Abstract. PM$_{2.5}$ filter samples have been collected in three megacities at the middle and lower reaches of the Yangtze River: Wuhan (WH), Nanjing (NJ), and Shanghai (SH). The samples were analyzed using ultra-high-performance liquid chromatography (UHPLC) coupled with Orbitrap mass spectrometry (MS), which allowed for detection of about 200 formulas of particulate organosulfates (OSs), including dozens of formulas of nitrooxy-organosulfates, with various numbers of isomers for each tentatively determined formula at each location. The number of aliphatic OS formulas represented more than 78% of the detected OSs at the three locations, while aromatic OSs were much less numerous. OSs with two to four isomers accounted for about 50% of the total OSs on average in these megacity samples, and the percentage of OSs with six and more isomers in WH sample was more significant than those in SH and NJ samples. Additionally, the molecular formula, average molecular weight, and degrees of oxidation and unsaturation of tentatively assigned OSs were compared. The results indicate that the OSs between NJ and SH shared higher similarity, and the characteristics of OSs in SH varied diurnally and seasonally. OSs derived from isoprene, monoterpenes, and sesquiterpenes were abundant in samples from the three megacities and could be produced through both daytime photochemistry and NO$_3$ night-time chemistry. The reaction pathways leading to isoprene-derived OSs probably varied in those locations because of the different NO$_3$ levels. In addition, a number of OSs that might be formed from polycyclic aromatic hydrocarbons were also detected, which underlies the importance of anthropogenic sources for this class of compounds.
1. Introduction

Atmospheric aerosols can scatter and absorb sunlight and provide cloud condensation nuclei. Hence, they have significant impacts on air quality and climate (Andreae and Crutzen, 1997; Hallquist et al., 2009). Aerosol particles contain a large fraction of toxic chemical substances and are harmful to human health (Magari et al., 2002; Ostro et al., 2007). Organosulfates (OSs)—i.e., sulfate esters and their derivatives formed from atmospheric heterogeneous and multiphase chemical reactions (Ma et al., 2012)—are a class of organic compounds that contribute to the total abundance of atmospheric aerosol particles (Tolocka and Turpin, 2012).

Surratt et al. (2007) were the first to identify isoprene- and α-pinene-derived OSs in ambient aerosols in the southeast US using high-performance liquid chromatography coupled with electrospray mass spectrometry. Since then, tremendous progress has been made in the understanding of the formation mechanisms of OSs. Experimental studies show that isomeric isoprene epoxidiols (IEPOX) and methacrylic acid epoxide (MAE) are formed during the oxidation of isoprene under low- and high-NOx conditions, respectively. Subsequent acid catalyzed-reactions of IEPOX and MAE in the presence of sulfates can lead to the formation of OSs (Darer et al., 2011; Lin et al., 2012c; Lin et al., 2013; Surratt et al., 2010; Paulot et al., 2009). OSs can be formed from reactions between α-pinene and OH radicals, NO3 radicals, and O3 in the presence of sulfates, from β-pinene under high-NOx conditions, from ozonolysis and photochemical reactions of other monoterpenes (α-terpinene and γ-terpinene), and from sesquiterpene (i.e., β-caryophyllene) under acidic conditions (Surratt et al., 2008; Inuma et al., 2007a; Inuma et al., 2007b; Chan et al., 2011). Sulfate/sulfite radical-induced oxidation reactions with unsaturated organic compounds including isoprene, methyl vinyl ketone, methacrolein, and α-pinene in the aqueous phase represent another potential formation route of OSs (Szmigielski, 2015; Rudzinski et al., 2009; Noziere et al., 2010; Schindelka et al., 2013). In addition, both reactive uptake of carbonyl compounds on sulfuric acid or sulfates (Liggio et al., 2005) and hydrolysis reactions of organonitrates can lead to formation of OSs (Darer et al., 2011; Hu et al., 2011). Very recently, OSs and sulfonates were revealed to form from
photo-oxidation of polycyclic aromatic hydrocarbons (PAHs) in the presence of sulfate seed (Riva et al., 2015b).

