We thank the reviewer for the comments that helped us to improve this MS. The suggestions are applied in the revised MS. The questions and comments are answered below.

**Comment 1:** The presented results are, in my opinion, limited in terms of new findings and correspond rather to a methodological paper on the development of 1-D model. In session 3 and 4, there is a lack of comparisons between results and references to support the reliability of the study. The text needs to be clarified and corrected to improve the original aspects of the paper for publication. Even if the purpose of this study is the estimation of atmospheric volcanic iron fluxes to the Ocean, it is an upstream work focusing on volcanic physico-chemical processes, which will be rather adapted to a journal on Earth problematic (as the majority of cited journal in the references)?

**Reply:** In general, a numerical model does not necessarily produce new concepts or laws. In other words, numerical models are diagnostic tools to analyze the behavior of a system and/or to understand the observational data based on the known theories (Jacobson 2005, Seinfeld and Pandis 2006). Likewise, our study does not intend or claim to formulate any new law or concept concerning the volcanic gas and ash. Instead, it assimilates a wide range of well-documented mechanisms and processes from volcanology (e.g. Rose and Durant, 2009), eruption plume dynamics (e.g. Mastin 2007), atmospheric chemistry (e.g. Jacobson 2005), ash dissolution (e.g. Oelkers and Gislason, 2001) etc. into a numerical model in order to quantitatively explain the ash-gas-aerosol interaction within the eruption plume. Therefore, similar to all model-based studies, the novelty of this work arises from investigating the role of “well-known” theories like those mentioned by the reviewer in governing the behavior of a “less-known” system here called “ash iron mobilization in volcanic eruption plumes”.

The model presented in this study considers, for the first time, volcanic ash as a chemically active agent in the eruption plume. Its approach in simulating the gas-ash-aerosol interaction is also novel and leads to original findings. For instance, it demonstrates how the efficiency of HCl, SO2 and HF scavenging by volcanic aerosols could be influenced by the proton consumption through ash dissolution. This can modulate the amount of the volcanic gases that reach the middle atmosphere and thus their climatic impacts. Therefore, this study sheds more light on the impacts of in-plume and in-cloud processing on not only the ash iron mobilization but also the gas scavenging efficiency by aerosols within the eruption plume.

As mentioned above, this interdisciplinary research assimilates different methods and assumptions, which are developed and extensively used in various scientific disciplines. However, atmospheric chemistry and physics is the main stream of the methodology used in this paper (>90% of the processes). The results have also significant implications for the atmospheric science community for e.g. to better comprehend the fate of the volcanic emissions in the atmosphere and their climate impacts. Therefore, despite of its multidisciplinary nature, we regard this MS fully within the scopes of the ACP journal.

**Comment 2:** The title is very general and needs to be changed, e.g. “Investigation on the physicochemical processes implied on ash iron mobilization in volcanic eruption plumes (by 1-D modelling)”.

**Reply:** Based on this comment, the title is revised as follow: “Ash iron mobilization through physicochemical processing in volcanic eruption plumes: a numerical modeling approach”

**Comment 3:** 32537 L5: It is mentioned that “iron near the volcanic vent is mostly insoluble”, that means? Several studies on the solubility of fresh volcanic ash (< 1 or 2 hours) show that Fe ash has a very low solubility but is as soluble as dust Fe and that solubility seems to decrease with the age of
volcanic ash, so probably with the distance to the source (e.g. Olgun et al., 2011). Mostly insoluble vs low solubility: what is the order of magnitude? Is it really this difference of solubility which can explained the fertilizing role of volcanic ash? Or simply the large deposition of volcanic particles (as developed in your paragraph p32553 L3). Please develop these points to support the rationale of the study.

Reply: As suggested by the reviewer, we revised this part in the MS to better clarify the rationale of the study (please see the highlighted text in P2 of the revised MS):

“Upon eruption and near the volcanic vent, iron in the ash occurs mostly in non-soluble forms, i.e., in silicate glass and in primary Fe-bearing silicates and Fe-oxide minerals [Heiken and Wohletz, 1992, Schmincke, 2004]. In the surface ocean however, the soluble species on the ash surface are suggested to be the main source of the iron altering the ocean’s biogeochemistry [Hamme et al., 2010; Duggen et al., 2010; Achterberg et al., 2013]. Solubility of iron in airborne particles is known to be strongly linked to its chemical speciation and mineralogy [von der Hyden et al. 2012]. However, it is not yet fully understood which volcanic and atmospheric processes can modulate these properties thereby modify the ash iron solubility.”

Comment 4: 32539 L9: It is known for other mineral particles, in particular dust, that cloud processing, acidification, mineralogical composition... are major parameters playing on iron solubility (e.g. Desboeufs et al., 2001; Hand et al, 2004; Schroth et al., 2009). I think that this literature should be mentioned in the background session then discussed in comparison of your results.

Reply: The suggested literature is added to the revised MS (please see the highlighted text in for e.g. P2 L36 and P8 L259 of the revised MS). Volcanic ash and mineral dust are known to be dissimilar in terms of chemical, physical and mineralogical properties [Langmann 2013]. Besides, volcanic ash plumes and clouds are extremely wet and acidic environments in comparison to the mineral dust clouds [Langmann 2013]. Hence direct comparison between iron mobilizations processes affecting two dissimilar components within two distinct systems is not vigorous. Accordingly, despite of utilizing the methods presented in the mineral dust research, we avoid comparing our work with the results of the mineral dust studies. Only some general discussions concerning for e.g. the impact of the pH and mineralogy on dissolution efficiency (Desboeufs et al. 2001) are added to the revised MS (please see the highlighted text in for e.g. P11 L347 of the revised MS).

Comment 5: 32544: Size distribution of the ash: The paper focuses on the processes improving iron mobilization in the volcanic plumes to estimate its biogeochemical impact on phytoplankton, i.e. particles which can be advected and deposed from volcanic plumes to the Ocean. The size distribution of transported volcanic particles in plume (even close to the volcano) seems to be limited to 100 µm with a main fraction inferior to 20 µm (e.g. Martin et al., 2008 or Mather et al., 2004). Why do you consider particle sizes < 1mm, i.e. fine ash rather than really volcanic aerosols?

Reply: While the ash particles refer to the solid material generated through magma fragmentation inside the volcano, the particles studied by Martin et al., 2008 or Mather et al., 2004 are the liquid aerosols formed due to microphysical processes inside the volcanic plume and cloud. Therefore, these two kinds of particles in the eruption plume have quite different origins and physicochemical characteristics. For a detailed explanation about the fine ash size distribution please see Rose and Durant (2009).

Furthermore, we focus on “plinian and sub-plinian eruption plumes” in this study while the studies mentioned by the reviewer (Martin et al. 2008; Mather et al 2004), investigate “quiescent eruption plumes”. These two plume systems are entirely different in terms of physical chemistry as well as
dynamics (Sparks et al 1997). Quiescent eruption plumes have usually no ash as a major player in the system (see also Martin et al 2012, Mather et al 2003 for more details). Thus the mechanisms of aerosol formation within these two distinct systems are dissimilar. While in “quiescent eruption plumes” homogenous nucleation of sulfate particles is the main particle growth mechanism (Martin et al. 2012), in presence of ash particles in “plinian and sub-plinian” plumes, such a mechanism is known to be unlikely (Textor et al. 2003). Instead, condensation of sulfuric acid on the ash surface is the main sulfate formation mechanism in such plumes (Textor et al. 2003, Tabazadeh and Turco, 1993). Water condensation and halogen uptake by such particles is accordingly different (Textor et al. 2003).

**Comment 6:** 32548 L9: It is interesting to know the iron dissolution from fine ash, but in a biogeochemical context, could you provide the amount of generate soluble iron salts dependent on this dissolution, since it is this amount which will be critical to estimate the soluble iron from volcanic aerosols? Globally, it is a pity that the fraction of soluble salts is not estimated in the paper since it is really the paramount information to estimate the impact of iron ash after deposition to the ocean!

**Reply:** We agree with the reviewer that such estimation is scientifically very interesting. However, this could be a huge leap from talking of Fe mobilization in volcanic ash to then estimating the fraction of soluble Fe salts that may forms at ash surface through aqueous chemistry and cloud microphysics. These processes are beyond the scope of this MS. Although this estimation at global scale is not feasible in the framework of this study, we certainly keep this suggestion in mind for our future works in this filed, which will be focused on aqueous chemistry and cloud processing.

**Comment 7:** 32549 L1: The pH between 0.3 and 0.5 (Table 4) found by modeling. In order to support the reliability of your chemical results, please specify if it is an usual pH of cloud droplets in volcanic plumes?

**Reply:** To our knowledge, there is unfortunately no direct measurement of such pH values on volcanic ash. This is mainly because the analyzed ash samples in the literature have already undergone several other cloud processes (e.g. freezing/melting, condensation/evaporation) that significantly affect the pH but are beyond the scope of this research. Nevertheless, it is strongly suggested in several studies that the aqueous phase at the ash surface reach most likely pH<1 within the first hours in the eruption plume (Ayris and Delmelle 2012, Moune et al 2009)

**Comment 8:** 32549 L11: Results show an impact of HCl scavenging on pH which itself control iron dissolution. Please mention that pH effect on iron dissolution from oxide is already known (e.g. Schwertmann, 1991), in particular with HCl (Sidhu et al., 1981).

