model are shown in Table 1. Unless otherwise noted, all rate constants were calculated for a temperature of 248K, consistent with average ambient conditions in Barrow for this time (NOAA Barrow Observatory). This mechanism includes halogen, HOₓ, NOₓ, and VOC chemistry associated with ozone depletions in the Arctic spring. The inorganic iodine reaction scheme used here is adapted from McFiggans et al. (2000, 2002), Calvert and Lindberg (2004a), and Saiz-Lopez et al. (2008). Organic iodine compounds are not included. Although some organic iodine compounds have been observed in coastal and marine locations (Carpenter et al., 1999; Jones et al., 2010), I₂ is likely the major source of atmospheric iodine (Saiz-Lopez and Plane, 2004) and, thus, was assumed to be the reactive I source in this model. It should also be noted that while I does not...
react appreciably with VOCs, it is likely that I
and IO do react with RO$_2$ radicals (Sommariva et
al., 2012). However, these reactions are not included here. Thus, though the iodine reaction
scheme agrees with previous studies, it is likely incomplete; therefore, modeled iodine chemistry
should be taken only as potential impacts to help direct future research efforts.

Photodissociation reactions included in this model are listed in Table 2. For many of the
species, time-varying $J$ coefficients were calculated using a modified version of the Tropospheric
Ultraviolet and Visible (TUV) Radiation model (Madronich and Flocke, 1999) based on in situ
0.1 Hz measurements of downwelling actinic flux conducted throughout the duration of the
OASIS campaign and a surface albedo of 0.8. Upwelling flux was estimated as a function of
solar zenith angle assuming clear sky conditions. The sum of upwelling and downwelling
radiation was used by the TUV model to calculate the total photolysis frequencies. $J$ coefficients
for solar noon on 25 March (listed as $J_{\text{max}}$) are provided in Table 2 as an example. $J$ coefficients
were input into the model at 10-minute time steps for O$_3$ and NO$_2$. All other $J$ values were
scaled to $J_{\text{NO}_2}$ in the modeling code.

$J$ coefficients from OASIS were not available for OCIO, HOCI, or iodine compounds.
An estimate for $J_{\text{max}}$ for OCIO was taken from Pöhler et al. (2010) and that for HOCI was taken
from an Arctic model study by Lehrer et al. (2004), which were then scaled to $J_{\text{NO}_2}$. $J$
coefficients for iodine compounds were calculated according to the work of Calvert and
Lindberg (2004a, 2004b), who also simulated conditions for late March in Barrow, although we
note that there is a larger uncertainty for the photolysis coefficients for the iodine species, with
the exception of I$_2$. Time-varying $J$ coefficients for the iodine species were calculated using a
fourth-order polynomial and varying the solar zenith angle from 98.4 to 72.3°.
Deposition of species to the snowpack is estimated based on measured dry deposition velocities and applied using Equation (1) to calculate transfer coefficients \( k_t \) from the gas to aqueous phase.

\[
k_t = \frac{V_d}{h}
\]  

\( V_d \) is the dry deposition velocity (in \( \text{cm} \cdot \text{s}^{-1} \)), and \( h \) is the boundary layer height. Most previous estimates of ozone deposition velocities to snow in the Arctic range from 0 to 0.2 \( \text{cm} \cdot \text{s}^{-1} \) (Gong et al., 1997; Helmig et al., 2007). Here, we use an average value of 0.05 \( \text{cm} \cdot \text{s}^{-1} \) for ozone, similar to the modeling studies of Cavender et al. (2008) and Michalowski et al. (2000). However, there is large uncertainty in this parameter and often-contradictory observations from field measurements (Helmig et al., 2007, 2012). For 25 March, the boundary layer height in Barrow was estimated at 300 m based on radiosonde data and model simulations (R. Staebler, Environment Canada, personal communication). This corresponds to a \( k_t \) for ozone of 1.67x10^{-6} \( \text{s}^{-1} \). Because dry deposition velocities to snow have not been determined for the halogen acids, we use the estimation method of Michalowski et al. (2000) and assume a transfer coefficient 10 times greater than that for ozone. Thus, for HBr, HCl, HOBr, HOCl, and HOI, \( k_t = 1.67 \times 10^{-5} \text{ s}^{-1} \) (Table 3). Similarly, we assume an equivalent deposition velocity for the oxidized acidic nitrogen compounds (i.e. HNO\(_3\), HO\(_2\)NO\(_2\), HONO, N\(_2\)O\(_5\)), though a full mechanism of aqueous-phase nitrate chemistry is not included in this model (see Custard et al. 2015 for a more detailed investigation of nitrate chemistry).

As mentioned above, in the final version of our model we used the observed values of Br\(_2\) and Cl\(_2\) to constrain the halogen precursors, however, our model was initially developed to utilize only multiphase chemistry to produce Br\(_2\) (and Cl\(_2\)) with a mechanism adapted from Michalowski et al. (2000). Transfer coefficients into and out of the particle phase were
calculated as described in Jacob (2000), and the snowpack volume available for heterogeneous reaction was limited to a column 10 cm deep, based on the effective UV extinction depth for Arctic snow (King and Simpson, 2001). Constant concentrations of chloride and bromide ions in the aerosol and snowpack were used throughout the duration of the simulation, as it is likely that these represent an inexhaustible source of chloride and bromide (Lehrer et al., 2004). Concentrations of Br\(^-\) and Cl\(^-\) in the snowpack were calculated by assuming all bromide and chloride from bulk snow measurements over “thick first-year ice” near Barrow (Krnavek et al., 2012) were contained within the quasi-liquid layer (QLL) (Cho et al., 2002). We used a pH of 4 for the QLL as an estimate, which is in line with previous modeling studies (Thomas et al., 2011, 2012). Aerosol halide concentrations were used as reported for the bulk aerosol chloride and bromide measurements from Barrow, Alaska (Li and Winchester, 1989), and we used an estimate of H\(^+\) for Arctic aerosols from the ARCPAC flight campaign (Fisher et al., 2011). Additionally, upward mixing of chemical species emitted from the snowpack heterogeneous reactions was simplified such that it was assumed to be limited only by vertical mixing from the surface and did not include diffusion through the snowpack interstitial air, which is dependent mostly on wind pumping (a parameter not included in this 0-D model). The aqueous phase reactions included in the model are listed in Table 4.

Using this multiphase mechanism, we were able to produce sufficient gas-phase Br\(_2\) in the model solely from the snowpack/aerosol heterogeneous reactions with aqueous bromide, however, we could not reproduce the day-to-day variability in [Br\(_2\)] from only the heterogeneous chemistry; thus, since our main objective was to examine interactions between halogen radical species, we chose to constrain the model to observed Br\(_2\). This was necessary to ensure that [Br] and [BrO] were accurately represented, so that we could properly examine interactions with
other radicals, e.g. HO$_2$, ClO, and IO. There was a period of missing Br$_2$ data during 29 and 30 March. For these days, we used an average Br$_2$ diurnal cycle from the previous days, which was then scaled until the modeled BrO was in agreement with observations. It should be noted, also, that the uncertainty in the BrO measurements is high during ODEs as the observed values are very near the detection limit (LOD of $\sim$2 pptv with uncertainty of -3/+1 pptv near the LOD), and thus the uncertainty in modeled [Br] would be greatest during these periods. Only daytime BrCl was used as produced in the model multiphase mechanism. BrCl measurements from OASIS are sparse, however, the daytime simulated BrCl mole ratios of 0 – 10 pptv are in agreement with the available observations for the campaign.