Identification and quantification of OSs in atmospheric particulate samples have been widely performed around the world (e.g., Kristensen and Glasius, 2011; Stone et al., 2009; Olson et al., 2011; Zhang et al., 2012). Many studies indicate that the total abundance of OSs varies from one region to another. OSs accounted for about 4% of the total organic mass in ambient aerosols over the southeast Pacific Ocean (Hawkins et al., 2010), whereas this contribution was estimated to be about 30% at the forested site of K-puszta in Hungary during summer (Surratt et al., 2008). The abundance of a given OS also shows clear variation between different sampling locations. The level of four aromatic OSs was estimated to be 234.4 pg m\(^{-3}\) in atmospheric PM\(_{2.5}\) in Pakistan, which were much more abundant than those in California (8.9 pg m\(^{-3}\)) or Nepal (3.9 pg m\(^{-3}\)) (Staudt et al., 2014).

In a given location, there are seasonal variations of OSs. For example, the \(\alpha\)-pinene-related nitrooxy-OSs were detected at high concentrations during the winter period, followed by autumn, spring, and summer at a rural background site in Hamme, Belgium (Kahnt et al., 2013). Ma et al. (2014) also showed that the total mass concentration of 17 OSs was the highest in summer and lowest in winter, while no clear seasonal trend was observed in the mass concentration of benzyl sulfate (BS). However, BS showed the highest concentration in winter and the lowest one in summer in Lahore, Pakistan (Kundu et al., 2013), which underlies the role of both regional constraints and meteorological conditions.

Recently, ultra-high-resolution mass spectrometry has been applied for tentative determination of the molecular formulas of OSs in atmospheric aerosols samples. Owing to the high mass resolution and mass accuracy of the ultra-high-resolution mass spectrometer, the molecular formulas of analytes can be tentatively determined without the authentic standards required with low-resolution mass spectrometers. Lin et al. (2012a, 2012b) studied aerosols sampled at a rural location of the Pearl River Delta Region in China and suggested that the arbitrary signal intensities of OSs obtained from the humic-like fraction are often the strongest in the electrospray...
ionization ultra-high resolution mass spectra, and that the degrees of oxidation of OSs
and nitrooxy-OSs are quite high. Using a similar approach, O’Brien et al. (2014)
showed that a significant portion of OSs was formed from biogenic precursors
through the epoxide pathway in Bakersfield, CA, USA. In addition, by using a
mixture of acetonitrile and toluene instead of a mixture of acetonitrile and water as the
working solvent for nano-DESI ionization, Tao et al. (2014) tentatively determined
many OSs with long aliphatic carbon chains and low degrees of oxidation and
unsaturation, which were presumably formed from anthropogenic precursors emitted
by cars in Shanghai (SH).

Although it has been accepted that OSs are an important component of ambient
particulate matter, studies on their characteristics are rather sparse in China, especially
in the Yangtze River region. Ma et al. (2014) identified and quantified 17 OSs in SH.
As mentioned, Tao et al. (2014) compared OS characteristics such as the degrees of
oxidation and saturation between samples from SH and Los Angeles. While SH has
been a relative hotspot for OS characterization, the characteristics of OSs in the
general Yangtze River region have yet to be elucidated. Wuhan (WH), Nanjing (NJ),
and SH are three megacities at the middle and lower reaches of the Yangtze River
with populations of over 10, 8, and 24 million, respectively (as of 2014). Tremendous
amounts of energy are consumed owing to the large population and rapid economic
development, leading to extensive emissions of anthropogenic pollutants including
particulate matter, volatile organic compounds (VOCs), sulfur dioxide, and nitrogen
oxides (Huang et al., 2011; Wang et al., 2013). At the same time, these three cities are
located in the subtropical zone with high emissions of biogenic VOCs (Guenther et al.,
1995). Hence, substantial amounts of OSs are likely to exist in WH, NJ, and SH
aerosol particles. In this study, OSs, including nitrogen-containing OSs, were
specifically searched for in WH, NJ, and SH PM$_{2.5}$ samples using an UHPLC coupled
to an Orbitrap-MS. Characteristics of OSs including the molecular formula, number
of isomers, molecular weight, and the degrees of oxidation and unsaturation were
analyzed and compared. The potential precursors in the megacities are also discussed.
2. Material and methods