**Reply:** The suggested literature is added to the revised MS (please see the highlighted text in for e.g. P2 L36, P8 L259, P11 L347 of the revised MS).

**Comment 9:** 32549 L25: “Since iron content of fayalite...is much higher than that of the glass, we can safely neglect the release from the glass.”. I’m not agree with that: Even if iron content in glass is low, if its solubility is very superior to the iron solubility in magnetite, the glass could be the major provider of released iron. See paper of Journet et al., 2008) which showed that illite (Fe = 2wt%) is an higher provider of soluble iron than goethite (Fe=62wt%).

**Reply:** The reviewer is correct that glass dissolution rate is generally faster than that of minerals. But this may no longer hold at pH<2 (Hamilton et al., 2000). To better clarify the assumptions concerning the ash initial conditions, this part of the MS is rewritten as below (please see the highlighted text in P8 of the revised MS):
“Ash composition in this study refers to the composition of the ash surface rim with a thickness of <100 nm (Achteberg et al. 2013, Gislason et al. 2011, Hoshyaripour et al. 2014). This rim undergoes substantial physicochemical interactions with gases and aerosols within the plume and cloud that can eventually lead to generation of a salt layer on the ash surface (Achteberg et al. 2013, Gislason et al. 2011). This salt layer is suggested to be the main source of soluble iron in volcanic ash upon contact with sea water (Duggen et al. 2010). Iron at the ash surface leaving the high-temperature zone mainly occurs as component of glass and as Fe-carrying phases (Bayhurst et al., 1991; Nakagawa and Ohba, 2003). Iron release from Fe-carrying minerals involves breaking only one Fe-O bond while in glass it may require breaking several metal-oxygen bounds through nonstoichiometric dissolution (Oekler 2001). Furthermore, at pH<2 mineral may dissolve even faster than the corresponding glass (Hamilton et al. 2000). Considering this and given the limitation of data on nonstoichiometric iron release from the ash at pH<2 and T< 25°C, here we consider the minerals as the main source of iron within the ash particle and regard glass as a sink for protons (See Table 2).

It is suggested that iron mobilization efficiency is connected to its redox state in the minerals (von der Hyden 2010, Desboeufs et al. 2001). To evaluate this hypothesis for volcanic ash we consider three redox end-members: fayalite as the non-oxidized, magnetite as moderately-oxidized and hematite as highly-oxidized Fe-carrying phases at the ash surface (see Hoshyaripour et al. (2014) for more details). Ash in this reference scenario consists of magnetite (Fe3O4) since it contains iron in both oxidation states (ferric and ferrous). It is also extensively observed in volcanic ash samples (Gislason et al. 2011, Censi et al., 2010; Bayhorst et al. 1987). The impacts of other minerals as well as silicate glass are discussed in a detailed sensitivity study in Sect. 4.2.”

Comment 10: 32552 L24: the results presented in the table 5 show a large range of calculated RFe. This range is important to compare with the experimental data! So, please discuss on the parameters explaining this range (is it exclusively due to the range of Di?) in order to validate the comparison with the experimental data.

Reply: The large range in table 5 is mainly due to range of Di that is itself governed by two independent factors: halogen content of the gas and iron oxidation state in the ash surface. This is already mentioned in the MS but a short explanation is also added (as the reviewer suggested) to facilitate the interpretation of the reported values and their comparison with the experimental data (please see the highlighted text in P14 L445 of the revised MS).

Comment 11: Table 4: please precise in the legend: CP, DP, H and the cases A, B, C and D.

Reply: The legends are explained in the revised MS. The abbreviations CP, DP and HS are replaced with halogen-rich, carbon-rich and sulfur-rich gas in the revised MS, respectively.

Comment 12: Table 5: please precise the legend: CFe, Di, RFe

Reply: The legends are explained in the revised MS.

Answer to the comments of Dr. Morgan Jones

We thank the reviewer for the comments that helped us to improve this MS. The suggestions are applied in the revised MS. The questions and comments are answered below.

1) I believe too much of the focus on nutrient release from volcanic ash concerns iron.

While very important and a key limiting nutrient in some open ocean settings, it is not the only nutrient to do so. Nitrogen, P, Si, Ca and many transition metals are all important to the healthy functioning of an ecosystem, and the fertilisation potential of volcanic ash deposition reflects that many of these elements are present in soluble surface ash coatings. HNLC regions are only 20% of the world’s oceans, so this focus on just one element is counterintuitive. I suggest a revision to use Fe as an important nutrient and also a proxy for poorly soluble metals, rather than the inferred suggestion that it is the sole driver of primary productivity.

Reply: We completely agree with the reviewer about that one should not overlook the role of other nutrients rather than iron in the primary productivity. A short sentence is added to the revised MS to highlight this important point.

2) There have been recent studies (e.g. Pearce et al., 2013) using basaltic fluvial sediment and isotopic analysis that show that insoluble elements (in this case Nd, but the same would apply for Fe) rapidly change the isotopic composition of seawater once they arrive in estuaries without changing the dissolved concentrations. This means that there are fluid-rock interactions (dissolution and precipitation, and/or element exchange) that occur in saline fluids could release Fe from glass and minerals without the need for surface coatings. In other words, ash iron may not be as insoluble as first thought, due to the effects of salt, organic breakdown, or a combination of factors. An article currently in press by Morin et al. (2015) would be good to read as well if it is published in time for this revision.

Reply: This is a very interesting point. It implies that iron mobilization can take place within the aquatic environments after deposition. This effect could be however limited by the residence time (sedimentation rate) of the ash particles in the surface ocean (Lindenthal et al 2013). But it definitely requires more detailed investigations to distinguish the iron mobilization happening in the eruption cloud and the surface ocean.

3) Line 25: There are previous investigations that showed a link between ash deposition and fertilisation, namely Uematsu et al. (2004) and Censi et al. (2010). These should also be cited here.
Reply: The suggested literature is added to the revised MS (please see the highlighted text in for e.g. P2 L35 of the revised MS)

4) Lines 55-60. It is not clear from the current text why Fe-salts are found in insufficient quantities. Please clarify, and add the caveat that while these species were clearly not the main source of Fe from Kasatochi ash, this is still a sample size of one.

Reply: Ayris et al. (2014) does not provide any quantitative measure that can be used to estimate the amount of iron chloride salt formed in the experiment. Therefore, it is difficult to evaluate their claims concerning iron mobilization in volcanic ash. The text is revised to better clarify this point and the suggested remarks are added to the revised MS (please see the highlighted text in P3 L36, P8 L259, P11 L347 of the revised MS).

5) Given the range of volcanic ash compositions within each tectonic setting, I do not find it useful to classify volcanic products on the basis of convergent plate, divergent plate and hotspot. There is more in common between basaltic volcanism from all of these settings than the range of eruption chemistries at convergent plate boundaries. This section still merits attention, but I think it needs altering to reflect explosive products are likely to be silica rich and/or phreatomagmatic. With the latter, the washing/incorporation of acids by excess water is an important factor for the availability of acids for leaching. The authors even acknowledge that the initial subdivision by Olgun et al. (2011) was based on a limited dataset. The extensive review by Witham et al. (2005) should also be referenced here. The message here that melts with high Cl (which may be more prevalent at convergent boundaries, but also coastal volcanoes such as Surtsey) and higher acid species are more likely to release more Fe from solid phases.

Reply: As explained in the MS, we use tectonic settings to represent the variations in the magmatic gas composition and not the ash composition. But we agree with the reviewer that this partitioning might be confusing. Therefore we replaced the names convergent plate (CP), divergent plate (DP) and hot spot (HS) with halogen-rich, carbon-rich and sulfur-rich gas, respectively. The suggested literature is also added to the revised MS (please see the highlighted text in P8 of the revised MS).

6) The abbreviations CP, DP and HS confuse matters and should be deleted.

Reply: The abbreviations CP, DP and HS are replaced with halogen-rich, carbon-rich and sulfur-rich gas in the revised MS.
7) Table 3 – please put in the caption where this data is from. Also mention in the main text that these are just a snapshot of volatile speciation, and that volcanic gas chemistries can vary considerably.

Reply: The caption is modified and the suggested remark is added to the revised MS.

8) Figure 2. – Recent ash-fall particle size measurements from Eyjafjallajökull and similar have shown that in some instances the fine fraction can be considerably greater than measured by Rose and Durant (2009). Given that this would strongly affect the available surface area from nucleation, it is worth mentioning here.

Reply: The suggested remark is added to the revised MS.
Ash iron mobilization through physicochemical processing in volcanic eruption plumes: a numerical modeling approach

G. Hoshyaripour 1, M. Hort 1, and B. Langmann 1

Correspondence to: Gholam Ali Hoshyaripour (gholamali.hoshyaripour@uni-hamburg.de)

Abstract.

