Abstract

The oxidative capacity of the cloud aqueous phase is investigated during three field campaigns from 2013 to 2014 at the top of the puy de Dôme station (PUY) in France. Forty-one cloud samples are collected, and the corresponding air masses are classified as highly marine, marine and continental. Hydroxyl radical ($\text{HO}^\cdot$) formation rates ($R_{\text{HO}^\cdot}$) are determined using a photochemical setup (Xenon lamp that can reproduce the solar spectrum) and a chemical probe coupled with spectroscopic analysis that can trap all of the generated radicals for each sample. Using this method, the obtained values correspond to the total formation of $\text{HO}^\cdot$ without its chemical sinks. These formation rates are correlated with the concentrations of the naturally occurring sources of $\text{HO}^\cdot$, including hydrogen peroxide, nitrite, nitrate and iron. The total hydroxyl radical formation rates are measured as ranging from approximately $2 \times 10^{-11}$ to $4 \times 10^{-10}$ Ms$^{-1}$, and the hydroxyl radical quantum yield formation ($\Phi_{\text{HO}^\cdot}$) is estimated between $10^{-4}$ and $10^{-2}$. Experimental values are compared with modeled formation rates calculated by the model of multiphase cloud chemistry (M2C2), considering only the chemical sources of the hydroxyl radicals. The comparison between the experimental and the modeled results suggests that the photoreactivity of the iron species as a source of $\text{HO}^\cdot$ is overestimated by the model, and $\text{H}_2\text{O}_2$ photolysis represents the most important source of this radical (between 70 and 99 %) for the cloud water sampled at the PUY station (primarily marine and continental).

1 Introduction

In the atmosphere, many trace gases are transformed by the hydroxyl radical ($\text{HO}^\cdot$), which is considered the most efficient environmental oxidant (e.g., Seinfeld and Pandis, 2006). Evaluating the production of this short-lived species is crucial because it determines the fate of many chemical compounds. In atmospheric water drops and aqueous particles, the hydroxyl radical also controls the fate of inorganic and organic species.
The sources of hydroxyl radicals in the aqueous phase strongly differ from those in the gas phase because of the presence of ionic species and metal ions. Aqueous phase reactants that produce HO\(^*\) present high concentrations in water drops and aqueous particles, likely enhancing the HO\(^*\) photochemical production in the condensed phase. This radical can be generated in the aqueous phase by direct photolysis of hydrogen peroxide (H\(_2\)O\(_2\)) (Herrmann et al., 2010; Yu and Barker, 2003), iron complexes (Deguillaume et al., 2005), nitrate (NO\(_3^−\)) (Zellner et al., 1990) and nitrite ions (NO\(_2^−\)) (Zafiriou and Bonneau, 1987). The other significant source of HO\(^*\) in cloud water is the uptake from the gas phase (Arakaki and Faust, 1998). The relative importance of the different hydroxyl radical sources depends on the chemical composition of the aqueous phase, which is also strongly variable (Deguillaume et al., 2014). HO\(^*\) is further scavenged in the aqueous phase, primarily by dissolved organic compounds. Evaluation of this sink is difficult because the dissolved organic matter is diverse, complex and poorly characterized (Herckes et al., 2013).

Uncertainties in HO\(^*\) sinks and sources make its concentrations in atmospheric water highly difficult to estimate. For this estimation, models describing the multiphase cloud chemistry have been developed and have considered the reactivity in the gas and aqueous phases along with the mass transfer between the two phases (Ervens et al., 2014; Long et al., 2013; Tilgner and Herrmann, 2010). These numerical tools allow the estimation of the steady-state concentration of HO\(^*\) ([HO\(^*\)]\text{ss}) , which is a crucial quantity to understand the fate of atmospheric pollutants (Arakaki et al., 2013). The
range of the maximal HO\(^*\) concentration varies from \(10^{-16}\) to \(10^{-12}\) M, depending on the “chemical scenario” (i.e., emission/deposition and the initial chemical conditions) used in the modeling study. The amounts of organic matter and iron are key parameters controlling the \([\text{HO}^*]_{\text{ss}}\). These models are expected to underestimate the radical sinks because organic scavengers cannot be exhaustively described in the aqueous chemical mechanism (Arakaki et al., 2013).