Volumetric fluxes were also introduced into the model for HONO and I$_2$. The fluxes of HONO and I$_2$ were scaled to $J_{NO_2}$ since HONO$_x$ and likely I$_2$$_x$ are photochemically produced (Honrath et al., 1999; Zhou et al., 2001; Saiz-Lopez et al., 2011). The HONO flux was adjusted to agree with observed gas-phase concentrations (Villena et al., 2011), with daytime averages near 10 pptv and spikes in excess of 20 pptv, as shown in Figure 3A. Although the flux is included, and is necessary for measured HONO to agree with observations across all seven days of the simulation, the contribution of the flux is small in comparison to gas phase production through NO$_x$ chemistry, with the exception of 26 – 28 March, when gas phase NO$_x$ is especially low. Figure 3B shows a time series of the NO and NO$_2$ observations that has been re-scaled to a smaller range on the y-axis so that the relatively higher NO$_x$ on 29 and 30 March can be discerned. A recent paper by Lin et al. (2014) speculates a possible additional gas phase source of HONO from the reaction of NO$_2$ with an HO$_2$·H$_2$O complex. However, as laboratory studies are still required to quantify the efficiency of this mechanism, the rate constant of this reaction, and the product yield of HONO, this mechanism was not included in our model.
To investigate the impacts that different levels of iodine chemistry could have on ozone depletions, two iodine scenarios were used, which will be referred to as “Low Iodine” and “High Iodine.” For the Low Iodine case, the I$_2$ flux was chosen such that average daytime gas-phase mole ratios of IO remain near 1 pptv (i.e., near or below the detection limit of DOAS and in line with previous indications of [IO] in the Arctic) for the majority of days (as shown in Figure 4). Only during the ozone depletion period did simulated IO reach close to 2 pptv, for the chosen I$_2$ flux. The higher [IO] during ozone-depleted periods is a result of the constant I$_2$ flux that is utilized for iodine, in contrast to bromine and chlorine species, which use actual observations. Because the I$_2$ flux is constant during the ODE, while Br$_2$, and especially Cl$_2$ are decreased, iodine becomes more dominant for reaction with the remaining O$_3$ (~1 – 2 ppbv) and [IO] increases. I$_2$ averages ~0.025 pptv throughout the Low Iodine simulation. The High Iodine scenario uses a flux that is adjusted so that I$_2$ averages 0.5 pptv across the simulated period. This results in IO mole ratios ranging from 5 to 10 pptv (see Figure 3).

3 Results and Discussion

3.1 Comparison of modeled and observed mole ratios for select species

Those species that are not specifically prescribed in the model (e.g. all radical species and many inorganic halogen compounds) by inputting time-varying observations or by introducing a flux are allowed to freely evolve. Here we compare modeled versus observed mole ratios for only those species that are most important for this analysis on halogen interactions.

Since the contribution of each halogen atom to ozone destruction is a function of its concentration, it is important that the model simulates halogen radicals at levels that are consistent with observations. Comparisons of the multi-day model output with observed BrO
and ClO are shown in Figures 2B and 2E. ClO observations are limited, but the model captures the occurrence and general shape of the ClO peak observed on 29 March. However, the model generally under predicts ClO where there are available observations. A question to address is the extent to which there are other sources of Cl atoms during this time, such as HOCl or chlorinated organic compounds that are not included here. In Figure 2B, the simulated BrO output generated through bromine chemistry constrained by observed Br$_2$ is compared with BrO observations. The model represents the overall temporal profile and magnitude of [BrO] throughout this period.

This is important for the analysis of the interactions between BrO, ClO, and IO, which is the focus of this work. It has been suggested that daytime Br$_2$ observed by CIMS contains a contribution from HOBr conversion to Br$_2$ on the inlet, and that daytime Br$_2$ should be below detection limits on average due its fast photolysis rate (Liao et al., 2012). However, this modeling study suggests that Br$_2$ should indeed be present in the daytime (given the agreement with observed [BrO]), though it is acknowledged that there is some degree of interference from HOBr, as is apparent from the model over-prediction of BrO on 31 March. Considering an e-folding photolytic lifetime of Br$_2$ at solar noon of 23 s ($J_{\text{max}} = 0.044$ s$^{-1}$), and using the method of Guimbaud et al. (2002), the effective daytime mixing height ($Z*$) of Br$_2$ in the stable air typical of the Arctic ($K_c = 95$ cm$^2$·s$^{-1}$) is ~ 0.5 m. Assuming simple first-order kinetics, the [Br$_2$] remaining after mixing up from the surface to the intake of the CIMS (~1 m or 2 lifetimes) is 10% that at the surface. A recent study examining Br$_2$ production from surface snow in Barrow demonstrates that enhanced Br$_2$ production is observed in the presence of solar radiation (Pratt et al., 2013). Given that the Br$_2$ concentrations in the snowpack interstitial air should be elevated due to heterogeneous production mechanisms (e.g., the bromine explosion), and that production should be greater during sunlit periods, it seems reasonable to conclude that Br$_2$ should
sometimes be observable during the day. Indeed, Br\textsubscript{2} mole ratios needed in the model to reproduce BrO observations agree with the “uncorrected” Br\textsubscript{2} observations (shown as the red data in Figure 2A), as reported in Liao et al. (2012).

Figures 2A and 2D compare the model output for Br and Cl atom concentrations (black trace) with steady-state approximations of [Br] and [Cl] (red trace) following the method of Stephens et al. (2012), as direct observations of Br and Cl atoms have not yet been achieved. In both cases, the model-simulated output is greater than the steady-state approximations on a few days, sometimes by as much as 90%, although both methods capture the diurnal trends and fluctuations. A notable feature of Figure 2A is the rather high Br atom concentrations during the three-day ODE, with concentrations up to $3 \times 10^9$ molecules·cm\(^{-3}\) (~100 pptv), though as mentioned previously, this should be considered an upper limit due to the uncertainty of the Br\textsubscript{2} and BrO measurements and the potentially positive model bias during this time. Nonetheless, higher [Br] (and [I]) is expected during periods of complete ozone depletion due to the loss of this dominant Br atom chemical sink. However, these concentrations are on the high end of previous estimates using hydrocarbon measurements, which range from $1 \times 10^6$ to $1 \times 10^9$ for ODEs (Jobson et al., 1994; Ariya et al., 1998; Rudolph et al., 1999). While [Br] peaks during periods of low O\textsubscript{3}, [Cl] is enhanced when O\textsubscript{3} is present due to the elevated Cl\textsubscript{2} mole ratios that are observed only when O\textsubscript{3} is above ~10 ppbv (Figure 1A; Liao et al., 2014). The model predicts Cl atom concentrations of $2 \times 10^5$ to $6 \times 10^5$ molecules·cm\(^{-3}\), which is also higher than previous estimates of $1 \times 10^3$ to $1 \times 10^5$ determined from hydrocarbon measurements (Jobson et al., 1994; Ariya et al., 1998; Rudolph et al., 1999; Boudries and Bottenheim, 2000; Keil and Shepson, 2006). As discussed in Stephens et al. (2012), the hydrocarbon-based methods average over the
transport path, which can be aloft and consist of several days, and thus should be lower than that observed near the surface, if the surface is the Cl\textsubscript{2} and Br\textsubscript{2} source.

Model simulations of [OH] and [HO\textsubscript{2}] (Figures 2F and 2G) lie within the bounds of measurement uncertainty for the ambient data, with the exception of 29 March when the model under predicts HO\textsubscript{2} by factor of ~3. The accurate simulation of OH and HO\textsubscript{2} is important since halogen chemistry, especially that involving chlorine, can have a significant impact on the HO\textsubscript{x} budget. The discrepancy between the modeled and observed HO\textsubscript{2} for 29 March may lead to a less than realistic impact of HO\textsubscript{2} on oxidation chemistry for this day. The model captures the temporal cycle of HOBr well; however, it generally over predicts the daytime peak mole ratios (Figure 2C). It is unclear why this should be the case, given that both BrO and HO\textsubscript{2} are well-represented, with the exception of the BrO over-prediction early on 31 March. This suggests that either our simple parameterization of deposition to snow and particle surfaces is slower than that occurring in nature, or that we are missing some other important HOBr sink.