It has been shown that volcanic ash fertilizes the Fe-limited areas of the surface ocean through releasing soluble iron. As ash iron is mostly insoluble upon the eruption, it is hypothesized that heterogeneous in-plume and in-cloud processing of the ash promote the iron solubilization. Direct evidences concerning such processes are, however, lacking. In this study, a 1D numerical model is developed to simulate the physicochemical interactions of the gas-ash-aerosol in volcanic eruption plumes focusing on the iron mobilization processes at temperatures between 600 °C and 0 °C. Results show that sulfuric acid and water vapor condense at ~150 °C and ~50 °C on the ash surface, respectively. This liquid phase then efficiently scavenges the surrounding gases (>95% of HCl, 3–20% of SO₂ and 12–62% of HF) forming an extremely acidic coating at the ash surface. The low pH conditions of the aqueous film promote acid-mediated dissolution of the Fe-bearing phases present in the ash material. We estimate that 0.1 to 33% of the total iron available at the ash surface is dissolved in the aqueous phase before the freezing point is reached. The efficiency of dissolution is controlled by the halogen content of the erupted gas as well as the mineralogy of the iron at ash surface: elevated halogen concentrations and presence of Fe²⁺-carrying phases lead to the highest dissolution efficiency. Findings of this study are in agreement with the data obtained through leaching experiments.

1 Introduction

In 2010, sockeye salmon unexpectedly reached record numbers in British Columbia’s Fraser River after low numbers during recent decades (Larkin, 2010). It has been hypothesized that the solu-
ble iron contained in the volcanic ash from the eruption of Kasatochi volcano, Aleutian Islands, in 2008, could have indirectly provided a feast for the salmon (Parsons and Whitney, 2012) through an enhanced marine primary productivity (MPP) and phytoplankton bloom upon ash deposition into Fe-limited ocean surface waters (Olgun et al., 2013a). This phytoplankton bloom was indeed the first direct evidence of a fertilization effect of volcanic ash iron on the surface ocean (Langmann et al., 2010; Hamme et al., 2010). While small-scale ash iron fertilization events (e.g., after Eyjafjallajökull eruption in 2010, Iceland) trigger perturbations in the local marine biogeochemistry (Olgun et al., 2013b; Achterberg et al., 2013), large-scale events (e.g., the 1991 eruption of Mt. Pinatubo, Philippines) may stimulate the MPP and in turn, the atmospheric CO₂ drawdown globally (Sarmiento, 1993; Watson, 1997) with significant impacts on the climate system (Robock, 2000).

Upon eruption and near the volcanic vent, iron in the ash occurs mostly in non-soluble forms, i.e., in silicate glass and in primary Fe-bearing silicates and Fe-oxide minerals (Heiken and Wohletz, 1992). In the surface ocean however, the soluble species on the ash surface are suggested to be the main source of iron altering the marine biogeochemistry (Hamme et al., 2010; Duggen et al., 2010; Achterberg et al., 2013; Censi et al., 2010). Solubility of iron in airborne particles (e.g., mineral dust) is known to be strongly linked to its chemical speciation and mineralogy (Schroth et al., 2009; Journet et al., 2008). However, it is not yet fully understood which volcanic and atmospheric processes control these properties and thereby modulate the ash iron solubility.

Volcanic ash is the tephra with a diameter <2 mm (Rose and Durant, 2009) typically composed of silicate glass and crystalline materials generated by fragmentation of the rising magma as well as erosion of the conduit wall rock (Heiken and Wohletz, 1992). While physical properties of the ash (size distribution, specific surface area etc) are usually dictated by the fragmentation and eruption mechanism, its bulk mineralogy and composition are controlled by cooling and crystallization of the source magma (Dingwell et al., 2012).

During the transport from the magma fragmentation to the high altitudes in the atmosphere and finally to the surface ocean, ash undergoes numerous physicochemical processes within the volcanic conduit, plume and cloud (Table 1). As a result, the surface of the ash does not necessarily mirror the mineralogy and composition of the source magma since it constantly interacts with volcanic gases, aerosols and ambient air (Horwell et al., 2003; Delmelle et al., 2007). For instance, Bagnato et al. (2013) observed a significant difference between the leachate compositions of the proximal and distal ash deposits of Eyjafjallajökull eruption in 2010, Iceland. These alterations in the ash leachate composition are attributed to the in-plume and in-cloud processing of the volcanic ash surface (Bagnato et al., 2013). Reviews of such processes are provided, for e.g., by Textor et al. (2005). Here we briefly summarize those processes that are relevant for ash iron mobilization during plinian and sub-plinian eruptions (for a detailed review please see Ayris and Delmelle, 2012).

In-conduit processes refer to high-temperature post-fragmentation subterranean gas-ash interaction. Large explosive eruptions with deep magma fragmentation are likely to be affected by sig-
nificant in-conduit gas-tephra interaction at temperatures above 600 °C (Ayris et al., 2013). Such interactions can account for SO$_2$ scavenging by glass-rich tephra that proceeds by a Ca$^{2+}$ diffusion-driven mechanism (Ayris et al., 2013). It is also suggested that high-temperature HCl adsorption prior to the mixing of the erupted material with the ambient air could produce minor quantities of Fe-bearing salts on the ash surface (Ayris et al., 2014). Although these findings provide valuable experimental evidences, it is difficult to quantitatively estimate the contribution of such processes in the ash iron mobilization and its relevance to the ocean fertilization. Therefore, the question of whether or not such high temperature processes can be considered as the dominant mode of ash iron mobilization is difficult to answer.

In-plume processes encompass a wide range of temperature (from magmatic temperatures down to ambient temperature) and distance (from the vent up to the neutral buoyancy level (NBL)) during which the volcanic ejecta is mixed with the ambient air. As shown in Table 1, we can identify three temperature-dependent sub-zones within the in-plume region: high-, mid- and low-temperature (hereafter referred to as high-, mid- and low-T). Hoshyaripour et al. (2014) investigated the high-T in-plume processes (T>600 °C) through modeling the direct gas-ash interactions governed by mixing of the magmatic gas and ash with the ambient air. They reported that such processes do not solubilize the iron directly but significantly control its mineralogy and oxidation state at the ash surface within a <100 nm thick rim. They emphasized that further in-plume and in-cloud processes can play the major role in ash iron mobilization.

Mid- and low-T reactions (T<600 °C) within the eruption plume could alter the ash surface composition, and thus potentially influence further (photo)chemical reactions during transport of ash in the atmosphere (Ayris and Delmelle, 2012). It is suggested that sulfuric acid condenses first which is then followed by water condensations in the cloud zone (Óskarsson, 1980). This process develops an acidic coating on the ash surface that is expected to dissolve the ash iron efficiently (Delmelle et al., 2007). In-cloud processing of volcanic ash, which is mainly governed by heterogeneous reactions involving liquid water and ice, could also mobilize the insoluble iron contained in the ash surface through, for e.g., dissolution/precipitation and freezing/melting cycles (Duggen et al., 2010).

Ayris and Delmelle (2012) speculated that these processes could eventually lead to formation of soluble Fe-sulfate/chloride/fluoride salts on the ash surface. However, direct theoretical and experimental evidences supporting these hypotheses are required.

Previous modeling investigations on physical chemistry of volcanic eruption plumes have mainly focused on gas chemistry (e.g., Bobrowski et al., 2007), micro-physical processes like condensation, scavenging and freezing (Tabazadeh and Turco, 1993; Textor et al., 2003) and also particle aggregation (Textor et al., 2006b, a) leaving the chemical interactions of the aqueous phase and the ash surface nearly unexplored. As a result, despite of advancements made by individual studies, a detailed insight into the in-plume and in-cloud processes that control the iron mobilization in volcanic ash remains lacking. This study therefore aims to investigate the role of these processes in ash iron
mobilization through numerical modeling of the gas-ash-aerosol interactions. The main objectives are 1) to find out how much iron (ferrous and ferric) is mobilized from the ash surface (dissolved in the aqueous phase) during its vertical transport within the eruption plume and 2) to identify the favorable conditions/processes for iron mobilization in volcanic ash. In the following sections, first the modeling concepts and methods are presented. Then the results of the simulations and their sensitivity to different parameters are discussed. Finally the results are compared with experimental measurements and conclusions are given.

2 Methodology

2.1 Modeling framework

Figure 1 shows the main in-conduit, in-plume and in-cloud interactions of gas-ash-aerosols. In-conduit and high-T in-plume zones (zones 0 and 1 in Fig. 1) have been investigated previously (Hoshyaripour et al., 2014; Ayris et al., 2013, 2014). In this study we explore mid- and low-T in-plume and warm in-cloud zones (zones 2, 3 and 4 in Fig. 1, respectively) through a simplified 1D modeling approach. In other words, the lower boundary is the material leaving the high-T zone and entering zone 2 (T=600 °C) and the upper boundary is the output of zone 4 (T~ 0 °C). Sulfuric acid condenses first (at the boundary between zones 2 and 3) followed almost immediately by water condensation (at the boundary between zones 3 and 4) and thus, dissociates to H⁺ and HSO₄⁻ where we can assume that the processes are similar to conventional in-cloud processes considered in atmospheric sciences (Seinfeld and Pandis, 2006). In this study we assume that ash particles are active as condensation nuclei for sulfuric acid and water condensation (Textor et al., 2006b).