In this study, we propose the investigation of the hydroxyl radical formation in real cloud water sampled at the puy de Dôme mountain (France). The hydroxyl radical formation rate is quantified for 36 cloud water samples collected during 3 field campaigns (2013–2014). Because the main photochemical sources (hydrogen peroxide, iron, nitrite and nitrate) are also quantified, we can calculate their relative contributions to the production of the hydroxyl radicals. For this purpose, the contribution to the hydroxyl radical formation rate of more concentrated inorganic photochemical sources is investigated separately in synthetic solution. In parallel, the model of multiphase cloud chemistry (M2C2) is used to simulate HO\(^*\) formation rates. This model considers explicit aqueous chemical mechanisms, and a “simplified” version of the model is used to reproduce the bulk water irradiation experiments (lamp spectrum) under variable physico-chemical conditions (pH, initial concentrations of HO\(^*\) sources) corresponding to the cloud water samples. The comparison between the modeled and experimental HO\(^*\) production rates facilitates quantification of the various HO\(^*\) sources and enables validation of the model to reproduce the oxidative capacity of the atmospheric aqueous phase.

2 Materials and methods

2.1 Chemicals

Hydrogen peroxide (30 % in water, not stabilized), sodium nitrate (purity > 99 %) and ferrozine (purity > 97 %) were obtained from Fluka, while sodium nitrite (purity > 98 %)
and terephthalic disodium salt (purity > 99%) were purchased from ProLabo and Alfa Aesar, respectively. All of the other chemicals (purity reagent grade) used for the analysis were obtained from Sigma-Aldrich.

Solutions are prepared with deionized ultra-pure aerated milli-Q water from Millipore (resistivity = 18.2 MΩ cm) under a laminar flux hood. Moreover, glass containers and injection material are washed three times with ultra-pure water before use. If necessary, the pH values are adjusted with perchloric acid (1 N) and NaOH (1 N) using a JENWAY 3310 pH-meter within ±0.01 pH unit. All of the solutions are stored under dark conditions, and the final preparations are performed in a room equipped with a sodium lamp (589 nm emission).

2.2 Cloud water sampling

Cloud water is sampled at the puy de Dôme (PUY) station (48° N, 2° E; 1465 m a.s.l.) in the Massif Central region (France). Three campaigns occurred during autumn 2013 from 14 October to 6 November, during spring and autumn 2014 from 22 March to 5 April and from 4 to 19 November. During these periods, the station was primarily located in the free troposphere; thus, the air masses from various origins were not influenced by the local pollution (Hervo, 2013).

The cloud droplet sampling is performed by a one stage cloud droplet impactor (Deguillaume et al., 2014). With the air flux used, the lower limit of the aerodynamic diameter is approximately 7 µm (Brantner et al., 1994). The impactor used for this study is constructed of stainless steel and aluminum, and cloud droplets are collected by impaction onto a rectangular aluminum plate with an average sampling time of two hours. Cloud water samples are filtered using a 0.45 µm PTFE filter within 10 min after sampling to eliminate all of the microorganisms and particles that can interfere with the spectroscopic analysis.

Measurements performed immediately after cloud collection are conductivity, redox potential, pH, UV-visible spectroscopy, H₂O₂ and iron concentrations. Ion chromatography (IC), total organic carbon (TOC), and nitrite analysis are determined less than
24 h after sampling. At each stage, sampling and analyses are performed with the greatest precaution to minimize all possible external contaminations, and the solutions are stored at 277 K under dark conditions. Hydroxyl radical formation rates ($R_{\text{HO}^\cdot}$) and polychromatic quantum yields ($\Phi_{\text{HO}^\cdot}$) are calculated using polychromatic wavelengths.