### 3.2 Contribution of Br, Cl, and I to ozone depletion and the rate and timescale of ozone loss

An important question regarding ozone depletion events is the contribution of the halogen radicals, Br, Cl, and I, to the total destruction of ozone and the rate of ozone depletion. Based on field measurements of reactive bromine compounds, primarily BrO, it is generally accepted that bromine is the dominant reactant leading to ozone destruction (Simpson et al., 2007). However, this has not been quantified over highly variable chemical conditions since prior to OASIS, simultaneous high-time resolution measurements of such a large suite of chemical species had not been performed. Few studies have examined the impact of Cl on ozone depletion, and these
have not had the benefit of in situ observations of Cl₂ and ClO with which to compare their models. This observational data set and model thus represents a unique opportunity.

In this study, “Base Model” runs are those that include both bromine and chlorine. “Br Only” simulations are performed by removing Cl₂ and chloride; likewise “Cl Only” simulations are performed by removing Br₂, bromide, and organobromine compounds. Simulations with iodine are conducted by introducing fluxes of I₂ of a magnitude necessary to keep the average daytime IO near 1 pptv (Low Iodine) or at 0.5 pptv I₂ (High Iodine), as described previously (reference Figure 4). It is important to note that the model is adjusted to fit observations using the Base Model only. No re-adjustments are made to the model when either bromine or chlorine is turned off, or when iodine is turned on, to observe the effect of a one variable change.

The time-varying fraction of ozone depleted by bromine, chlorine, and iodine was calculated by considering those reactions that destroy ozone (i.e. Reaction R2 for Br and the analogous reactions for Cl and I) while correcting for those reactions that result in the regeneration of O₃. Here, photolysis of BrO, ClO, or IO, as well as reaction of XO with NO, ultimately lead to O₃ production. The rate of O₃ loss by halogen X is determined by Equation (2), where X = Br, Cl, or I, and the total chemical O₃ loss rate is calculated using Equation (3). The fractional contribution for each halogen is then determined by dividing the two quantities.

\[
Rate of O_3 loss by X = k[X][O_3] - k[XO][NO] - J[XO] \quad (2)
\]

\[
\]

While we recognize that considering only the sum of the rates of XO + XO reactions (where X = Br, Cl, or I) has generally be used in previous studies to estimate the rate of ozone destruction (Le Bras and Platt, 1995; Platt and Janssen, 1995), we have chosen to use Equations 2 and 3 as it
is likely that these complex interactions are oversimplified by the XO + XO method. Indeed, we
show in a forthcoming manuscript (Thompson et al., Bromine atom production and chain
propagation during springtime Arctic ozone depletion events in Barrow, Alaska, manuscript in
preparation) that the XO + XO method underestimates chemical ozone loss by Br and Cl atoms
when compared to Equation 2.

Figure 5 shows the fraction of the rate of O₃ depletion by Br and Cl for the Base, the Base
+ Low Iodine, and the Base + High Iodine model scenarios as a diurnal average for the daytime
hours of only 25 and 29 – 30 March, for conditions in which O₃ is > 5 ppbv, since this quantity is
only meaningful when O₃ is present. Br accounts for the vast majority of O₃ depletion in the
Base scenario, at about 95%, whereas Cl only accounts for 5 – 10% of ozone loss on average. In
the Low Iodine plot it can be seen that the levels of iodine considered (1 ppt IO) contribute more
to O₃ destruction than does chlorine on average, with a contribution of to 20 - 40%. This also
decreases the Br contribution to 60 – 80%. When High Iodine is included, the relative
importance of Br and I switch, such that I now contributes ~60% to ozone loss, whereas Br is
reduced to 30 – 40%. Thus, it is clear that iodine can have a significant contribution to ozone
depletion even at low levels.

To investigate this in further detail, we used a focused version of our model that
simulated a 1.5 h period fixed at mid-day conditions to facilitate instantaneous calculations of
ozone depletion. We used chemical mole ratios similar to those of 29 March. This day has Br₂ at
6.7 pptv and Cl₂ at 80 pptv, and ozone at background concentrations near 30 ppbv. We chose
not to use 25 March, as this day was impacted by local pollution during the first half of the day
(as evidenced by NOₓ and CO in Figure 1). The mid-day version of our model was run with
constant molecular halogen and VOC concentrations, thus, although the conditions are similar to
March, the results are not directly comparable.

The fractional contribution of each halogen to ozone destruction was calculated using
Equation (4) for ten different model scenarios with different combinations of halogens present
and with no halogens. In Equation (4), $P$, $Q$, $R$, $S$, $T$, $U$, and $V$ represent the total value for model
“counters” for each process in parentheses, and the denominator is the sum of chemical ozone
loss terms. Because photolysis of O$_3$ can result in fast reformation of O$_3$ through the reaction of
O(\(^3\)P) + O$_2$, the O(\(^1\)D) + H$_2$O reaction is used to represent the ozone that is destroyed via
photolysis.

$$F_X = \frac{P(X+O_3) - Q(XO) - R(XO+NO)}{S(O_3+OH) + T(O_3+HO_2) + U(O_3+NO_2) + V(O_1D+H_2O)}$$ (4)

Results of this calculation are shown in Table 6 for the scenarios studied. In addition to the
fraction of O$_3$ loss by each halogen, Table 6 also shows the total change in O$_3$ across the
simulated period ($\Delta$O$_3$), the total O$_3$ production via the O(\(^3\)P) + O$_2$ reaction, and the sum of the
O$_3$ loss terms (denominator of Equation 4).

It is clear from Table 6 that Br is the primary driver of O$_3$ loss with at least 64% contribution in all cases that it is present, reaching up to 87% in the “Br and Cl” (Base) scenario, and 97% in the “Br Only” simulation. In the “Br and Cl” run, Cl accounts for 11.5% of the loss (at Cl2 levels somewhat enhanced at 80 pptv), which is a minor, though significant, contribution.

On an absolute basis, the addition of chlorine chemistry also enhances the O$_3$ depletion caused by bromine, with the total ozone depleted by Br increasing from 2.21 ppbv in the Br Only scenario to 3.61 ppbv in the Br and Cl scenario (data not shown). This is primarily a result of the efficient cross-reaction between BrO and ClO that regenerates Br and thereby increases the
Comparing “Br Only” with “Br and Low I”, it is apparent that iodine chemistry directly contributes a significant amount to ozone depletion, at a fractional contribution of 11.9% with just 1 ppt IO present, due to both the fast reaction between I and O$_3$ and IO and BrO, as well as the lack of known competing sinks for I. When iodine is increased, as in the “Br and High I” scenario, the iodine contribution jumps to 35.0%. From examination of the fractional ozone depletion, it appears that iodine chemistry decreases the Br-destruction of ozone; however, on an absolute basis, there is an increase in the total amount of ozone destroyed by Br in the “Br and Low I” simulation (2.55 ppbv O$_3$ destroyed) compared to the “Br Only” simulation (2.21 ppbv O$_3$); this is even greater in the “Br and High I” scenario, at 3.92 ppbv O$_3$. The ΔO$_3$ also increases by a factor of 1.3 for the “Br and Low I” case and 2.8 for the “Br and High I” case over the integrated 1.5 h simulation period. When low iodine is added to the base model, there is a factor of 1.2 increase in ΔO$_3$, with iodine contributing ~9% to the ozone depletion; this increases to a factor of 3.3 increase in ΔO$_3$ and 28.8% contribution from I when high iodine is included. In the “Br, Cl, and Low I” case, Cl atoms actually contribute more to the ozone depletion, however, this is a function of the much higher Cl$_2$ (80 pptv) than I$_2$ (0.025 pptv) in this scenario. On a per atom basis, iodine is more efficient than chlorine at depleting ozone. That is partly due to the fact that ~50-100% of I atoms are lost via reaction with O$_3$, while only ~20% of Cl atoms are lost via O$_3$ reaction.