Since freezing has a significant impact on the physicochemical interactions (Textor et al., 2003), we consider two subsections for the in-cloud zone: warm (without ice/before freezing) and cold (with ice/after freezing). In the warm in-cloud zone, the aqueous phase scavenges the volatiles (e.g., HF, HCl and SO₂) from the surrounding atmosphere and also dissolves the constituents of the ash surface. These processes release cations (e.g., Na⁺, Fe²⁺, Al³⁺) and anions (e.g., Cl⁻, SO₄²⁻, F⁻) into the liquid phase, which can react with each other generating soluble salts (Stumm and Morgan, 1996). When the temperature of the system reaches the freezing point (cold in-cloud or zone 5 in Fig. 1), ice forms at the ash surface and interacts with the surrounding atmosphere (Textor et al., 2003) and also with the ash surface. This zone is, however, beyond the scope of this study.

Approximate temperature ranges associated with different zones are shown in Fig. 1 and discussed in section 3. It is noteworthy that these boundaries can slightly change according to the atmospheric conditions and eruption dynamics and also may have some overlap with each other. For instance, the presence of ions in the liquid phase can cause a depression in saturation vapor pressure and shift the freezing point to lower temperatures leading to super-cooled water formation (Tabazadeh and Turco,
Nevertheless, these are reasonable boundaries to better distinguish the role of different environmental conditions on gas-ash-aerosol interactions.

### 2.2 Dynamics of the eruption plume

The focus of this work is on sub-plinian and plinian eruption plumes that can rise up to several tens of kilometers into the atmosphere carrying huge amounts of volcanic gas and ash (Sparks et al., 1997). The ash erupted in these events could be transported thousands of kilometers downwind to reach the ocean (Duggen et al., 2010; Schmincke, 2004).

As a first order approximation, the travel time from the vent to the NBL is 150-250 seconds during which the plume temperature is lowered by ~800-1000 °C (Hort and Gardner, 2000). Thus, the mixture cooling rate is in the range of 4-7 °C s\(^{-1}\) in the convective region of the plume. As a reference atmosphere we use the standard atmosphere having a sea level temperature of 0 °C, a thermal lapse rate in the troposphere of 6.5 K km\(^{-1}\), a troposphere thickness of 11 km, a 9-km-thick tropopause, and no humidity according to US Committee on Extension to the Standard Atmosphere (1976). Since processes involving ice (T<0 °C) and stratospheric processes are beyond the scope of this study, we set 0 °C plume temperature and/or 11 km as the upper boundary of our model. Assuming a vent altitude of 1 km together with the average rise time of 200 s, we obtain an average cooling rate of 5 °C s\(^{-1}\) and an average ascent velocity of 50 m s\(^{-1}\) for our reference scenario, both values being well in the range suggested in the literature (cooling rate of 4-7 °C s\(^{-1}\) (Hort and Gardner, 2000) and plume ascent velocity of 40-80 m s\(^{-1}\) (Mastin, 2007)). The results discussed below are not sensitive to these particular values over a wide range of variation. At each step, temperature and elevation of the plume are calculated as prognostic variables based on these presumed rates while pressure as well as the kinetic and thermodynamic reaction rates are derived as diagnostic variables.

### 2.3 Mass balance equations

Concentrations of gas- and particulate-phase species in the plume are determined by solving a system of coupled mass balance equations. In its most general form, this equation is (Meskhidze et al., 2005):

\[
\frac{d}{dt}[C_i] = P_i - D_i - \alpha_{dep}[C_i] - \alpha_{dill}[C_i] \quad \text{for} \quad i = 1, \ldots, n
\]  

where \(C_i\) is the concentration of species \(i\) within the plume in mole m\(^{-3}\), \(P_i\) and \(D_i\) are production and destruction rates for species \(i\) in mole m\(^{-3}\) s\(^{-1}\), \(\alpha_{dill}\) is a rate constant for dilution of the plume due to mixing with ambient air, \(\alpha_{dep}\) is the rate constant for loss of species contained within ash and aerosols due to fallout and deposition (wet and dry) and \(n\) is the number of species considered (see Table 2). In this study we focus on calculation of the terms \(P_i\) and \(D_i\) via kinetic and thermodynamic reactions between gases, aqueous phase and the ash surface. The term \(\alpha_{dill}\) is calculated based on
the expansion of the plume due to air entrainment, temperature and pressure changes following the equation of state. As we focus on in-plume and warm in-cloud processes with a time scale of few seconds to few minutes (see Table 1), for simplicity we can safely neglect the term $\alpha_{dep}$ for the fine ash. At each step, a system of $n$ ordinary differential equations (ODE) is solved using the ode15s solver in MATLAB (Shampine and Reichelt, 1997). All considered gas-phase reactions and their rate parameters are listed in the appendix (Table A1).

Beside kinetic reactions in the gas phase, processes like condensation of sulfuric acid and water as well as the dissolution of the ash in the aqueous phase are among the most important $P_i$ and $D_i$ terms in this study which are explained below.

### 2.4 Condensation

At mid temperatures ($150^\circ C<T<600^\circ C$) in the eruption plume, heterogeneous reactions involving the gas phase and the ash material take place. Although the direct emission of $H_2SO_4$ is small, some of the $SO_2$ oxides to $SO_3$, which upon cooling readily reacts with water vapor to form vapor-phase sulfuric acid ($H_2SO_4$) (Hoshyaripour et al., 2012). As cooling continues, the temperature eventually drops below the dew point of the gas mixture, allowing condensation of $H_2SO_4$ onto the ash surfaces. Sulfuric acid has the highest dew point of all magmatic gas constituents and therefore, always condenses first (Verhoff and Banchero, 1974). Details of calculating the sulfuric acid condensation rate are given in Appendix A1.

As soon as the saturation vapor pressure of water vapor is reached, liquid water condensation on the ash surface takes place. Since water vapor concentration is at least 3 orders of magnitude higher than that of $H_2SO_4$ in magmatic gas (Symonds et al., 1994), it readily dissociates the condensed sulfuric acid into $H^+$ and $HSO_4^-$. This process can eventually lead to high concentrations of dissolved $H_2SO_4$ in the condensate associated with the ash, and thus, to strongly acidic pH values on the ash surface (Ayris and Delmelle, 2012). Rate parameters of water condensation are summarized in Appendix A2.

### 2.5 Thermodynamic equilibrium

Once the concentrations of the major species listed in Table 2 have been determined at a given time step using the equations described above, these species must be speciated into their various possible chemical forms. This is accomplished in the model by invoking thermodynamic equilibrium between the gas and liquid phase. We use the mass flux iteration method (MFI) to solve for thermodynamic equilibrium (Jacobson, 2005). MFI solves each equilibrium equation iteratively and iterates over all equations while conserving mass and charge (for more details see Jacobson, 2005). The thermodynamic equilibrium reactions considered in this study (dissolution and dissociation) and the parameters for calculating their equilibrium coefficient are presented in Appendix A3.
2.6 Ash dissolution

The liquid film or droplets at the ash surface not only scavenge the volatiles from the gas but also dissolve the ash surface constituents. This dissolution process eventually results in the release of Fe$^{2+}$ and Fe$^{3+}$ from the ash in the aqueous phase (together with other cations and anions), which is central to further in-cloud processing of volcanic ash as the dissolved ions play a significant role in the aqueous chemistry. Dissolution rate in this study refers to "the steady-state temporal metal release rate divided by the stoichiometric number of moles of this metal in each mole of the dissolving mineral or glass" as defined by Oelkers (2001). In this context, steady state is defined as the conditions where dissolution is time independent and stoichiometric. Dissolution rate calculations used in this study are presented in Appendix A4.

2.7 Size distribution of the ash

Particle sizes <1 mm are considered in this study, which corresponds to the definition of fine ash (Rose and Durant, 2009). Fine ash is thought to represent a substantial contribution (50-97 wt%) to tephra deposits from plinian and sub-plinian volcanic eruptions (Rose and Durant, 2009). Particles in this size range not only have a higher surface to mass ratio (compared to the coarser particles) for interaction with the gases and aqueous phases (Delmelle et al., 2005) but also can be lifted to high altitudes and remain suspended in the atmosphere for several days before sedimentation (Sparks et al., 1997). Among others, Rose and Durant (2009) investigated the ash content of volcanic eruption plumes and suggested a typical polymodal size distribution for fine ash subdivided into 27 bins (Fig. 2a). For this binned representation of fine volcanic ash, the total number of bins between 0.01 $\mu$m to 1000 $\mu$m (see Fig. 2a) is denoted by nclass. Each bin $i$ is considered to be monodisperse with a radius $R_{pi}$ which is given by the following equation (Pirjola et al., 1999):

\[
\log_{10}(R_{pi}) = \log_{10}(r_{min}) + \frac{\log_{10}(r_{max}) - \log_{10}(r_{min})}{\text{nclass}} (i - 1)
\]  

(2)

Here we use nclass=27 (Fig. 2a). Using $R_{pi}$ and an ash density of 2300 kg m$^{-3}$ (Rose and Durant, 2009), we calculate the mass of a single particle in each bin. Assuming that near the vent approximately 3 wt% of the plume is gas and about 97 wt% is ash (Sparks et al., 1997), for each mole of volcanic gas (with an average weight of 25 g), the erupted material contains approximately 830 g ash, which at T=1000 °C and P=1 bar corresponds to in-plume ash concentration of 0.005 g cm$^{-3}$ near the vent. Finally, using wt% of each size bin (Fig. 1a), the mass of a single particle and the ash concentration calculated above, we compute the number of particles in each bin per cm$^3$, which is shown in Fig. 2b. According to this plot, we estimate the total number concentration near the vent to be approximately 10$^{12}$ particles per cm$^3$ having a total surface area of ash 45 cm$^2$cm$^{-3}$. According to previous studies, the specific surface area of fine volcanic ash is in the range 0.2-2.1 m$^2$g$^{-1}$. 