### 2.3 Physico-chemical measurements

Different parameters are monitored, including pH, conductivity and redox potential, which are measured using a Hanna multiparameter instrument. The UV-Vis spectrum of the collected cloud water is determined with an Agilent Technologies Cary 60 UV-vis spectrophotometer. The TOC concentration is determined with a TOC 5050A analyzer (Shimadzu). Hydrogen peroxide concentration is estimated using p-hydroxyphenilacetic acid (HPAA, purity > 98 %) and horseradish peroxidase (POD) (solid containing 150–200 units per mg), according to the spectrophotometric quantification method (Miller and Kester, 2002). The formation of the dimer of HPAA is correlated with the concentration of hydrogen peroxide and is detected using a Varian Cary Eclipse Fluorescence Spectrophotometer setting excitation wavelengths at 320 nm, while emission is registered from 340 and 500 nm. The maximum signal is quantified at 408 nm. The scan rate is 600 nm min$^{-1}$, and a bandpass of 10 nm is set for excitation and emission. Nitrite ions concentration is determined by derivatization with 2,4-dinitrophenylhydrazine (DNPH) (purity > 97 %), in acidic solution (HCl 37 %). The UV-absorbing derivative (2,4-dinitrophenilazide) is detected by HPLC. The HPLC system (Waters Alliance) equipped with a diode array detector is used with an Eclipse XDB-C18 column (Agilent, 4.6 mm × 150 mm, 5 µm), and an isocratic method is adopted, using 40 % acidified water (0.1 % phosphoric acid) and 60 % methanol. The flow rate is 1 mL min$^{-1}$, and 2,4-dinitrophenilazide is eluted with a retention time of 4.1 min (Kieber and Seaton, 1995) and detected at 307 nm. Fe(II) and Fe(III) concentrations are determined by the spectrophotometric method by complexation with ferrozine (purity > 97 %), as described by Stookey (1970). Fe(II) and Fe(III) represent the oxidative state of the iron species (free or complexed). Ascorbic acid (purity reagent
grade) is used as the reducing agent to determine total iron. The complex absorption is measured with a Varian Cary 300 Scan Spectrophotometer at 562 nm. It has been previously demonstrated that filtration does not modify the soluble iron quantification in natural cloud water samples (Parazols et al., 2006; Vaitilingom et al., 2013). It is not possible to measure particulate iron because the ferrozine method cannot solubilize solid phase iron (the contact time between acidic reagents and particulate iron is too short). Moreover, the iron particle is expected to be less reactive than the solubilized iron; consequently, its contribution can be neglected (Arakaki and Faust, 1998).

Ion chromatography (IC) analysis is performed employing a DIONEX DX-320 equipped with an IonPac AG11 (guard-column 4 mm × 50 mm) and an IonPac AS11 (analytical column 5 mm × 250 mm) for anions and a DIONEX ICS-1500 equipped with an IonPac CG16 (guard-column 4 mm × 50 mm) and an IonPac CS16 (analytical column 5 mm × 250 mm) for cations.

2.4 Statistical analysis

Principal component analysis (PCA) and hierarchical clustering analysis (HCA) are performed with R-3.1.2 software (R Core Team, 2013) using the FactoMineR package (version 1.28, Lê et al., 2008). This statistical analysis provides a synthetic representation of experimental data as a function of the correlations between variables considered and similarities present among the analyzed samples. This technique allows the determination of information contained in a set of multivariate data, summarizing it in a few linear combinations of the variables (Deming et al., 1988). HCA data are grouped by similarity, considering all of the information contained in the data set. HCA is a statistical method to qualitatively study the composition of cloud water and can be used to identify the grouping variables that are not well detectable using only PCA.
2.5 Irradiation experiments

To evaluate the contribution of each possible photochemical source (nitrate, nitrite or hydrogen peroxide) to the hydroxyl radical formation in cloud water, synthetic solutions doped with a single source of oxidant are irradiated to quantify their contribution to the total generation of hydroxyl radicals in a more complex medium.

The photochemical device is composed of a Xenon lamp equipped with a water cooler to avoid the increase of temperature due to the infrared radiations and a mirror to reflect the light vertically. A Pyrex filter was located before the reactor for filtering of light at wavelengths below than 290 nm, corresponding to the lowest wavelengths of the solar emission spectrum. The reactor is a 40 mL cylindrical Pyrex container cooled by water circulation at a temperature of 278±2 K to limit thermal reactions. Samples are continuously stirred with a magnetic stirrer using a Teflon bar to ensure homogeneity.

In Fig. 1, the emission spectrum of the lamp recorded using fiber optics coupled with a charge-coupled device (CCD) spectrophotometer (Ocean Optics USD 2000+UV-VIS) is reported. The energy was normalized with the actinometry results using a paranitroanisole (PNA)/pyridine actinometer (Dulin and Mill, 1982). Over the wavelength range of 290 to 600 nm, a total flux of 157 Wm$^{-2}$ is measured. The intensity values of the sun emission under clear sky and cloudy conditions at the puy de Dôme mountain in autumn 2013 are also presented in Fig. 1.