The presence of multiple halogen species leads to synergistic effects, where the total amount of O$_3$ destroyed is greater than the sum of the species run in isolation. This synergism is primarily due to the efficient cross-reactions between BrO, ClO, and IO that reform O$_3$-depleting halogen atoms. The absolute ozone destruction by Br is enhanced more by iodine than by chlorine as a result of the very fast reaction between BrO and IO. Indeed, the increase of 1.41
ppbv of O$_3$ destroyed by Br when chlorine is included (“Br and Cl” case vs. “Br Only” case) corresponds to an increase of only 0.02 ppbv of O$_3$ destroyed per pptv of Cl$_2$, whereas the enhancement in ozone destruction by Br provided by low iodine is nearly 7 ppbv of O$_3$ per pptv of I$_2$. Therefore, while Cl acts primarily to enhance Br chemistry, I both increases the efficiency of bromine catalyzed ozone destruction, and directly depletes ozone.

Chlorine is an especially interesting case because it contributes to both O$_3$ depletion (though relatively minor) and O$_3$ production. Indeed, in the “Cl Only” run, there is a net increase in O$_3$ that is greater than in the “No Halogens” scenario by a factor of nearly 8. This increase is due to the efficient reaction of Cl with nearly all VOCs, and the resultant production of RO$_2$ and HO$_2$. Br, in contrast, does not react appreciably with most VOCs, although its reaction with HCHO will also lead to HO$_2$ production, as evidenced by the increase in O$_3$ production in the “Br Only” scenario compared to the “No Halogens” case. I does not react to produce HO$_2$, thus, there is no additional O$_3$ production in the “Low I Only” case, and only a slight increase in the “High I Only” case, likely as a result of IO reaction with NO to form NO$_2$. It is clear that fully understanding ODE chemistry will require a complete understanding of all three halogen radical families.

Platt and Janssen (1995) indicate that ~99% of Br atoms react with O$_3$ when present at background levels, while only ~50% of Cl atoms react with O$_3$ due to efficient reactions with many VOCs. However, this quantity is highly dependent on the mole ratios of O$_3$, HCHO, CH$_3$CHO, and the VOCs, which can fluctuate independently of each other. To further investigate how the three halogens contribute to ozone depletion, we considered the fraction of available Br, Cl, and I atoms that react with O$_3$ over all other competing pathways across the seven-day simulation with iodine included (Low Iodine) as shown in Figure 6. The inclusion of
iodine does not significantly change the result for Br and Cl, thus only the simulation including I is shown. Br atoms were simulated to react with O₃ 55–95% of the time when O₃ is not depleted, but this fraction fluctuates significantly and is at times below 25% when O₃ is depleted (i.e., < 5 ppbv). Cl atom reaction with O₃ varies between 10-20% on average, and is always less than 30% for this time period. These numbers are lower than those estimated previously, likely because we are using actual measurements of all of the known Br and Cl atom sinks that contribute to this quantity, e.g. HCHO, CH₃CHO, numerous VOCs and NOₓ. Based on our chemical mechanism, I atoms can react with O₃ up to 100% of the time, and usually up to 90% (though with high variability during O₃ depleted periods), consistent with the estimates of Platt and Janssen (1995), who determined 99% for I. However, as stated previously, it is likely that our iodine reaction scheme is incomplete, e.g. for IO reaction with peroxy radicals.

Not all halogen atom reactions with O₃ result in a net loss of ozone. Though up to 90% of Br atoms react with O₃, most of these reactions do not ultimately destroy ozone as it can be reformed via e.g., BrO photolysis or BrO reaction with NO. When considering only Br and Cl in our mid-day model, 70% of the BrO formed regenerates O₃ through photolysis or reaction with NO, whereas this quantity is only 12% for ClO, which photolyzes much more slowly. While this suggests that Cl atoms are actually more efficient at destroying ozone on a per atom basis, the lower concentration of Cl due to the numerous competing Cl-atom sinks and the low fraction of Cl atoms that react with O₃ make it a minor player in ozone depletion. When iodine is included at low levels, thus opening the BrO + IO cross-reaction, the percentage of BrO that reforms O₃ drops to 64% and that for IO is comparable at 65%.

A highly significant finding from the OASIS 2009 campaign was the observation of unexpectedly high levels of Cl₂ (Liao et al., 2014). Given the observed [Cl₂] maxima of 100 –
400 pptv, a sensitivity study was performed to investigate the impact that such high concentrations could have on ozone depletion chemistry. Table 7 shows the results of modeling runs for midday of 29 March performed by varying Cl$_2$ between 25 to 400 pptv (recall that the Base scenario here for 29 March has 80 pptv Cl$_2$). These particular runs included only bromine and chlorine chemistry. Here it can be seen that the high Cl$_2$ levels observed in Barrow can have significant impacts on O$_3$ depletion, with Cl atoms accounting for over 30% of O$_3$ loss when present at 400 pptv. At Cl$_2$ levels less than 100 pptv, however, Cl destruction of O$_3$ is $\leq$11%, thus, chlorine must be relatively elevated to make an appreciable impact on O$_3$ depletion. While the amount of O$_3$ production also increases at higher Cl$_2$ (by an additional 0.58 ppbv O$_3$ at 400 pptv Cl$_2$ compared to 25 pptv Cl$_2$), the increase in the O$_3$ destruction by both the additional Cl atoms (2.8 ppbv O$_3$) and by the enhanced efficiency of Br atoms through the synergy of the halogen cross-reactions (4.37 ppbv O$_3$), far outweighs the O$_3$ production. Thus, when both bromine and chlorine are present, our modeling results do not show indications of a “chlorine counter-cycle” hindering ozone depletion as suggested by Piot and von Glasow (2009).

It is useful to also consider the rate of ozone depletion. Often, fast apparent ozone depletions, in which O$_3$ is observed to decrease over timescales of hours, have been attributed to air mass transport of ozone-depleted air, whereas local chemistry is believed to result in a more gradual depletion (Bottenheim and Chan, 2006; Simpson et al., 2007; Halfacre et al., 2014). The ozone depletion rate and the resulting timescale for depletion induced by Br, Cl, and I, both in isolation (for Br and I) and when allowed to interact was investigated with model runs conducted for “Br Only” and “I Only”, as well as with different combinations of the above, including both Low Iodine and High Iodine conditions. Cl was not run in isolation here, since as was shown in Table 6, the “Cl Only” simulation did not result in a net loss of O$_3$. Here, we considered only the
ozone depletion rate at mid-day of 29 March, determined using the delta O₃ for the 1.3 h simulation time (as shown in Table 6), to calculate the depletion timescale. Table 8 shows the resulting ozone depletion rates in ppbv·h⁻¹ for the different permutations of halogen radicals studied, along with the resultant timescale for total ozone depletion from a background of 35 ppbv to 5 ppbv, our definition of a major ODE (assuming a constant ozone depletion rate, which represents an upper limit as the rate of ozone depletion decreases as [O₃] decreases).

For the chemical conditions observed on this day, bromine chemistry alone is capable of depleting ozone on a timescale of 16.2 h at a rate of 1.85 ppbv·h⁻¹, whereas low iodine levels would require 13.9 days at a rate of 0.09 ppbv·h⁻¹. High iodine alone depletes ozone at a rate of 1.72 ppbv·h⁻¹ in 17.4 hours. Again, the synergy that exists between the halogen species is apparent, such that the combination of any halogen species depletes ozone at a faster rate than the sum of the components run in isolation. This is a result that was previously found for the interaction of bromine and iodine in modeling studies by Calvert and Lindberg (2004a, 2004b), Saiz-Lopez et al. (2008) and Mahajan et al. (2010). The greatest ozone depletion rate of 6.07 ppbv·h⁻¹, with a timescale for complete depletion of only 4.9 h, results when all three halogens are present, with I₂ set at the High Iodine level of 0.5 pptv. Based on these results, it can be concluded that iodine has the potential to have a much greater impact on ozone depletion than chlorine. The combination of Br, Cl and low iodine, resulting in an 8.5 hr depletion timescale is consistent with the fast-end timescales observed over the Beaufort Sea by Halfacre et al. (2014).