7
We find 0.9 m²g⁻¹ as the specific surface area of the fine ash in this study, which is well in the range mentioned above.

### 2.8 Initial gas and ash composition

It is known that plinian and subplinian eruptions are more likely to occur within convergent plate volcanism than other tectonic systems (Schmincke, 2004). The magmatic gases erupted from such eruptions are usually chlorine-rich (Symonds et al., 1994; Gerlach, 2004). Therefore, we consider a chlorine-rich magmatic gas composition in the reference scenario for this study (Cl-rich composition in Table 3). This composition reflects the magmatic gas and air mixture leaving the hot core of the plume (T>600 °C or zone 1 in Fig. 1), and is taken as the initial condition of our modeling study which focuses on 0 °C < T < 600 °C. Carbon and sulfur-rich magmatic gases that usually erupt from divergent plate and hot spot volcanoes, respectively (Symonds et al., 1994), are considered in the sensitivity study. We note that as volcanic gas composition can vary considerably, the compositions in Table 3 do not fully reflect all these variations but they satisfactorily represent the geochemical differences between tectonic settings (e.g., water, sulfur, carbon and halogen contents) (Gerlach, 2004).

Ash composition in this study refers to the composition of the ash surface rim with a thickness of <100 nm (Achterberg et al., 2013; Gislason et al., 2011; Hoshyaripour et al., 2014). This rim undergoes substantial physiochemical interactions with gases and aerosols within the plume and cloud that can eventually lead to generation of a salt layer on the ash surface (Achterberg et al., 2013; Gislason et al., 2011). This salt layer is suggested to be the main source of soluble iron in volcanic ash upon contact with sea water (Duggen et al., 2010). Iron at the ash surface leaving the high-temperature zone mainly occurs as component of glass and as Fe-carrying phases mentioned in Table 2 (Bayhurst et al., 1991; Nakagawa and Ohba, 2003). Iron release from minerals through dissolution usually involves breaking only one Fe-O bound while in glass it may require breaking several metal-oxygen bounds through nonstoichiometric dissolution before reaching the steady state (Oelkers, 2001). Furthermore, at pH<2 mineral dissolution rate is similar to that of the corresponding glass (Hamilton et al., 2000). Considering this and given the limitation of data on iron release from the glass at pH<2 and T< 25°C, here we consider the minerals as the main source of iron within the ash particle and regard glass as a sink for protons (see Table 2).

It is suggested that iron mobilization efficiency is connected to its redox state in airborne particles (Desboeufs et al., 2001). Iron oxidation state at the ash surface is mainly controlled by the efficiency of high-temperature oxidation reactions occurring at T>600 °C (for more details please see Hoshyaripour et al., 2014). Thus, we consider three redox end-members: fayalite as the non-oxidized, magnetite as moderately-oxidized and hematite as highly-oxidized Fe-carrying phases. Since glass is a major constituent of volcanic ash (40–80 wt% (Blundy et al., 2006), ash in this reference scenario (here after refer to as Gla+Mag) consists of glass (70%) and magnetite (30%).
Magnetite contains iron in both oxidation states (ferric and ferrous) and is also extensively observed in volcanic ash samples (Bayhurst et al., 1991; Gislason et al., 2011; Censi et al., 2010) making it an appropriate Fe-carrying phase for the idealized composition in the reference scenario. The impacts of the iron oxidation state as well as other minerals on iron mobilization efficiency are discussed in a detailed sensitivity study in section 4.2.

3 Results

3.1 In-plume zones: water and sulfuric acid condensation

Figure 3 shows the vertical profile of water and sulfuric acid in both vapor and liquid phases. Left and right y-axis show the plume elevation and the temperature, respectively. H₂SO₄ condenses first at \( \sim 120 \, ^\circ\text{C} \) (boundary between mid and low-T in-plume zones). The conceptual model of Óskarsson (1980) suggests the temperature of 338 °C as the condensation point of sulfuric acid corresponding to the dew point of pure H₂SO₄ at 1bar (Verhoff and Banchero, 1974). However, this value is too high for volcanic plumes considering the low mixing ratio of H₂SO₄ in the gaseous phase (<1 mole%) as well as the low pressure at high elevations in the atmosphere.

The concentration of sulfuric acid droplets increases and reaches a plateau near 40 °C (boundary between in-plume and in-cloud zones). At this temperature water vapor starts condensing which is followed by rapid depletion of H₂SO₄ due to its dissociation in contact with liquid water (see Fig. 3a). At \( T<50 \, ^\circ\text{C} \) gaseous sulfuric acid continues to condense (H₂SO₄(g) in Fig. 3a) and dissociate rapidly into \( \text{H}^+ \) and \( \text{HSO}_4^- \), thus no liquid H₂SO₄ forms anymore (H₂SO₄(aq) in Fig. 3b). More than 80% of the sulfuric acid (all fractions given in this paper are mass fractions) condenses in the low-T in-plume and warm in-cloud zones.

We note that the eruption dynamics and gas composition can slightly vary the boundaries of mid and low-T in-plume zones. Based on several simulations conducted in the course of this research we suggest average values of 150 °C and 50 °C for H₂SO₄ and H₂O condensation point in volcanic plumes, respectively. It is also noteworthy that the altitudes at which the plume reaches these temperature-dependent boundaries are significantly variable in different eruptions.

3.2 Warm in-cloud zone

3.2.1 Scavenging of gases

It has been observed that volcanic particles scavenge gas species in volcanic eruption plumes (Rose, 1977; Óskarsson, 1980). Water condensation generates a liquid coating on the ash surface (in the warm in-cloud zone) that scavenges the surrounding gases (Textor et al., 2003). Since the solubility of HCl is about four orders of magnitude higher than that of SO₂, it is likely to be completely scavenged by water drops (Tabazadeh and Turco, 1993) thereby increasing the acidity of the aqueous
phase and consequently decreasing SO₂ scavenging which is observed in our simulations (Fig. 4, right panel). While more than 98% of the HCl is removed from the gas phase, only less than 5% of the SO₂ is scavenged by the liquid water in the reference scenario. Therefore, in consistency with previous studies (Tabazadeh and Turco, 1993; Textor et al., 2003), high fractions of SO₂ can reach the stratosphere, while a much lower fraction of HCl remains in the gas phase.

In general, the solubility of acid gases decreases with increasing acidity of the aqueous phase (Atkins, 1986). Since HCl dissolves more efficiently, it increases the acidity of the aqueous phase and hinders SO₂ scavenging. Neglecting HCl scavenging (Fig. 4, left panel), which can also represents eruptions with very low halogen content, increases the SO₂ removal from the gas phase to 15%.

As noted before, dissolution of the major gas species in the aqueous phase is usually followed by their rapid dissociation (see E8 to E14 in Table A2). Figure 5 shows the major products of the dissociation processes. Formation of all these anions is concurrent with H⁺ release in the aqueous phase, which increases the acidity of the solution. Since Cl⁻ has the highest concentration (2 to 9 order of magnitudes greater than that of other anions), HCl dissolution and dissociation mainly control the pH. The final pH of the liquid phase in the reference scenario is 0.32 (extremely acidic), which significantly affects the ash dissolution efficiency discussed below. HSO₄⁻, HSO₃⁻ and F⁻, which form due to dissociation of H₂SO₄, SO₂ and HF, respectively, are the most abundant species following Cl⁻.

3.2.2 Ash dissolution

The condensation, dissolution and dissociation processes in the plume acidify the liquid coating on the ash surface which dissolves the minerals and other solids (e.g., silicate glass). Figure 6 shows the dissolved iron (ferric and ferrous) from the ash in the reference scenario. The acidic liquid phase (pH <0.5) dissolves the ash with an average dissolution rate of 6.44 × 10⁻¹² mole cm⁻²s⁻¹, which is in the range of the ash dissolution rates reported in experimental studies (Delmelle et al., 2007). This process consumes H⁺ and produces cations (Fe²⁺ and/or Fe³⁺), which can also react with the anions in the aqueous phase and generate soluble iron salts. These salts can precipitate at the ash surface after water has evaporated. This is supported by the observation of a thin salt layer on volcanic ash surface containing chlorine, fluorine and sulfate together with iron, alkali and alkali-earth metals (Naughton et al., 1974; Delmelle et al., 2007).