2.6 Hydroxyl radical formation rate and quantum yield determination

The hydroxyl radical formation rate is determined using terephthalate (TA) (terephthalic disodium salt, purity > 99 %) as a probe (Charbouillot et al., 2011). Formation of hydroxyterephthalate (TAOH) is quantified using a Varian Cary Eclipse Fluorescence Spectrophotometer, setting excitation wavelengths at 320 nm, while the emission maximum is measured at 420 nm. The scan rate is 600 nm min$^{-1}$, and a bandpass of 10 nm is set for excitation and emission. Terephthalate is a useful probe because it allows the determination of hydroxyl radical formation rates in the presence of fluorescent
dissolved organic matter. The concentration of the probe is in a large excess (2 mM) compared with the concentration of organic matter to trap all of the photogenerated hydroxyl radicals and then to estimate a value for the hydroxyl radical formation rate not affected by depletion of HO* by other sinks.

The reaction between TA and the hydroxyl radical leads to the formation of fluorescent TAOH and non fluorescent secondary products Reaction (R1), as follows:

\[
TA + HO^* \rightarrow TAOH + \text{products}
\]  

(R1)

The formation rate of hydroxyl radical \( R_{HO^*}^f \) and TAOH \( R_{TAOH}^f \) can be expressed as follows:

\[
R_{HO^*}^f \simeq \gamma R_{TAOH}^f = k_{HO^*,TA}[HO^*]_{ss}[TA]
\]  

(1)

where \( k_{HO^*,TA} = 4.0 \times 10^9 \text{ M}^{-1} \text{ s}^{-1} \) is the second order rate constant of the reaction between HO* and TA (Charbouillot et al., 2011), and [TA] is the initial concentration of terephthalate and \( \gamma \) is the TAOH formation yield calculated as a function of solution pH. This value is found to be linearly correlated with the pH value and is estimated between the values of 0.15 and 0.25 over the pH range of 4 to 7.

Assuming that the concentration variation of TA is negligible during the irradiation time (10 min), we can assume that [TA] = [TA]_0, where [TA]_0 = 2 mM is the initial concentration of TA. Rearranging Eq. (1) gives the following equation:

\[
[HO^*]_{ss} = \frac{\gamma R_{TAOH}^f}{k_{HO^*,TA}[TA]}
\]  

(2)

Other radicals, such as sulfate (SO_4^{2-}) or chlorine/dichlorine (Cl^-/Cl_2^-), can react with TA, leading to the H-abstraction as first chemical reaction. However, their direct generation is nearly exclusively due to the electron transfer reaction from the corresponding anion (i.e., SO_4^{2-} and Cl^-, respectively) to the hydroxyl radical. Moreover, considering...
that the second order rate constant of aromatic compounds with the dichloride radical anion and the sulfate radical is expected to be one or two orders of magnitude lower than that with hydroxyl radical (Neta et al., 1988), and considering a relatively low concentration of sulfate and dichlorine radicals in our cloud samples, the TA reactivity can be attributed exclusively to the HO·.

The quantum yield of hydroxyl radical formation (ΦHO·290-400 nm) is defined as the ratio between the formation rate of HO· (R(RHO·)) and the number of absorbed photons in Einstein per unit time in the overlap range of 290 to 600 (λ₁ and λ₂) (Eq. 3).

This value evaluates the photochemical process efficiency independent of the experimental photochemical conditions.

\[
\Phi_{\text{HO}}^{290-400 \text{ nm}} = \frac{R_{\text{HO}}^{\lambda}}{I_a} \tag{3}
\]

where \( I_a \) can be calculated from the following equation:

\[
I_a = \int_{\lambda_1}^{\lambda_2} I_0(\lambda)(1 - 10^{-\text{Abs}(\lambda)})d\lambda \tag{4}
\]

where \( I_0 \) (photons m\(^{-2}\) s\(^{-1}\)) is the incident photon flux corresponding to the lamp emission and Abs is the absorption of cloud water (normalized considering the optical path length of 5 cm inside of the thermostated reactor).

### 2.7 Back-trajectory plots

Backward trajectories of collected air masses are calculated using the HYSPLIT (hybrid single-particle Lagrangian integrated trajectory) model with the GDAS1 meteorological data archive and the model of vertical velocity (http://ready.arl.noaa.gov/HYSPLIT.php). Backward trajectories are calculated for 72 h (Draxler and Rolph, 2012).
2.8 Model description

The M2C2 combines detailed multiphase chemistry along with the parameterization of the microphysics (Leriche et al., 2001, 2000; Deguillaume et al., 2004). Particularly, the detailed chemistry of $H_xO_y$, chlorine, carbonates, $NO_y$, sulfur, transition metal ions (iron, copper, manganese) and the oxidation of volatile organic compounds (VOCs) is included. Photolysis rates are calculated in the gaseous and aqueous phases, and the pH is calculated following the $H^+$ concentration. Numerical results consist of following the time evolution of the concentrations of each chemical species and calculating at each time step the relative contribution of chemical reactions in the production/destruction of chemical compounds.