It should be noted, however, that the ozone lifetimes discussed above simply represent the calculated ozone lifetime, as determined from measurements conducted within the surface layer. As discussed in detail in Tackett et al. (2007), the current view of the boundary layer is one that is very chemically stratified, with the most important source of Br₂ and Cl₂ likely from
the snowpack surface. Thus, the concept of “boundary layer” is one that has been defined in terms of the height over which ozone is observed to be depleted, i.e. typically ~400 m (Bottenheim et al., 2002; Helmig et al., 2012). It is likely, however, that ozone is depleted largely in the very near surface layer, and the time scale for that depletion is thus determined in significant part by the time scale for downward diffusion of ozone in the 0 – 400 m range to the near-surface layer in which BrO₅ concentrations are large. In short, when averaged over the entire boundary layer, the actual ozone depletion timescale may potentially be slower than that calculated here using only surface measurements, because of diffusion limitation.

In Table 9, we show the average ozone depletion rate (calculated as discussed for Table 8) for the five different scenarios with varying [Cl₂]. When Cl₂ is present at only 25 pptv, the timescale for depletion is 13.2 h, which is longer than for the Base model (with 80 pptv Cl₂), but still less than one day, primarily due to the activity of bromine. 100 pptv Cl₂ decreases the timescale for depletion to 9.55 h, while at 400 pptv, the timescale is only 5.24 h (again assuming constant Cl₂ mole ratios). For comparison, the Base Model with low iodine as shown in Table 8, has an ozone depletion timescale of 8.47 h, whereas the Base with high iodine has a depletion timescale of 4.94 h. Thus, the presence of only 0.025 pptv of I₂ has a greater effect on the ozone depletion rate than does 100 pptv of Cl₂, and sustained levels of Cl₂ greater than 400 pptv would be required to have a comparable impact on ozone depletion as does 0.5 pptv I₂.

Although the depletion timescales reported here, both for base model conditions and for elevated [Cl₂], represent relatively fast ozone depletion and, as stated, represent an upper limit assuming a constant ozone depletion rate, total ozone depletions are often observed to occur on timescales of a day or less (Tang and McConnell, 1996; Simpson et al., 2007; Halfacre et al., 2014), and a fast ozone depletion of ~7 h attributed to local chemistry was reported over the
Arctic Ocean by Jacobi et al. (2006). Thus, the ozone depletion rates calculated here (including for elevated [Cl\textsubscript{2}]) show that rapid photochemical ozone depletion events are possible, and thus one should not assume that all fast ODEs represent transport, without appropriate supporting information. Back-trajectories for periods of very high [Cl\textsubscript{2}] during OASIS indicate air mass transport over the surface of the Arctic Ocean (Stephens et al., 2012). Ozone instruments on-board the O-Buoy network of sea ice-tethered buoys (Knepp et al., 2010) in the Arctic Ocean have also indicated very fast ozone depletions, with a median timescale of 10.4 hours and numerous individual events much faster than that (Halfacre et al., 2014). Unfortunately, we are limited by a lack of Cl\textsubscript{2} measurements from across the frozen Arctic Ocean, and thus, it is not possible to speculate how widespread this elevated Cl\textsubscript{2} may be.

3.3 The impact of chlorine chemistry on oxidative capacity

One of the primary objectives of this work was to assess the impact of chlorine on bromine chemical cycles relating to ODEs in light of the recent discovery of unexpectedly high [Cl\textsubscript{2}] in Barrow during OASIS. We discussed the contribution of observed levels of chlorine to ozone depletion in Section 3.2 and the impact of varying concentrations of Cl\textsubscript{2} on the rate and timescale of ozone depletion. These results show that chlorine itself plays only a minor role in the direct destruction of ozone until Cl\textsubscript{2} reaches over 100 pptv. That Cl atoms do not directly contribute significantly to ozone depletions is not surprising, given their lower ambient concentration compared to Br (see Figure 2), due to the multitude of Cl atom sinks. In the model, the rate of Cl atom production from Cl\textsubscript{2} and BrCl (assumed to be surface emitted species) is also on average only 20% of the rate of Br production from Br\textsubscript{2} and BrCl. The Br/Cl ratio for the Arctic has been estimated to range from 80 to 1200 when ozone is not fully depleted (Jobson et
al., 1994; Keil and Shepson, 2006; Cavender et al., 2008) based on observations of halocarbons and hydrocarbon decay. Our model predicts daytime Br/Cl ratios for non-O3 depleted days ranging from a low of 18 up to 1300, consistent with previous estimates. When ozone is fully depleted (i.e., < 5 ppbv), [Br] becomes much greater than [BrO], due to the loss of its primary atmospheric sink and the resultant lack of production of BrO, and the Br/Cl ratio increases dramatically to $8 \times 10^3$ – $2.5 \times 10^5$. During these periods when the ozone concentration is low, CH$_3$CHO becomes an important Br atom sink, with a rate of reaction with Br comparable to that of Br + O$_3$ (Figure 7). This supports the hypothesis by Shepson et al. (1996) that aldehydic compounds, including CH$_3$CHO, represent important Br sinks during ODEs. HCHO is at times a major Br atom sink, but only when ambient concentrations are high enough to compete with CH$_3$CHO (e.g., towards the second half of 28 March where [HCHO]/[CH$_3$CHO] = ~0.8). Interestingly, NO$_2$ also represents a major Br sink during ODEs. In comparison to other Arctic locations, Barrow can have relatively high NO$_x$, and thus NO$_2$ would likely not be as important a Br sink in more pristine Arctic environments. A detailed study into the impact of these increased NO$_x$ levels in Barrow is the subject of Custard et al. (2015), and thus is not discussed extensively here.

Although Cl chemistry can generate HCHO and CH$_3$CHO in the gas phase through oxidation of methane and ethane, respectively (e.g., Reactions R13 – R15), it is likely not the case that these important Br sinks are the result of such reactions during ODEs. From the time series of ambient Cl$_2$ observations (Figure 1A), and as discussed in Liao et al. (2014), it is apparent that substantial mole ratios of Cl$_2$ are only observed when O$_3$ and radiation are present. When O$_3$ is fully depleted during 26 – 28 March, Cl$_2$ is nearly absent. Moreover, the efficiency of production of HCHO and CH$_3$CHO is NO$_x$-dependent, with hydroperoxide production more
important at low NOx levels typical of more remote Arctic environments. Thus, while some
significant gas-phase production of HCHO and CH3CHO can occur if [Cl] is high (Sumner et al.,
2002), it is far more likely that in the Arctic, surface concentrations of these compounds are
primarily derived from snowpack emissions (Grannas et al., 2007; Barret et al., 2011). The
production of HCHO and CH3CHO from the snowpack has been documented in previous studies
(Sumner and Shepson, 1999; Grannas et al., 2002) and strong vertical fluxes of both compounds
were observed during OASIS (Barret et al., 2011; Gao et al., 2012).

As discussed previously, and shown in Figure 6, only a small fraction of available Cl
atoms react with O3. This is due to the very efficient reactions of Cl with numerous organics,
with rate constants much faster than analogous oxidation by OH. In Figure 8, we investigate the
most important Cl atom sinks. Indeed, reaction with organic compounds dominates the Cl atom
reactivity for both non-ODE and ODE days. Reactions with reduced hydrocarbons (red trace)
are the primary sink under both circumstances, at 63% and 78% respectively. When O3 is present,
the O3 reaction sink accounts for ~27% of Cl atom reaction (calculated as the median across 29
and 30 March), with oxygenated organic compounds (OVOCs) accounting for 9%. When ozone
is depleted, the OVOCs make up 22% of the Cl atom reactivity. The remaining sinks (i.e., HOx,
NOy, and other inorganic halogen compounds) are insignificant in comparison. Thus, one of the
most important impacts of Cl chemistry in this environment is its direct contribution to the
oxidative capacity of the near surface boundary layer via oxidation of organic compounds.