Only 0.15 wt% of the magnetite at the ash surface is dissolved which releases Fe²⁺ and Fe³⁺ in the aqueous phase. Although this relative quantity seems very small, one has to take into account that huge amounts of ash are usually erupted during major eruptions. Thus, an infinitesimal portion of that material has a sizable mass. This is further discussed in section 5.1.
4 Sensitivity analysis

4.1 Gas composition

As discussed in section 3.2, scavenging and dissociation of the volcanic gases control the pH of the aqueous phase. Chemical composition of the erupted gas is known to be correlated with the tectonic setting of the volcano (Symonds et al., 1994). Therefore, we use gas compositions of three types of volcanic settings: convergent plate (CP), divergent plate (DP) and hot spots (HS) (Table 3) which tend to emit Cl-, C- and S-rich gases, respectively (Symonds et al., 1994). The Cl-rich composition is used in the reference scenario discussed above. Table 5, left panel, shows the key parameters relevant to iron mobilization calculated during the reference and sensitivity runs. It can be seen that the dissolution rate, pH and total dissolved iron are in the same order of magnitude for different gas compositions and vary by 10-20%.

In all scenarios, HCl is almost readily scavenged by the aqueous phase which consequently controls the HF and SO$_2$ scavenging, pH of the liquid and finally the dissolution rate. In the Cl-rich scenario the lowest pH, the highest dissolved iron and dissolution rate are attained. Figure 7 shows the changes in pH versus HCl concentration in the gas phase and also the dissolution rate. It can be seen that the HCl scavenging controls the pH of the system and consequently the dissolution rate. This is in agreement with previous studies concerning the impact of pH on dissolution of the iron species in mineral dust (Schwertmann, 1991; Desboeufs et al., 2001) especially in presence of hydrochloric acid (Sidhu et al., 1981). Therefore, Cl-rich magmatic gases (typical gas composition at CP volcanism) could be favorable for mobilizing the ash iron through acid-mediated dissolution. This will be further discussed in section 5.2.

4.2 Ash composition

One important aspect of this study is that volcanic ash contains different minerals (and not only glass and magnetite as assumed above (Nakagawa and Ohba, 2003). Therefore, we carry out a sensitivity study to evaluate the impact of changes in the ash composition on the iron mobilization efficiency. The gas compositions in these runs are constant and identical to the reference scenario (Cl-rich in Table 3).

4.2.1 Iron redox state

As mentioned earlier, the redox state of the iron can play a significant part in its dissolution rate (Schroth et al., 2009). Thus, we consider fayalite and hematite as the Fe$^{2+}$- and Fe$^{3+}$-bearing phases, respectively (Hoshyaripour et al., 2014) to reflect the possible iron oxidation states within the ash. This leads to 3 additional idealized ash compositions (Gla+Hem, Gla+Fay and Gla+Fay+Mag+Hem) shown in Table 4.
Table 5, right panel, shows the results of the sensitivity study concerning ash composition. It can be seen that when ash contains hematite instead of magnetite, the pH and the amount of scavenged SO$_2$ and HF are not significantly different from that of the reference scenario. The dissolution rate is however one order of magnitude smaller than that of magnetite (the reference scenario). For the compositions including fayalite at the ash surface (compositions Gla+fay and Gla+Mag+Hem+Fay), significant changes in pH, SO$_2$ and HF scavenging are observed. Since the fayalite dissolution rate is two orders of magnitudes greater than that of magnetite (reference scenario), 33% and 13.85% of the total iron is dissolved in the aqueous phase in the warm in-cloud zone for compositions Gla+fay and Gla+Mag+Hem+Fay, respectively. This enhanced dissolution efficiency of Fe$^{2+}$-carrying phases is observed previously in mineral dust particles (Desboeufs et al., 2001). Such an elevated dissolution rate consumes H$^+$ more rapidly (see Table 5), reduces the acidity and consequently enhances the SO$_2$ and HF scavenging. This increases the SO$_2$ and HF scavenging from 2.8% and 12.5% to 19.6% and 61.55%, respectively. The subsequent dissociation of the SO$_2$ and HF can increase the acidity again and intensify the ash dissolution. This cycle can dominantly promote the ash iron mobilization. These results may suggest that volcanic settings that buffer iron mainly as Fe$^{2+}$ in the ash surface (reduced magmatic conditions at DP and HS volcanism (Hoshyaripour et al., 2014)) could eventually lead to very high iron mobilization rates. This is further discussed in section 5.2.

4.2.2 Alkali and alkali-earth metals

Dissolution of alkali and alkali-earth metals contained in the minerals and glass (usually referred to as network-modifying cations) may consume protons in the aqueous phase thereby reducing the duration of highly acidic conditions at the ash surface and affect the iron release (Ayris and Delmelle, 2012). Despite of the rich body of literature dealing with the natural glass dissolution (Oelkers, 2001; Oelkers and Gislaslon, 2001, and the references therein) a comprehensive data compilation to be used for geochemical modeling of alkali and alkali-earth metal release due to glass dissolution at pH<2 and T<25°C is unavailable. Hamilton et al. (2000) showed that under acidic conditions the dissolution behavior of the minerals is identical to that of their corresponding glass. Therefore, here we use the minerals containing alkali and alkali-earth metals assuming that they behave identical to the glass in acidic solutions (Hamilton et al., 2000). Inclusion of these minerals results in an idealized ash compositions (Gla+Mag+Min) shown in Table 4.

Last column in Table 5 shows the results of the sensitivity run. The ash containing alkali and alkali-earth minerals together with glass and magnetite (Gla+Mag+Min) shows an enhanced iron mobilization efficiency compared to the reference scenario (containing only glass and magnetite). Despite of the identical Fe-carrying spices in both scenarios (magnetite), inclusion of alkali and alkali-earth minerals has approximately tripled the amount of dissolved iron. This is against the common expectation that considers such metals as proton consumers that should decrease the acidity and iron mobilization efficiency (Ayris and Delmelle, 2012). The fact that such minerals dissolve...
faster than magnetite is also evident from the ash dissolution rate which is about five times greater than that of reference scenario. However, dissolution of alkali and alkali-earth metals might diminish the acidity and iron mobilization only if there is no external source to compensate the proton consumption in the aqueous phase. In the volcanic plume, HF and SO$_2$ scavenging from the gas phase seem to be this external source that offset the reduced acidity. It can be seen that HF and SO$_2$ scavenging are increased by approximately 50% compared to the reference scenario. In other words, consumption of the protons through dissolution of highly soluble species is immediately compensated by HF and SO$_2$ absorption and dissociation in the aqueous phase which is thermodynamically much faster than the ash dissolution (Stumm and Morgan, 1996). Therefore, existence and dissolution of other cations (alkali and alkali-earth metals) along with iron species in volcanic ash does not necessarily hamper the iron dissolution but may even enhance the iron mobilization efficiency.

5 Discussion

5.1 Comparison with experimental data

Based on the results presented above, acid-mediated dissolution of the ash seems to be the major process that mobilizes the ash iron. Dissolution and dissociation of halides (HCl and HF) in the aqueous phase mainly control its pH and therefore, ash dissolution efficiency (see Fig. 7). The crucial role of chlorine and fluorine in enhancing ash dissolution reactions has been emphasized previously (Delmelle et al., 2007; Wolff-Boenisch et al., 2004; Moune et al., 2007). It has been suggested that the ash dissolution is most efficient within the eruption plume possibly occurring during the first minutes of the transport dictating the surface composition of ash (Moune et al., 2006; Delmelle et al., 2007). The fingerprint of these in-plume processes (namely the preferential enrichment of Cl and F on tephra surfaces) is dominant in proximal samples that deposit before being significantly affected by cloud processes (Delmelle et al., 2007). Therefore, we use proximal samples data obtained in experimental studies to evaluate the correlation between pH, halide and iron release from the ash. Jones and Gislason (2008) measured the concentrations and fluxes of elements into de-ionized water through leaching experiments on 8 unhydrated volcanic ash samples. Five ash samples (Galeras, Montserrat, Hekla, Sakura-Jima and Lascar) are selected for evaluation in this study since they are collected <15 km away from the vents and thus, could be considered as proximal samples (Jones and Gislason, 2008, for more details see).

Figure 8 shows concentration of iron and halides (Cl+F) released from ash samples as a function of pH. This figure unambiguously shows the higher the chlorine and fluorine concentrations, the lower the pH and the higher the iron release. The absolute pH values in this figure are higher than those calculated in this study (Table 5) because ash samples are influenced by freezing/melting, precipitation/evaporation cycles as well as aqueous chemistry during further in-cloud processing, which are not considered in our model simulations. All these processes may change the absolute pH values.
and also iron and halide speciation (Desboeufs et al., 2001). However, their relative quantities still buffer the correlation of pH, iron dissolution efficiency and the chlorine and fluorine concentrations.