2.1 Collection of PM$_{2.5}$ samples

Eight PM$_{2.5}$ samples were collected at three locations: two in WH, two in NJ, and four in SH, as shown in Figure 1 and Table 1. Samples covering 24 h were collected in WH from January 26 to 27 (sample ID: WH winter, WHW) and from June 15 to 16, 2012 (sample ID: WH summer, WHS). The WH site was located on the rooftop of a dormitory building (30°29′N, 114°24′E) that is about 20 m above ground at ZhongNan University of Economics and Law near a commercial street. NJ samples were collected from August 29 to 30, 2012, for 12 h for each sample (samples ID: NJ summer daytime, NJSD; NJ summer nighttime, NJSN). The NJ site was located in the Chinese national meteorology observatory facility at the Nanjing University of Information Science and Technology (32°12′N, 118°42′E), which is about 15 km north of the downtown area and about 2 km west of clusters of steel mills and petrochemical refinery facilities (Zheng et al., 2015).

SH samples were collected for 12 h from January 17 to 18, 2013 (sample ID: SH winter daytime, SHWD; SH winter nighttime, SHWN), and July 28 to 29, 2013 (sample ID: SH summer daytime, SHSD; SH summer nighttime, SHSN). The SH site was located on the rooftop of a teaching building at Fudan University (31°18′N, 121°30′E) about 20 m above ground with surrounding residential and commercial properties and a major highway to the south of the site (Xiao et al., 2015; Ma et al., 2014). Table S1 provides a comparison of air quality and meteorological conditions between the sampling days and the seasonal average in SH.

PM$_{2.5}$ was collected on 90 mm quartz-fiber filters (Whatman Company, UK) using a middle-flow impact aerosol sampler (Qingdao Hengyuan Tech Co., Ltd., HY-100) operating at 100 lpm. All filters were prebaked at 500°C for 5 h to remove residual organics before use. After sample collection, filters were wrapped in prebaked aluminum foil and stored at -20°C before further analysis.

2.2 Sample analysis

One-fourth of each filter was put into an amber vial with 6 mL of methanol
(Optima® LC/MS, Fischer Scientific, UK) and shaken for 20 min on an orbital shaker set to 1000 rpm. The extract was then filtered through a glass syringe on a 0.2µm PTFE membrane (13 mm, Pall Corporation, USA). These two steps were performed twice, and the extracts of each filter were recombined and blown almost to dryness under a gentle stream of nitrogen. The extracts were then reconstituted in 1 mL of a 1:1 v/v mixture of water (Optima® LC/MS, Fischer Scientific, USA) and acetonitrile (Optima® LC/MS, Fischer Scientific, USA). For the analysis, 100 µL of the final reconstituted extract was diluted by adding 100 µL of water. 5µL of these diluted solutions (50 µL in the case of the NJSD sample) were analyzed by UHPLC (Dionex 3000, Thermo Scientific, USA) coupled to a Q-Exactive Hybrid Quadrupole-Orbitrap MS (Thermo scientific, USA). The efficiency and the repeatability on three replicates of the extraction protocol were checked using four standards: methyl sulfate, octyl sulfate, dodecyl sulfate, and camphor sulfonic acid. The results showed that their average extraction efficiencies were 71.4, 95.0, 97.7, and 94.0%, respectively (Table S2). Analytical replicates were not considered because the final sample extract volume was quite low (200 µL), and the remaining volume after the first injection was preferentially kept in case of specific analytical doubt rather than systematically injected.