In this study, a simplified version of the model is used. The cloud chemical mechanism is restricted to inorganic chemistry ($H_xO_y$, nitrogen, iron) that leads to the $HO^*$ formation (see Table SM1 for details about the considered reactions). The complexation of iron by oxalate is also considered in the model because it can interfere with the $HO^*$ formation rates (Long et al., 2013). Laboratory irradiation experiments are simulated with the M2C2 model considering its chemical module and neglecting microphysical processes and mass transfer parameterizations. Temperature and pH remained constant during the simulation time. We set the pH for each cloud water sample to the values reported in Table SM2, and the temperature is fixed at 278 K, which corresponds to the temperature of the irradiated solutions. The simulated irradiation intensity is held constant and homogenous throughout the experiment. The actinic flux of the experimental lamp is discretized in the tropospheric ultraviolet-visible (TUV) model in 156 non-regular intervals over a wavelength range of 120 to 750 nm (Madronich and Flocke, 1999). The photolysis rates of the chemical species are calculated in TUV according to the experimental quantum yields and absorption cross-sections and are indicated in Table SM1. Experimental chemical concentrations (Table SM2) are used to initialize the model ($H_2O_2$, nitrite, nitrate, iron). Moreover, oxalic acid is considered as an organic complexant during the Fe(II)/Fe(III) cycle. The formation rate of $HO^*$ is calculated by
the model considering the modeled contribution of each reaction producing HO\(^*\) during one hour of experiment.

3 Results and discussion

3.1 Classification of cloud samples

Recently, physicochemical parameters and concentrations of the major organic and inorganic compounds of cloud samples collected over the last ten years at the puy de Dôme are measured and statistically analyzed by PCA (Deguillaume et al., 2014). Along with the corresponding back-trajectory plots, 4 different categories of air masses reaching the summit of the PUY could be distinguished, as follows: polluted, continental, marine and highly marine. Highly marine clouds exhibited high concentrations of \(\text{Na}^+\) and \(\text{Cl}^-\), and the marine category presented a lower concentration of ions but more elevated pH, while the two remaining clusters, classified as “continental” and “polluted”, are characterized by the second-highest and highest levels of \(\text{NH}_4^+\), \(\text{NO}_3^-\), and \(\text{SO}_4^{2-}\), respectively.

In Table SM2, the measured physico-chemical composition of the cloud water samples is reported for this study. We use the same statistical analysis to classify these cloud water samples as Deguillaume et al. (2014). PCA is performed using the pH and the concentration of sulfate, nitrate, chloride, sodium and ammonium ions as variables. Figure 2 reports the scores plot for samples used for the previously reported classification as a function of the attributed class and for the new samples. Three types are identified, as follows: (i) highly marine, (2 samples) characterized by pH values of 5.0 and 5.6, respectively, high concentration of chloride and sodium and low concentrations of nitrate, nitrite and ammonium; (ii) marine cloud waters (28 samples), showing pH values between 4.7 and 7.6 and very low concentrations of anions and cations, and (iii) continental samples (11 samples), with pH values from 4.1 to 6.9 and a medium concentration of nitrates, sulfates and ammonium, while sodium and chloride concen-
trations are very low. No sample could be classified as polluted cloud water because polluted cloud waters have been characterized by concentrations of nitrates, sulfates and ammonium higher than 350, 70 and 330 µM, respectively. This statistical analysis confirms that the majority of the collected samples are of marine origin. This statistical analysis is confirmed by the back-trajectory plots from the HYSPLIT model, showing that most of the air masses reaching the puy de Dôme arises from the west sector i.e., from the Atlantic Ocean.

3.2 Determination of the hydroxyl radical formation rates and photolysis rates

The concentration of the main photochemical sources of HO• for each sample is reported in Table 1. Particularly, the Fe(II) and Fe(III) concentrations are below the detection limit (0.01 µM) for the majority of the collected samples. The highest value found for the Fe(II) concentration is 0.7 µM, while it is 0.6 µM for Fe(III), corresponding to typical values found for marine origin cloud waters (Parazols et al., 2006). The H₂O₂ concentration values range between 6 and 50 µM, nitrate is evaluated between 2 and 220 µM, while the nitrite concentration is between 0 and 1.4 µM.