The ash sample from Hekla has two orders of magnitude higher iron release than those of the other samples. The reason of this exceptional iron release from Hekla ash stems mainly from its unusual composition (erupted gas and ash composition), with a combined hot spot and divergent plate margin magma source, coupled with high fluorine in the eruptive products (Óskarsson, 1980; Moune et al., 2006). Petrological estimates suggest reduced conditions for the basaltic Hekla magma prior to eruption (Moune et al., 2007). As a result, the observed mineral phases in the Hekla ash include olivine, clinopyroxene and spinel (Höskuldsson et al., 2007), which is close to the Gla+Fay and Gla+Fay+Mag+Hem ash compositions in Table 5. As discussed above, the wt% of the dissolved iron is mainly governed by two independent factors: halogen content of the gas and iron oxidation state in the ash surface. Thus, having Fe$^{2+}$-carrying species and high halide content concurrently in the Hekla eruption plume can mobilize 13.85–33% of the total iron at the ash surface. Since there is no evidence for such exceptional conditions for the other eruptions considered in Fig. 8, we use the range of 0.03–0.15% (according to the ash compositions Gla+Mag and Gla+Hem together with the Cl-rich gas composition in Table 5) as the wt% of mobilized surficial iron in these samples. To estimate the iron release from the ash $R_{Fe}$ (mole g$^{-1}$ ash) based on proposed theoretical values in this study, the following equation is used:

$$R_{Fe} = C_{Fe}l_s D_i/M_{Fe}$$

(3)

where $C_{Fe}$ is the iron wt% in the bulk composition, $l_s$ is the ash surface layer weight ratio (1–5% of the total ash mass), $D_i$ is the wt% of the dissolved iron according to Table 5 and $M_{Fe}$ is the molar weight of iron (55.84 g mole$^{-1}$). Considering both experimental (Gislason et al., 2011) and theoretical (Hoshyaripour et al., 2014) estimates concerning the thickness of ash surface layer, we assume the thickness of the ash rim to be on average 10 nm. Having a specific surface area of 1.1-2.1 m$^2$/g (Delmelle et al., 2005), the surface rim in each gram ash with density of 2500 kg/m$^3$ has the weight of approximately 0.01–0.05 g or 1–5% of the total ash mass. This range is used here for $l_s$. The $R_{Fe}$ values calculated in this study and also measured by Jones and Gislason (2008) are shown in Table 6. The measured iron release from four ash samples is satisfactorily in the calculated range based on Eq. 3. Only the Galeras ash is slightly outside the range. Therefore, according to Fig. 8 and Table 6 there is a good overall agreement between the results of the theoretical approach of this study and experimental measurements of ash iron release. This confirms the strong connection between iron release from ash with the halide concentrations and pH.

The relative quantity of the mobilized iron discussed above may seem minor (especially the 0.03–0.15% in the reference scenario). But this needs to be considered in the context of the massive ash content of the volcanic ejecta. For instance, the eruption of Kasatochi volcano in 2008 produced
approximately $6 \times 10^{11}$ kg of ash (Langmann et al., 2010) containing 5–10 wt% iron in the bulk composition (Wang et al., 2010). Assuming the mass of the ash surface rim as approximately 1–5% of the total mass, the surface rim of the ash from Kasatochi eruption carries approximately 0.6–3×10^8 kg iron. Mobilization of 0.03–0.15% of the iron at the ash surface (as in the reference scenario) according to Eq. 3 means 5–134 nmol Fe g$^{-1}$ ash which is close to the measured iron released from Kasatochi ash (61–81 nmol Fe g$^{-1}$) reported by Olgun et al. (2013b). Although the fate and speciation of the dissolved iron depend on further in-cloud processes, the calculations above indicate that even a very small percentage of mobilized iron in the ash means a huge mass with potentially significant impacts on the receiving environment.

5.2 Favorable conditions for iron mobilization

Duggen et al. (2010) and later, Olgun et al. (2011) reported a correlation between tectonic setting of volcanoes and the ash iron fertilization suggesting the arc volcanism (CP) as the favorable setting for soluble iron production compared to non-arc volcanoes (DP and HS). However, in their comparisons, they neglected the exceptionally high iron release from the ash of the Hekla eruption in 2000 which is located in a non-arc setting. The distribution of their samples seems also statistically biased toward CP volcanism as they analyzed 40 samples from such volcanoes and only 4 samples from other settings. As mentioned earlier, emissions from arc volcanism are known to be Cl-rich (Symonds et al., 1994). Thus, according to the results of this study, development of highly acidic coatings on the ash surface is very likely in CP eruptions resulting in elevated ash dissolution rates.

The efficiency of acid-mediated dissolution however, depends not only on acidity and temperature but also on the mineral composition (Schwertmann, 1991; Blesa et al., 1994). Fe$^{2+}$-carrying phases (reduced iron minerals) show 1–2 order of magnitude higher dissolution rates under acidic conditions (see section 4.2 and also (Palandri and Kharaka, 2004)). Non-arc volcanic settings (DP and HS) typically record reduced conditions in comparison to the CP setting (Lindsley, 1991). Thus, DP and HS settings could be favorable for iron fertilization too with respect to iron oxidation state. Hekla eruption in 2000, Iceland, had both reduced magmatic conditions (as usual for DP and HS) and high halides content (as usual for CP) (Moune et al., 2009) which leads to an exceptional iron release behavior.

Therefore, our results suggest that attributing the fertilization potential of the ash to the tectonic setting of volcano is an inconsistent hypothesis. Instead, elevated halogen content in the gas (HCl and HF) and reduced conditions in the magma (that essentially modulate the pH and iron redox state, respectively) seem to be the favorable conditions for ash iron mobilization. This is comparable with the results of the mineral dust studies that report a strong correlation between the water-soluble fraction of Fe-carrying aerosols, pH and the iron redox state (Sidhu et al., 1981; Desboeufs et al., 2001).
6 Conclusion and implications

The 1D numerical model introduced in this study simulates the heterogeneous interactions of the gases, liquid phase and the ash surface within the volcanic eruption plume in the temperature range of 600 °C to 0 °C. It provides the first theoretical constraints on the impacts of such processes on ash iron mobilization. Although determining the fate of the dissolved species in the aqueous phase requires further investigations, our first attempt reveals that the ash dissolution can even modulate the gas scavenging efficiency through changing the pH of the liquid coatings. Therefore, ash needs to be considered as a reactive component in modeling the physical chemistry of volcanic eruption plumes and clouds. **This study constitutes a base for the future elaboration of an ash and aerosol evolution scheme in volcanic plumes.**

According to the results, in halogen-rich eruption plumes, dissolution and dissociation of HCl (and partly HF) mainly controls the pH of the aqueous phase at the ash surface in the warm in-cloud zone. For these volcanoes SO₂ scavenging by liquid particles could be negligible and seems to be more efficient in contact with ice particles as suggested by Textor et al. (2003). On the other hand, during carbon- and sulfur-rich eruptions (DP and HS volcanism, respectively) SO₂ scavenging by the aqueous phase is more likely and could be the main process controlling the pH and thus, the ash dissolution. The sensitivity analysis also revealed that changes in the halogen content of the gas phase modifies the iron mobilization efficiency by 10-20% while changes in the iron redox state at the ash surface may result in 1–2 order of magnitude difference in the mobilization efficiency.

Under acidic pH conditions, the dissolution of iron oxides could be greatly enhanced in the ice phase compared to that in water (Jeong et al., 2012). As dissolution consumes H⁺, it reduces the acidity and can accelerate the SO₂ scavenging by ice (Textor et al., 2003). Therefore, sulfur scavenging by volcanic ash and aerosols seems to be less efficient during mid and low-T in-plume as well as the warm in-cloud processes. Instead, high-T (both in-conduit (Ayris et al., 2013) and in-plume (Hoshyariipour et al., 2014)) and cold in-cloud zones (Textor et al., 2003) appear to be more relevant to the sulfur scavenging. These effects should be considered in interpreting the results of leaching experiments on ash deposits to distinguish the fingerprint of the in-plume and in-cloud processes on the ash surface composition.

The local, regional and global impacts of volcanism upon the Earth system (atmosphere, hydrosphere, pedosphere, cryosphere and biosphere) are initially induced by the physicochemical properties of the ash and gas. Several lines of evidence indicate that the in-plume and in-cloud processes can significantly alter these properties and thus, their impacts on Earth system. **For instance, the efficiency of HCl, SO₂ and HF scavenging by volcanic aerosols could be influenced by the proton consumption through ash dissolution. This can modulate the amount of the volcanic gases that reach the middle atmosphere.** Therefore, the in-plume and in-cloud processing of the volcanic ejecta need to be considered in future investigations on, for e.g., injection of volcanic gases into the stratosphere and its climatic impacts.
In addition to the ash and gas composition, which are largely governed by the composition of the source magma, other factors can considerably vary the efficiency of iron mobilization at the ash surface. Particle size distribution basically controls the surface area to mass ratio, which is a key parameter for condensation, scavenging and dissolution processes. Smaller particles with lower surface area to mass ratio tend to be more efficient agents in these processes (Rose, 1977). Although magma fragmentation dictates the initial ash size distribution (Rose and Durant, 2009), in-plume and in-cloud particle aggregation can significantly alter it (Brown et al., 2012). The influences of aggregation on ash size distribution and thus, on physical chemistry of the ash-gas-aerosol interactions could be notable and is the topic of on-going investigations. Another important factor is the time that ash particle spend in different zones of the plume and cloud. Dynamics of the eruption as well as the ambient environmental conditions govern the spatial and temporal evolution of the eruption plume and cloud (Sparks et al., 1997). Impacts of these factors on ash chemistry could be constrained by incorporating the chemistry modules into dynamical models of volcanic eruption plumes.

In this study we used idealized ash compositions which satisfactorily replicate the behavior of the ash in the real system. However, upon availability of data, real ash surface mineralogy and compositions (within 100 nm rim) should be used in future studies. Moreover, iron release from glass component of the volcanic ash need to be studied experimentally in order to obtain detailed reaction rate parameters to be used in numerical modeling investigations.