Analytes were separated using a Waters Acquity HSS T3 column (1.8µm, 100×2.1mm) with mobile phases consisting of (A) 0.1% formic acid in water (Optima® LC/MS, Fischer Scientific, USA) and (B) 0.1% formic acid in acetonitrile (Optima® LC/MS, Fischer Scientific, USA). The concentration of eluent B was initially kept at 1% for 2 min, then increased to 100% in 11 min, kept at 100% for 2 min, decreased to 1% in 0.1 min, and kept at 1% for 6.9 min. The Q-Exactive Hybrid Quadrupole-Orbitrap mass spectrometer was equipped with a heated electrospray ionization source. It was operated in the negative ion mode with a spray voltage of -3.0kV, a mass resolving power of 140 000 at m/z 200, and a scanning range of 50–750 m/z. The Q-Exactive mass spectrometer was externally mass calibrated daily using a 2 mM sodium acetate solution that provides a series of negative adduct ions in the range of 50–750 m/z.
2.3 Data processing

The obtained chromatograms were analyzed with Progenesis QI software (V1.0, Waters Corporation) by assuming that the extracted ions in the range of 50–750 m/z [M-H] were formed from loss of a proton from the analytes. In contrast to direct infusion, the LC separation provides meaningful help in distinguishing quasi-molecular ions and potential in-source formed adducts for the same chromatographic retention time. A molecular formula calculator was then used to mathematically assign all possible formulas for an extracted quasi-molecular ion with a mass tolerance of ±2 ppm. These molecular formulas can be expressed as $C_cH_hO_oN_nS_s$, where $c$ is the number of carbon atoms in the range of 1–40, $h$ is the number of hydrogen atoms in the range of 2–80, $o$ is the number of oxygen atoms in the range of 0–40, $n$ is the number of nitrogen atoms in the range of 0–3, and $s$ is the number of sulfur atoms in the range of 0–2. Formulas were further constrained by setting H/C, O/C, N/C, S/C, and double bond equivalent to carbon number ratios (DBE/C) in the ranges of 0.3–3.0, 0–3, 0–0.5, 0–0.2, and 0–1, respectively. This was done to ensure that the retrieved molecular formula do exist in nature (Fuller et al., 2012; Lin et al., 2012a; Lin et al., 2012b).

The number of ions with more than one reasonable formula within 2 ppm mass tolerance accounted only for 1.5% of the total number of tentatively determined ions, and the formulas with the best accuracy are listed in Table S3. The peak intensities of isotopically substituted ions were constrained by their low abundance and were hence not systematically checked. Compounds that satisfy these criteria and present a number of oxygen atoms greater than or equal to $4s+3n$ ($4s+3n\leq o$) were tentatively regarded as OSs or nitrooxy-OSs. However, tandem MS experiments were not conducted on the S- and N-containing ions detected in these eight ambient samples. Therefore, other S- and N-containing compounds, such as sulfonates or compounds bearing nitro groups, may also be involved (e.g., Riva et al., 2015b; El Haddad et al., 2013) due to the lack of using tandem MS experiments to provide insights into the structures of these ions.
In this study, the abundance of an OS refers to the area of its chromatographic peak, and the number of isomers for an OS is based on the number of chromatographic peaks observed for given m/z values. Note that the obtained number of isomers may vary significantly when the separation method is further optimized. Then, the arbitrary abundances of all isomers for a given m/z value are added up. The arbitrary abundance of the most abundant OS or nitrooxy-OS in each sample is defined as 100%, and only OSs and nitrooxy-OSs with an arbitrary abundance larger than 0.5% of the most abundant one in the same sample are presented. The signal-to-noise ratios of the least abundant OSs in each sample are greater than 10 with a noise level of ca. $1 \times 10^4$ arbitrary units. Note that the arbitrary abundance of a given OS does not directly reflect its concentration compared to others in the same sample because the ionization efficiency is compound and solvent specific in electrospray ionization. Also, similar ionization efficiency is assumed for a given OS in different samples as similar retention times are observed and as UHPLC separation resolves most of the matrix components.