The \( R_{\text{HO•}}^f \) was measured in pure water doped with different concentrations of hydrogen peroxide, nitrate and nitrite on the same order of magnitude as the collected natural samples. The conditions were those used for natural cloud samples (see Sect. 2.6). A linear correlation between \( R_{\text{HO•}}^f \) and the concentrations of photochemical precursors is found (Fig. 3). The photolysis rate \( (J) \) (s⁻¹) is then estimated from the slopes and are reported in Table 4. For H₂O₂, the \( J \) value is half of the experimental slope because H₂O₂ provides two HO• radicals.

The hydroxyl radical formation rate \( (R_{\text{HO•}}^f) \) is determined for 36 samples, and its value is estimated between \( 3.3 \times 10^{-12} \) and \( 4.2 \times 10^{-10} \) M s⁻¹. Higher values are obtained for cloud water samples of continental origin, while the values found for marine and highly marine cloud waters are less than \( 1.4 \times 10^{-10} \) M s⁻¹. The quantum yield of the formation of hydroxyl radicals under polychromatic irradiation between 290 and
400 nm (Φ_{290–400 nm}^{HO^*}, see Eq. 3) is estimated as between 10^{-5} and 10^{-2}. Steady-state concentrations [HO^*]_{ss} are estimated from 1.4 \times 10^{-18} to 5.2 \times 10^{-17} M (Table 2).

To our knowledge, only a scarce number of data are available in the literature concerning measurements of hydroxyl radical formation rates (R_f^{HO^*}) and estimated steady-state concentrations [HO^*]_{ss} in real cloud waters (Table 3). Faust and Allen (1993) measured the photoformation rates of HO^* (ranging from 1.3 to 8.3 \times 10^{-10} M s^{-1}) under monochromatic light (313 nm) and hydroxyl radical quantum yield (between \sim 5 \times 10^{-4} and 10^{-2}) of six continental cloud water samples. Anastasio and McGregor (2001) investigated the photoreactivity of two cloud waters from the Tenerife Islands to compare the obtained values with fog waters. The authors found R_f^{HO^*} ranging between 3.0 and 6.9 \times 10^{-10} M s^{-1} and a [HO^*]_{ss} ranging between 3.4 and 6.6 \times 10^{-16} M. The values approximately 1 order of magnitude higher than those reported in this study for marine cloud waters, and the differences can be attributed to the air mass origin, as suggested by Faust and Allen (1993). The authors suggested that long-range terrestrial aerosol and gas transport in continental clouds could provide an additional source of hydroxyl radicals compared with other marine or remote clouds.

### 3.3 Modeling the hydroxyl radical formation rates

We simulate the hydroxyl formation rate, R_f^{HO^*} mod, using the model along with the relative contribution (%) of each chemical source (Table SM3). In Fig. 4, the differences between the modeled and experimental HO^* formation rates are estimated calculating the bias error \left(\frac{(R_f^{HO^*} \text{ mod} - R_f^{HO^*} \text{ exp})}{R_f^{HO^*} \text{ exp}} \times 100\%\right). Globally, for the whole cloud water samples (black boxplot), the model can reproduce the range of measured hydroxyl radical formation rates with a slight model underestimation (median of the bias error equal to −23 %). However, if the cloud samples are discretized as a function of different iron concentration ranges (boxplots in color), then the model tends to overestimate the hydroxyl radicals formation for iron concentrations (Fe(II) + Fe(III)) more than 0.1 μM. For concentration of iron between 0.1 and 0.4 μM (8 cloud samples), the
median of the bias error is 61% whereas for iron concentrations over 0.4 µM (5 cloud samples), the median reaches 260%. For cloud samples in which the iron concentration is 0.4 µM, the modeled contribution to the hydroxyl radical formation of iron (Fenton reaction and photolysis of aqua-complexes) can reach 80% (Table SM3). In the model, Fe(III) is partially complexed with oxalic acid, but the majority of iron for these cloud samples is simulated as aqua-complexes (mainly Fe(OH)²⁺ and Fe(OH)³⁺). Therefore, iron can act as a significant HO⁺ source due to its efficient photolysis (Reactions R7–R9, Table SM1) and the Fenton reaction with H₂O₂ (Reaction R11, Table SM1).