Based on the reaction scheme shown in R13 – R15, and similar VOC oxidation pathways
involving Cl atoms, Cl chemistry generates HO2 as a by-product, a very significant BrO sink
(though relatively unimportant for Br atoms) and itself an important atmospheric oxidant;
however, this too is dependent on NOx. It has been suggested that the presence of chlorine will
significantly increase HO₂ (Rudolph et al., 1999; Piot and von Glasow, 2009). Figure 9A presents results of a sensitivity study in which simulations with different combinations of halogens present were performed to investigate the impact on HO₂. For days when O₃ is not fully depleted (i.e., 25, 29, and 30 March), and when Cl₂ is present, the “Cl Only” simulation results in HO₂ concentrations up to 3x10⁸ molecules cm⁻³ (~10 pptv) for [Cl₂] nearing 100 pptv (March 29 and 30). Especially for 29 and 30 March, it is apparent that the “Br Only” simulations have much lower daytime HO₂, generally remaining below 1x10⁸ molecules cm⁻³. When Cl₂ is present (i.e., when O₃ is not depleted), the “Cl Only” simulation is nearly indistinguishable from the Base model, indicating the chlorine is dominating the halogen contribution to HO₂. However, in some cases, specifically when O₃ is depleted (and thus Cl₂ is absent as discussed above) HO₂ is indistinguishable from a “Br Only” case. During the 26-28 March period, there would be little HOₓ production from O₃ photolysis, and as Cl₂ is also nearly absent, bromine chemistry and photolysis of HOₓ precursors from the snowpack (e.g., HCHO or HONO) become the primary sources of HOₓ production.

The production of HO₂ as a result of chlorine chemistry is also apparent when examining the [HO₂]/[OH] ratio in simulations performed with and without chlorine. Table 10 presents [HO₂]/[OH], [BrO]/[Br], [ClO]/[Cl], and [IO]/[I] ratios, calculated for mid-day of 29 March, for a variety of model scenarios with no halogen chemistry and different combinations of halogens present. When halogen chemistry was excluded from the model, the [HO₂]/[OH] ratio was 115; this nearly doubled to 230 when only chlorine chemistry was added. This effect is in contrast to the “Br Only”, “Low Iodine Only”, and “High Iodine Only” simulations, where the addition of bromine or iodine served to decrease the [HO₂]/[OH] ratio. Furthermore, the addition of chlorine to any scenario shifted this ratio towards HO₂. For example, “Br Only” decreased this ratio from
115 to 63; upon the addition of chlorine for the “Br and Cl (Base)” scenario, the ratio was increased to 104. It is important to note that NO\textsubscript{x} chemistry has a very significant impact on both HO\textsubscript{x} and halogen chemistry. For these calculations NO and NO\textsubscript{2} were held constant (at 25 and 50 pptv, respectively) so that we could investigate the impacts of just adding or removing halogens without concomitant changes in NO\textsubscript{x}. If NO\textsubscript{x} is not constrained, the removal of halogens has the effect of leading to increased NO\textsubscript{x} levels (through removal of this sink), which then decreases HO\textsubscript{x}. This leads to a confounding influence on the HO\textsubscript{x} ratio that is due to increased NO\textsubscript{x} chemistry rather than removal of halogens.

To investigate further, time-varying rates of production of OH and HO\textsubscript{2} were determined from their primary source reactions (Figure 10). Under our modeling conditions for the 7 days studied, when O\textsubscript{3} is not fully depleted, HO\textsubscript{x} is produced primarily through photolysis of HONO (as postulated by Zhou et al., 2001 and Villena et al., 2011) and as a product of Br reaction with HCHO (orange and blue traces in Figure 8, 29% and 41% respectively for 30 March), with significant production from photolysis of HCHO (15% for 30 March), as well, confirming the importance of snowpack-emitted carbonyl compounds for the oxidation capacity of the Arctic boundary layer (Sumner and Shepson, 1999). When O\textsubscript{3} is fully depleted, HCHO is the primary direct HO\textsubscript{x} source via reaction with Br (84% for 27 March). This result explains the observation in Figure 8A, that on O\textsubscript{3}-depleted days, the “Br Only” and Base simulations give essentially identical results for [HO\textsubscript{2}]. Although these modeling results clearly indicate that Br\textsubscript{2} oxidation is the dominant HO\textsubscript{2} source during ODEs, the absolute value of the HO\textsubcript{2} production from this pathway during the ozone-depleted days should be regarded as an upper limit, since, as explained previously, the uncertainty in the BrO measurements is high during this time and it is possible
that [Br] is somewhat overestimated. Indeed, this is likely the reason behind the high bias of the model HO₂ compared to measurements for 26 - 28 March (Figure 2G).

Finally, an additional significant impact of chlorine chemistry on the oxidation capacity of the polar boundary layer (PBL) is the production of RO₂ through Reaction R13 and analogous oxidation reactions with higher order hydrocarbons. RO₂ reaction with BrO can also lead to production of HOBr through Reaction R17, which could enhance the heterogeneous production of Br through HOBr deposition and the bromine explosion mechanism.

\[
\text{BrO} + \text{R-CH}_2\text{OO} \rightarrow \text{HOBr} + \text{R-CHOO} \quad \text{(R17)}
\]

However, the presence of chlorine chemistry also decreases the [BrO]/[Br] ratio through the BrO + ClO reaction, so Reaction R17 may affect [HOBr] most under certain chemical conditions (e.g., lower [ClO]). [RO₂] (calculated as the sum of methyl through butyl forms) for simulations conducted with and without chlorine is shown in Figure 9B. This figure illustrates that when Cl₂ is high, i.e. 25, 29, and 30 March, there is sometimes a large impact on RO₂, as can by seen by comparing the “Br Only” case (blue trace) with Base model (black trace). Again, [Cl₂] is very low when ozone is depleted, so simulated [RO₂] during ozone-depleted days becomes nearly indistinguishable for the Base and “Br Only” scenarios, as was shown already for HO₂. These results support the hypothesis that Cl can substantially increase the oxidation capacity of the Arctic troposphere when present at elevated mixing ratios. The levels of RO₂ that are present when Cl is not included in the model are primarily a result of both Br- and OH-oxidation chemistry; the RO₂ spike on 31 March that is seen in the “Br Only” simulation, for example, is a result of the observed spike in CH₂CHO and reaction with Br. The impact of the increased RO₂ due to Cl chemistry appears to be less significant as a BrO sink, however, as CH₃OO (the dominant RO₂ species) represents only a minor sink for BrO (Thompson et al., manuscript in
preparation), and BrO is likewise a minor sink for CH$_3$OO in comparison to HO$_2$ and NO (median sink contribution of BrO to CH$_3$OO is 0.05%).

Based on our analysis, it appears possible that the presence of chlorine can promote the production of reactive bromine species through two distinct mechanisms: 1) oxidation chemistry due to chlorine, which under certain chemical conditions can (e.g., high Cl$_2$, elevated NO$_x$) increase [HO$_2$] and/or [RO$_2$], thereby increasing the production of HOBr, and thus, the heterogeneous recycling of bromine, and 2) gas-phase HOCl can react with Br$^-$ in the aqueous phase to produce BrCl, thus producing reactive bromine (though this pathway is not as significant for Br atom production as is Br$_2$). Conversely, the presence of both chloride and bromide ions in the aqueous phase can lead to a competition between the production of Br$_2$, BrCl, or Cl$_2$. When we initially ran our model with only heterogeneous production of molecular halogens, large increases in gas-phase [Br] were produced when aerosol chloride was decreased by three orders of magnitude, but no difference in [Br] occurred when snowpack phase chloride was decreased by an equivalent amount. The snowpack is by far the primary source of both Br and Cl atom precursors in our model, as shown in Michalowski et al. (2000); however, the greater sensitivity to the aerosol chloride loading suggests that the aerosol could be a potentially important source of Cl atom precursors to the atmosphere. This may likely be related to the aerosol pH. Laboratory and field studies would be required to test this hypothesis. It is clear that the interactions between bromine and chlorine are quite complex in that chlorine chemistry can produce reactive bromine sinks (when at elevated concentrations), but the presence of chlorine can also increase Br atom production under certain circumstances, thereby increasing the rate of ozone depletion in an indirect fashion.
3.4 The impact of iodine chemistry and bromine-iodine interactions

Several modeling studies have also investigated the potential impact of iodine on ozone depletion in the troposphere (e.g., (Chameides and Davis, 1980; Davis et al., 1996; Sander et al., 1997; Calvert and Lindberg, 2004b; Saiz-Lopez et al., 2008)), in each case concluding that it could be very important. Iodine is potentially one of the most important species in Arctic ozone chemistry, and yet there is very little observational information. To date, no conclusive measurements of IO in the High Arctic have been achieved, though recently our group has detected substantial concentrations of I₂ in the snowpack air in Barrow with CIMS (Raso et al., 2015), thus, there is evidence that iodine chemistry is present to some extent.