Aqueous chemistry, stratospheric chemistry and all the processes involving ice could also significantly affect the fate of the dissolved iron (e.g., SO₂ oxidation catalyzed by Fe ions (Harris et al., 2013)). Therefore, further modeling and experimental studies are necessary to comprehend the impact of in-cloud processes on iron chemistry in volcanic ash.

**Appendix A: Formulations of the processes**

**A1  Sulfuric acid condensation**

The dew point of sulfuric acid is calculated using the following equation (Jeong and Levy, 2012):

\[
\frac{1}{T_{\text{dew}}} = 2.27 \times 10^{-5} - 2.94 \times 10^{-7} \cdot \ln(P_{H_2O}) - 8.58 \times 10^{-6} \cdot \ln(P_{H_2SO_4}) \\
+ 6.2 \times 10^{-6} \cdot \{\ln(P_{H_2O}) \cdot \ln(P_{H_2SO_4})\} \tag{A1}
\]

where, \( P_{H_2O} \) and \( P_{H_2SO_4} \) are partial pressures of the water vapor and sulfuric acid, respectively, in mmHg. When the temperature of the plume drops below \( T_{\text{dew}} \) sulfuric acid condenses onto the ash particles. In this study the Fuchs-Sutugin interpolation formula is used to describe the conden-
sation rate of $\text{H}_2\text{SO}_4$ molecules to the ash particles (Fuchs and Sutugin, 1970). The single particle condensation coefficient is given by:

$$K_{FS} = \alpha K_{kin} \left[ 1 + \frac{3\alpha}{4Kn} \times \left( 1 - 0.623 \frac{Kn}{1 + Kn} \right) \right]^{-1}$$  \hspace{1cm} (A2)

where

- $\alpha$ = the accommodation coefficient of $\text{H}_2\text{SO}_4$ ($\sim 1$ in this study (Clement et al., 1996)),
- $K_{kin}$ = the kinetic condensation coefficient = $\pi R_p^2 c_b$,
- $c_b$ = the average thermal velocity of $\text{H}_2\text{SO}_4$ gas molecules = $[8kT/\pi M]^{1/2}$,
- $Kn$ = the particle Knudsen number = $l/R_p$,
- $l$ = the mean free path of $\text{H}_2\text{SO}_4$ molecules = $3D_b/c_b$,
- $D_b$ = the $\text{H}_2\text{SO}_4$ diffusion coefficient = 0.08 cm$^2$ s$^{-1}$,
- $T$ = the absolute temperature in Kelvin,
- $k$ = the Boltzmann’s constant,
- $M$ = the mass of $\text{H}_2\text{SO}_4$ molecule and
- $R_p$ = the particle radius.

With respect to the previous section, we calculate the condensation rate onto a polydisperse ash distribution. In that case, the condensation coefficient $X_c$ is defined as:

$$X_c = \int_0^{\infty} K_{FS}(R_p)n(R_p)dR_p$$  \hspace{1cm} (A3)

where $n(R_p)dR_p$ is the concentration of particles with radius between $R_p$ and $R_p + dR_p$ according to Rose and Durant (2009). The condensation rate onto a polydisperse distribution is finally given by:

$$CS = \int_0^{\infty} K_{FS}(R_p)n(R_p) \times [N_g - N_g^e(R_p)]dR_p$$  \hspace{1cm} (A4)

where $N_g$ is the $\text{H}_2\text{SO}_4$ vapor pressure in the gas phase and $N_g^e(R_p)$ is the equilibrium vapor pressure over a particle with radius $R_p$. In a volcanic eruption plume $N_g^e(R_p)$ is negligible in comparison to $N_g$. Hence equation (A4) simplifies to:

$$CS = X_c N_g$$  \hspace{1cm} (A5)
A2 Water condensation

The mass-flux of water condensing onto a single, spherical particle with radius $R_p$ is given by (Jacobson, 2005):

$$K_{FW} = \frac{4\pi D_v (p_v - p_{v,s})}{\frac{D_v}{k_a T} \left( \frac{L_v}{R_v T} - 1 \right) + R_v T}$$  \hspace{1cm} (A6)

where

$D_v = $ the molecular diffusion coefficient of water vapor in air $= 0.234 \text{ cm}^2 \text{ s}^{-1}$,
$p_v = $ the vapor pressure of water vapor in plume in hPa,
$p_{v,s} = $ the saturation vapor pressure at the particle surface $= 6.112 \exp(17.67 T_c/(T_c + 243.5))$,
$T_c = $ the temperature in degree Celsius,
$L_v = $ the latent heat of water evaporation $= 2260 \text{ J g}^{-1}$,
$R_v = $ the gas constant for water vapor $= 461.40 \text{ J kg}^{-1}\text{K}^{-1}$,
$k_a = $ the thermal conductivity of moist air $\approx k_d \left[ 1 - (1.17 - 1.02 \frac{k_v}{k_d}) \frac{n_w}{n_d + n_w} \right]$,
$k_d, k_v = $ the thermal conductivity of dry air and water vapor, respectively and
$n_d, n_v = $ the number of moles of dry air and water vapor, respectively.

Finally, the condensation rate of water onto a polydisperse aerosol distribution is calculated by:

$$CW = \int_0^\infty K_{FW}(R_p)n(R_p)dR_p$$  \hspace{1cm} (A7)

A3 Thermodynamic equilibrium

Thermodynamic equilibrium reactions are shown in Table A2. The equilibrium coefficient ($K_{eq}$) for each reaction at temperature $T$ is calculated by (Jacobson, 2005):

$$K_{eq}(T) = A \exp \left\{ B \left( \frac{T_0}{T} - 1 \right) + C \left( 1 - \frac{T_0}{T} + \ln \frac{T_0}{T} \right) \right\}$$  \hspace{1cm} (A8)

where $T_0 = 298.15 \text{ K}$, $A$, $B$ and $C$ values are listed in Table A2.

A4 Ash dissolution

The dissolution rate of the mineral species $i$ is calculated based on a simplified formulation proposed by Palandri and Kharaka (2004):

$$\log D_i = \log k_i - n_i \cdot \text{pH}$$  \hspace{1cm} (A9)
where $D_i$ is the dissolution rate in mole m$^{-2}$ s$^{-1}$, $\log k_i$ is the log rate constant computed at 25 °C and pH=0, $n$ is the reaction order with respect to H$^+$. Table A3 shows the rate parameters used in this study for different ash constituents. These parameters are accurate to a first order approximation over the range of acidic pH (Palandri and Kharaka, 2004). We note that the dissolution rates used here (equation A9) are temperature independent which is a valid assumption if one considers the short residence time of particles at a certain temperature in eruption column (few seconds).

Acknowledgements. We thank the reviewers for their comments that helped us to improve the manuscript. We also thank R. Hellmann and S. R. Gislason for the discussions concerning minerals and glass dissolution. <sup>a</sup> 1: (Palandri and Kharaka, 2004), 2: (Bandstra et al., 2007), 3: (Oelkers and Gislason, 2001)
Figure 1. The interaction between ash surface, liquid coating and the surrounding gases. During high-T zones (zones 0 and 1 in the color bar) direct gas-ash interaction significantly controls the iron speciation at the ash surface. At lower temperatures, however (zones 2, 3, 4 and 5), such interactions are negligible. The formation of liquid coating at the ash surface and its interactions with the surrounding gases (scavenging) and with the ash constituents (dissolution) mainly control the ash iron mobilization. Only the processes within the red dotted-line are considered in this study (*Ayris et al. (2013); **Hoshyaripour et al. (2014))

Figure 2. a) Typical distal ash-fall particle size analysis from Rose and Durant (2009) b) particle number concentration calculated based on the same data.
Figure 3. Vertical profile of the water (blue line) and sulfuric acid (red line) concentrations in the a) gas and b) aqueous phases in the eruption plume. Please note the significant differences between H₂O and H₂SO₄ concentration. Vertical axis on left and right show the elevation and the plume temperature, respectively.

Figure 4. SO₂ and HCl vertical profile. Left panel: without HCl scavenging (e.g., very low halide concentration in sulfur rich plumes); right panel: with HCl scavenging (e.g., HCl-rich plumes). Note that only the height >9 km is plotted here.
Figure 5. Vertical profile of the concentrations of major anions formed in the aqueous phase: a) $\text{HSO}_4^-$ and $\text{SO}_3^{2-}$ that form due to sulfuric acid dissociation b) $\text{HSO}_3^-$ and $\text{SO}_4^{2-}$ are the products of $\text{SO}_2$ scavenging and dissociation. c) $\text{Cl}^-$ and $\text{F}^-$ that are produced due to $\text{HCl}$ and $\text{HF}$ dissociation, respectively. Please note the different concentration scales. Vertical axis on left and right show the elevation and the plume temperature, respectively. Note that only the height $>9$ km is plotted here.

Figure 6. Vertical profile of magnetite ($\text{Fe}_3\text{O}_4$), iron II and iron III concentrations. Because of relatively slow dissolution rate in the reference scenario, changes in magnetite concentration are small. Note that only the height $>9$ km is plotted here.
Figure 7. Correlation between pH, HCl content of the magmatic gas and the ash dissolution rate.

Figure 8. Concentration of iron (blue) and halogens (Cl+F in red) released form ash samples during the leaching experiment of Jones and Gislason (2008) as function of pH.