However, in atmospheric natural water, the chemical composition of organic matter is still not very well characterized (Herckes et al., 2013). Part of this organic matter is expected to efficiently complex metals in cloud water (Okochi and Brimblecombe, 2002). Due to missing information about the iron speciation and complexation in natural cloud water, the model probably overestimates the free Fe(III). Moreover, iron organic complexes are not expected to directly generate hydroxyl radicals but primarily contribute to the oxidative capacity via Fe(II) generation and the Fenton process. To evaluate this hypothesis, we decide to consider the iron as totally complexed by the organic matter present in natural cloud waters. As a first general approximation, we consider iron as not reactive in the model. The new simulations show that the majority of the simulated values (75%) of the hydroxyl radical formation rates are now underestimated by the model (median of the bias error equal to −40%) (Fig. 5).

Based on the laboratory irradiation experiments (Sect. 2.6 and Fig. 3), new photolysis rates from nitrite, nitrate and hydrogen peroxide are previously estimated from the hydroxyl radical formation rates (Table 4). For nitrate and H₂O₂, the values calculated by the model are lower than the experimental ones; the experimental photolysis rates are higher by a factor ∼1.5 for H₂O₂ and ∼2 for nitrate. For nitrite, the experimental photolysis rate is approximately half of the modeled value. These discrepancies should partially explain the underestimation of HO⁺ formation by the model. Therefore, we consider the experimental photolysis rates in the model, and a new comparison of modeled HO⁺ formation rates with experimental values is shown in Fig. 5. The median
of the bias error is $-3\%$ with the 25 and 75\% at $-50$ and $60\%$, respectively. Table SM4 reports the distribution of the relative contributions of $\text{H}_2\text{O}_2$, $\text{NO}_3^-$ and $\text{NO}_2^-$ photolysis to the modeled $R_{\text{HO}^*}^f$. While the median value of the nitrite and nitrate contributions is calculated by the model as equal to 1 and 5\%, respectively (Fig. 6), the main $\text{HO}^*$ contributor is $\text{H}_2\text{O}_2$ photolysis (median value of 93\%, with the 25 and 75\% at 85 and 96\%, respectively). This result suggests that $\text{H}_2\text{O}_2$ is the key compound that drives the oxidative capacity of our cloud water samples when iron concentrations are relatively low or when iron is suggested to be totally complexed by organic matter.

4 Conclusion

In this study, we compare experimental and modeled $\text{HO}^*$ formation rates for 41 cloud water samples with contrasted chemical compositions depending on the origin of the air masses. This approach helps to elucidate the complex aqueous photoreactivity of natural cloud water that is expected to drive the oxidative capacity. Experimental data are obtained considering only the $\text{HO}^*$ formation sources with addition of an excess of chemical probe leading to the measurements of total generated $\text{HO}^*$ radicals. The first comparison with the M2C2 model shows that the model can reproduce the order of magnitude of measured $R_{\text{HO}^*}^f$ (from $1.1 \times 10^{-11}$ to $4.2 \times 10^{-10}$ $\text{Ms}^{-1}$ and from $1.1 \times 10^{-11}$ to $2.4 \times 10^{-10}$ $\text{Ms}^{-1}$ for experimental and modeled values, respectively). Some discrepancies appear for samples containing iron concentrations over 0.4 $\mu\text{M}$ in which the model overestimates the contribution of iron(III)-aqua complexes to the $\text{HO}^*$ production rate. Ultimately, the aqueous chemical mechanism in the model was modified considering new photolysis rates for $\text{H}_2\text{O}_2$, nitrite and nitrate estimated by laboratory irradiation experiments. As a sensitivity test, iron reactivity was also suppressed in the model to account for the total complexation of iron. The modeled production rates of $\text{HO}^*$ with the updated mechanism are closer to the experimental values. This supports the hypothesis that iron could be strongly complexed by the organic matter
in natural cloud water. These complexes could be more stable and less photoreactive, leading to less HO\(^{\cdot}\) production than that calculated by theoretical models in which only the photochemistry of Fe(III)-carboxylate is considered (Weller et al., 2014). In this context, evaluation of the complexation of iron by organic compounds in the cloud aqueous phase and the photoreactivity of these complexes should be pursued in the future. Their photoreactivity provides significant data to understand the specific role of iron species and, more generally, the oxidant capacity of this medium.

The Supplement related to this article is available online at doi:10.5194/acpd-15-13923-2015-supplement.