As discussed in section 3.2, iodine chemistry can greatly enhance the rate of ozone depletion, both through the direct reaction of I with ozone (given that ozone is the primary I atom sink, Figure 4) and through the indirect effect of increasing available Br atoms through the cross-reaction of IO and BrO. This can be seen in Table 10, where it is shown that the [BrO]/[Br] ratio is decreased from 7.65 in the “Br Only” simulation to 7.34 or 6.12 upon addition of low iodine or high iodine levels, respectively. In a similar fashion, iodine chemistry also shifts the ClOₓ partitioning, decreasing the mid-day [ClOₓ]/[Cl] for 29 March from 247 in the base model (Br and Cl) to 244 or 230 when low or high levels are iodine are present, respectively, due to the IO + ClO reaction and decreased [O₃]. The decreased [ClOₓ]/[Cl] ratio could then impact the radical distribution through RO₂ production. The [IO]/[I] ratio is much lower than either the BrOₓ or ClOₓ ratio due to fast photolysis of IO and far fewer known I atom sinks (Vogt, 1999). Under the conditions employed here on 29 March, the [IO]/[I] ratio ranges from 1.57 to 2.60.

Previous modeling studies have concluded that iodine chemistry can impact the partitioning of important atmospheric oxidants by decreasing the [HO₂]/[OH] ratio through the
formation of HOI and subsequent photolysis. The rate constant for the IO + HO₂ reaction is a factor of ~2.5 and 10 faster than the analogous BrO and ClO reactions, respectively, thus, iodine has the potential to have a significant impact on the [HO₂] / [OH] ratio, and HO₂ can represent a primary IO sink during periods of low [IO] and [BrO] (Vogt, 1999). As mentioned above and shown in Table 10, the [HO₂] / [OH] ratio at mid-day on 29 March with no halogens present is 115. The presence of bromine alone decreases this ratio to 63, and inclusion of iodine further decreases this to 60.8 or 53.1 when at low or high levels, respectively. There of course can be wide variability in the absolute ratios depending on specific chemical conditions, such as NOₓ or VOC levels. Saiz-Lopez et al. (2007b) determined a [HO₂] / [OH] ratio of 33 due to bromine-iodine chemistry in Antarctica.

The decrease in the ClOₓ ratio affected by iodine could also impact the oxidizing capacity of the PBL. In fact, we see a slight increase in [RO₂] when iodine is present at high levels in the multiday model, with a greater increase during O₃-depleted days when iodine is included (green trace, Figure 9B). Because iodine atoms do not oxidize VOCs, the increased RO₂ is likely a result of the combined effects of a shift in the ClOₓ ratio toward Cl, and a shift in the HOₓ ratio toward OH, resulting in a decrease of RO₂ sinks, and increase in production. These impacts suggest an important indirect role for iodine in mediating the oxidation potential of the PBL, in the presence of the other halogens.

We note, however, that the observed [Cl₂] and [Br₂] are lower during ozone-depleted days, than during non-ozone depleted days. This suggests a surface activation mechanism controlled by O₃, presumably in part through a snowpack halogen explosion mechanism, such as has been observed in laboratory studies by, e.g., Oum et al. (1998a, 1998b) and the recent Pratt et al. (2013) study using natural Barrow snow. In our model, because the production mechanism of
I$_2$ is undefined and we have no observations with which to compare, the I$_2$ flux is of the same magnitude each day, independent of [O$_3$]. Therefore, during the O$_3$ depleted days when [Br$_2$] and [Cl$_2$] are much reduced, iodine chemistry becomes dramatically more important in relative terms. However, laboratory studies have indicated that I$_2$ can be produced via O$_3$ oxidation of aqueous iodide (Garland and Curtis, 1981; Martino et al., 2009; Carpenter et al., 2013). If it were indeed the case that I$_2$ is also produced through an O$_3$-mediated activation mechanism, this would likely eliminate the large difference between depleted and non-depleted days that is seen here. More studies are required to determine the dominant mechanism and kinetics for the heterogeneous surface production of I$_2$.

As discussed previously, the calculations in Table 10 were performed by fixing NO and NO$_2$ concentrations so that we could investigate halogen impacts on HO$_x$. However, we did examine the impact of halogen chemistry on the [NO$_2$][NO] ratio. This was performed simply by initiating the model with NO and NO$_2$ mole ratios of 25 and 50 pptv, respectively, and then allowing them to freely evolve. For these sensitivity studies, the presence of halogen chemistry in our model increased the [NO$_2$][NO] ratio, primarily through Reaction R16, though Cl chemistry can further increase this ratio through the production of RO$_2$ (e.g., Reactions R13 – R14). However, though bromine increases the mid-day NO$_x$ ratio from 0.68 to 1.81 for March compared to a model run conducted with no halogens, the further addition of low iodine only increases it to 1.85. The absolute concentrations of [NO$_2$] and [NO] both decrease with the addition of halogens, but the [NO$_2$][NO] ratio increases because XO reaction with NO is generally faster than reaction with NO$_2$. However, in the case of iodine, IO reaction with NO$_2$ is faster than its reaction with NO, and I atoms also react very efficiently with NO$_2$. Thus, chlorine should have a greater effect on increasing the NO$_x$ ratio than iodine. Indeed, when the model
was run with bromine and chlorine (the Base scenario), the \([\text{NO}_2]/[\text{NO}]\) ratio significantly increased to 8.4.

4 Conclusions

The goal of this work was to investigate the interactions and impacts of halogen chemistry on ozone depletion using a model that is constrained to a very unique set of observed, time-varying chemical conditions at the time of the event. With this approach, we have been able to dissect some of the important chemical pathways pertaining to ODEs, focusing on the interactions between the halogen radicals. It is clear that the interactions between bromine, chlorine, and iodine are very complex and highly dependent on the concurrent conditions of relevant species, such as \(\text{O}_3\), \(\text{HO}_x\), \(\text{NO}_x\), and the VOCs. As these species fluctuate, the partitioning of halogen species will also change, and so too will their impact on chemistry of the PBL. Thus, a full understanding of halogen chemistry requires the careful measurement of all these species (including \(\text{Cl}_2\), \(\text{Br}_2\), \(\text{HOBr}\) and \(\text{HOCl}\)).

This work has demonstrated that bromine chemistry is clearly the dominant destruction pathway for ozone depletion episodes, but that chlorine and, especially, iodine, can contribute significantly to both the rate and timescale of ozone depletion. The new observations of high chlorine levels at Barrow potentially change the way we view ODEs. Often, observations of rapid decline in ozone at various locations have been attributed to transport because bromine chemistry alone was not enough to account for the ozone depletion rate (Hausmann and Platt, 1994; Tuckermann et al., 1997; Bottenheim et al., 2002). As we have shown, complete ozone depletions can occur on timescales of much less than a day, and at elevated chlorine levels, even as short as several hours. This result suggests that more of the ODEs that are observed could be the result of local scale chemistry, however, as noted previously, our calculated timescales for
ozone depletion are based upon measurements conducted within the near surface layer and may not necessarily reflect the overall depletion timescale through the boundary layer. While chlorine is clearly not necessary to cause ozone depletion, it can impact the rate of ozone depletion through synergistic effects of cross-reactions that enhance Br atom recycling. Moreover, the presence of elevated chlorine levels can impact important Arctic chemical budgets, including HO$_x$, NO$_x$ and VOCs, with implications for the oxidative capacity of the PBL. More field measurements, including over the frozen Arctic Ocean, are necessary to evaluate the ubiquity of these elevated chlorine levels. In light of these new data, it is crucial that future Arctic modeling studies take into account the activity of chlorine.

In our model, we prescribed a Cl$_2$ mixing ratio that was varied from 25 pptv – 400 pptv for 29 March in sensitivity studies to investigate the impact of elevated Cl$_2$. However, we also determined the Cl$_2$ fluxes that would be necessary to produce the desired gas-phase [Cl$_2$]. In our model, volumetric fluxes ranging from 5.5x10$^5$ molecules·cm$^{-3}$·s$^{-1}$ to 1.45x10$^6$ molecules·cm$^{-3}$·s$^{-1}$ were required. If we assume a boundary layer mixing height of 300 m, the corresponding surface fluxes would be 1.65x10$^{10}$ – 4.35x10$^{10}$ molecules·cm$^{-2}$·s$^{-1}$. Similarly, the fluxes necessary for Br$_2$ range from 1.0 x 10$^3$ – 9.0 x 10$^6$ molecules·cm$^{-3}$·s$^{-1}$. These numbers are consistent with those used by Piot and von Glasow (2009). However, there are no Br$_2$ or Cl$_2$ measurements aloft of the surface in the Arctic. Utilizing the method of Guimbaud et al. (2002), the effective mixing height, Z*, for Cl$_2$ at midday is only 2.15 m, making the calculated Cl$_2$ fluxes 1.2x10$^8$ – 3.1x10$^8$ molecules·cm$^{-2}$·s$^{-1}$; Z* for Br$_2$ is 0.5 m, leading to a calculated Br$_2$ flux of 5.0 x 10$^4$ – 4.5 x 10$^8$ molecules·cm$^{-2}$·s$^{-1}$. Therefore, field studies aimed at determining the magnitude of the surface flux of Cl$_2$ and Br$_2$ are warranted. This disparity also points out the
importance of measurements of the vertical profiles of molecular halogens above the snowpack/sea ice surface.

Finally, we find that iodine could be the most efficient halogen for depleting ozone on a per atom basis, given our assumed fluxes. We assume very low [IO] in our model (≤1 pptv), below the detection limit of the DOAS instrumentation, and yet the resulting enhancements in ozone depletion are quite significant. Higher levels of iodine would certainly have a dramatic effect on ozone chemistry, as illustrated by our simulations incorporating 0.5 pptv I$_2$ (~10 pptv IO). A possible mechanism for the production of I$_2$ in the polar regions is the activity of ice algae and phytoplankton that produce iodine-compounds, which are then wicked to the surface through brine channels (Mahajan et al., 2010). It has also been suggested that the primary productivity in Antarctic ice and waters may be higher than in the Arctic (Arrigo et al., 1997; Gosselin et al., 1997; Lizotte, 2001; Mahajan et al., 2010), possibly accounting for the difference in apparent iodine activity between the two poles. However, as the ice in the Arctic continues to thin, and as more multiyear ice has been replaced by seasonal sea ice (Nghiem et al., 2012), the algae and phytoplankton productivity in the Arctic has increased (Arrigo et al., 2008; Arrigo et al., 2012). This could lead to an increase in iodine emissions in the future, and thus to a greater occurrence of springtime ODEs. The further development of analytical methods capable of measuring the very low [IO] and [I$_2$] potentially present in the Arctic should be a high priority for the further advancement of this research.

Acknowledgements The modeling analysis presented herein was funded by the National Science Foundation grant ARC-0732556. Partial support for CT during preparation of this manuscript was provided by the NSF Atmospheric and Geospace Sciences Postdoctoral Research Fellowship program. The authors wish to thank the organizers of the OASIS 2009 field campaign, the Barrow Arctic Science Consortium for logistics support, and all of the researchers who contributed to the campaign.

Fig. 1. Ambient measurements of O$_3$, Cl$_2$, Br$_2$, NO$_2$, NO, CO, VOCs, and OVOCs that are incorporated into the model. Mixing ratios for the NMHCs that were collected as canister samples were interpolated between samples. Available canister sample data points are indicated on their respective plot. The photolysis rate coefficient ($J$) is shown for NO$_2$ as an example in Panel A. Time is expressed in Alaska Standard Time.
Fig. 2. Modeled (black) compared to observed (red) time-series for BrO, $\text{HOBr}$, ClO, OH, and $\text{HO}_2$. Modeled Br and Cl (black) are compared to steady-state approximations as calculated in Stephens et al. (2012) (red). All concentrations are shown in molecules cm$^{-3}$ on the left axis and...
as mole ratios in pptv on the right axis. Radiation is shown as the cyan trace as a reference. Time is expressed in Alaska Standard Time.

**Fig. 3.** (A) Time series of in situ HONO observations (red data) and modeled HONO including an additional flux (black trace) and without an added flux (blue data). (B) Time series of observed NO (black trace) and NO\(_2\) (red trace) that has been re-scaled to a smaller range on the y-axis to show the relatively higher NO\(_x\) mole ratios on 29 and 30 March.
Fig. 4. Simulated time-series of IO shown for the “Low Iodine” (solid line) and “High Iodine” (dashed line) scenarios. The “Low Iodine” scenario and the “High Iodine” scenario correspond to a daytime average of 0.025 pptv and 0.5 pptv I$_2$, respectively. Time is expressed in Alaska Standard Time.

Fig. 5. Average diurnal cycles of the fraction of O$_3$ depleted by Br, Cl and I atoms for the Base Model scenario, the Base + Low Iodine scenario and the Base + High Iodine scenario. Br is shown in the blue trace, Cl in the red trace, and I in green trace; radiation is shown in the cyan trace as a reference. Data shown is only for periods when O$_3 > 5$ ppbv. Time is expressed in Alaska Standard Time.
Fig. 6. A) Time-varying fraction of Br (blue), Cl (red), and I (green) atoms that react with O$_3$ across the 7 days of the simulation. B) Time-series of observed ozone mole ratios, with radiation is shown as the cyan trace as a reference. Time is expressed in Alaska Standard Time.
Fig. 7. Time-varying rates (in molecules cm\(^{-3}\) s\(^{-1}\)) of the important Br atom sinks during ODEs (O\(_3\) < 5 ppbv). The inset pie chart represents the fractional importance of each sink calculated as the median value across the three days shown. Time is expressed in Alaska Standard Time.
Fig. 8. Rates of reaction for the most important Cl atom reaction partners during ODE days (Panel A; O₃ > 5 ppbv) and non-ODE days (Panel B). The corresponding pie charts represent the fractional importance of each sink, calculated as median values across the days shown. HOₓ is defined as the sum of OH and HO₂, NOₓ is the sum of all nitrogen oxide compounds, VOCs includes all non-functionalized alkanes, alkenes, and acetylene, OVOCs includes all non-radical organic compounds with an oxygen (carbonyls, ketones, carboxylic acids), and halogens includes all inorganic halogenated species.
Fig. 9. Comparison of modeled HO$_2$ (Panel A) and RO$_2$ (Panel B) from four different modeling scenarios: Base (Br and Cl present; black trace), Br Only (blue trace), Cl Only (red trace), and Base + High Iodine (green trace). RO$_2$ is defined here as the sum of the methyl through butyl forms of alkyl peroxy radicals. Time is expressed in Alaska Standard Time.
**Fig. 10.** Comparison of HO$_x$ production rates (in molecules·cm$^{-3}·$s$^{-1}$) for five primary pathways: OH production from HONO photolysis (orange trace), OH production from O$_3$ photolysis and subsequent reaction with H$_2$O (black trace), HO$_2$ production from HCHO photolysis (green trace), HO$_2$ production from Br + HCHO reaction (blue trace), and HO$_2$ production from Cl + HCHO reaction (red trace). The corresponding pie charts represent the fractional importance of each source for a select ODE day (27 March; O$_3$ > 5 ppbv) and a select non-ODE day (30 March) calculated as the median value across each day. Time is expressed in Alaska Standard Time.