Acknowledgements. The authors acknowledge the financial support from the Regional Council of Auvergne, from the Observatoire de Physique du Globe de Clermont-Ferrand (OPGC), from the “Fédération de Recherche en Environnement” through the CPER “Environnement” founded by the “Reigion Auvergne”, the French ministry, FEDER from the European community. This work on the analysis of the cloud water chemical composition is supported by the French Ministry and CNRS-INSU. The authors are very grateful to the Agence Nationale de la Recherche (ANR) for its financial support through the BIOCAP project (ANR-13-BS06-0004).

Table 1. Concentration of main sources of hydroxyl radical in sampled clouds. 41 samples have been analyzed. BDL: below detection limit (0.01 µM for iron and 0.05 µM for NO$_2^-$), NM: not measured.
Table 2. Hydroxyl radical formation rate ($R^f_{\text{HO}^*}$ (M s$^{-1}$)), steady-state concentration [$\text{HO}^*$]$_{\text{ss}}$ and hydroxyl radical polychromatic quantum yield formation ($\Phi^*_{\text{HO}(290-400\text{ nm})}$) values estimated from cloud water samples. NM: not measured. Mar: Marine, H-Mar: highly marine and Cont: continental influence. The error on $R^f_{\text{HO}^*}$ are derived at the 1-σ level simply from the scattering of experimental data.

Figure 1. Absorption spectra of different cloud water samples (left axis) and the right-hand axis shows the emission spectrum of the adopted Xenon lamp reaching solutions over the range of 290 to 600 nm (total flux intensity = 157 W m\(^{-2}\)) compared with the sun emission spectrum (dashed line) for a sunny (353 W m\(^{-2}\)) and a cloudy day (90 W m\(^{-2}\)) in October 2013.
Figure 2. Scores plot obtained by PCA analysis of 137 samples collected before 2013 and grouped in four classes as a function of the previously described classification (Deguillaume et al., 2014) and 41 samples collected during 2013 and 2014. These new data correspond to 15 cloud events and are indicated in black triangles. Statistical analysis is performed using 6 selected variables (pH, [Na$^+$], [Cl$^-$], [SO$_4^{2-}$], [NO$_3^-$], and [NH$_4^+$]). The scree plot obtained from autoscaled data shows that two selected principal components (PC) containing a total variance of about 81%.
Figure 3. Scatter plot of hydroxyl radical formation rates vs. hydrogen peroxide, nitrate and nitrite concentrations using 2 mM of TA at pH 5.0 under Xenon lamp irradiation. The solid line is the linear fit, and dashed lines denote the 90% confidence of the linear fit.
Figure 4. Distribution of the bias error for the whole cloud water samples (black) and for cloud samples discretized as a function of different iron concentration ranges (in color). The bias error is defined by the ratio \((R_{\text{mod}}^{i} - R_{\text{exp}}^{i}) / R_{\text{exp}}^{i}\) in (%). The number of samples analyzed is indicated above each box plot. The bottom and top lines correspond to the 25 and 75 %, respectively. The full line represents the median values. The ends of the whiskers are the 10 and 90 %. 
Figure 5. Distribution of the bias error for the whole cloud water samples for the reference case and for two sensitivity tests performed with the model: (i) the iron chemistry (photolysis of Fe(III) and the Fenton reaction) is neglected in the model; (ii) the iron chemistry is neglected, and the new photolysis rate constants obtained from experimental measurements are implemented in the model. The bias error is defined by the ratio \( \left( \frac{R_{\text{HO}}^f \text{mod} - R_{\text{HO}}^f \text{exp}}{R_{\text{HO}}^f \text{exp}} \right) \) in (%). The number of samples analyzed is indicated above each box plot. The bottom and top lines correspond to the 25 and 75 %, respectively. The full line represents the median values. The ends of the whiskers are the 10 and 90 %. 

The number of samples analyzed is indicated above each box plot. The bottom and top lines correspond to the 25 and 75 %, respectively. The full line represents the median values. The ends of the whiskers are the 10 and 90 %.
Figure 6. Distribution of relative contributions of modeled HO\(^*\) formations rates for each photochemical source (H\(_2\)O\(_2\), NO\(^-\)\(_3\) and NO\(^-\)\(_2\) photolysis) for the whole cloud water samples. Model outputs are obtained from the sensitivity test in which the iron chemistry is not considered, and new photolysis rate constants from experimental measurements are implemented in the model. The number of samples analyzed is indicated above each box plot. The bottom and top lines correspond to the 25 and 75\%\, respectively. The full line represents the median values. The ends of the whiskers are the 10 and 90\%.