Blank filters were processed and analyzed in an identical way, and blank correction was made as follows. The presence of targeted quasi-molecular ions in the blanks was systematically verified, and if a chromatographic peak was indeed detected, then it was retained (i.e., considered as real) only if the sample-to-blank ratio of the peak area was greater than 10, with the blank value being subtracted prior to further processing. The DBE value of a molecule reflects the degree of its unsaturation. The DBE value is usually calculated as:

$$\text{DBE} = \frac{2c+2+n-h}{2}$$  \hspace{1cm} (Eq. 1)

Not taking into account the two double bonds involved in each sulfate group, the DBE values of OSs calculated by Eq. 1 represent the unsaturation degree of the side carbon chain (eventually bearing oxygen and nitrogen atoms). In addition, one can note that this equation adds one DBE unit for each nitrate group. Molecular formulas with DBE$<0$ and formulas that disobey the nitrogen rule were discarded. The difference between the DBE value and the number of N atoms (DBE-n) is the most conservative
criterion to determine whether a compound is aliphatic: the number of OSs with 
(DBE-n) < 4 can be regarded as the minimum number of aliphatic OSs (Lin et al., 
2012b).

Both DBE/C and the aromaticity index (AI) could be used as criteria to determine 
whether a compound contains aromatic rings with thresholds of DBE/C > 0.67 and 
AI > 0.5, respectively. However, AI is more conservative (Koch and Dittmar, 2006).
The value of AI can be calculated according to:

\[
AI = \frac{DBE_{AI}}{C_{AI}} = \frac{1+c-o-s-(0.5h)}{c-o-s-n} \quad \text{(Eq. 2)}
\]

where DBE_{AI} represents the sum of the minimum number of C=C double bonds and 
the number of rings in a formula containing heteroatoms, and C_{AI} represents the 
difference between the number of carbon and the number of potential double bonds 
caused by heteroatoms. If DBE_{AI} \leq 0 or C_{AI} \leq 0, then AI is defined to be zero. In 
contrast, AI > 0.5 and AI \geq 0.67 indicate the existence of aromatic and fused aromatic 
ring structures in a compound, respectively (Koch and Dittmar, 2006).

In the Kendrick mass defect diagram (KMD diagram), CH\textsubscript{2} (14.00000) was 
chosen as a base unit. The Kendrick mass (KM\textsubscript{CH2}) and the Kendrick mass defect 
(KMD\textsubscript{CH2}) can be determined by Eq. 3 and Eq. 4, respectively:

\[
KM_{CH_2} = \frac{\text{Observed Mass}}{14.00000} \quad \text{(Eq. 3)}
\]
\[
KMD_{CH_2} = \text{Nominal Mass} - KM_{CH_2} \quad \text{(Eq. 4)}
\]

where “Observed Mass” is the mass measured by the mass spectrometer, and 
“Nominal Mass” is the rounded integer mass of a compound.

3. Results and discussion

3.1 Isomers

UHPLC separation was applied prior to MS analysis for detection of potential 
isomers hidden behind a given m/z value and to provide another dimension of the 
ambient aerosol composition complexity. As an example, Figure 2 shows the 
extracted ion chromatograms for C\textsubscript{5}H\textsubscript{10}O\textsubscript{5}S. An OS with this molecular formula has 
recently been identified in laboratory-generated secondary organic aerosols either
from the ozonolysis of isoprene in the presence of sulfate aerosols or from the
transformations of isoprene coupled with S(IV)-autoxidation in the aqueous-phase,
but only one and two isomers were detected by UPLC-high-resolution MSs,
respectively (Riva et al., 2015a; Szmigielski, 2015). From our ambient samples, 11
isomers were detected in total, with varying numbers of isomers in each sample (see
Figure 2 and Table S3). On the other hand, only two isomers were detected in the
ambient PM_{2.5} samples from Diabla Gora rural site (Szmigielski, 2015). The reason
for this difference in the number of isomers among these studies might arise from the
different chromatographic conditions and additional precursors, including different
terpenes. In addition, it is difficult to assign which isomer has been detected by Riva
et al. (2015a) and Szmigielski (2015) due to different chromatographic conditions and
detectors.

Additional extracted ion chromatograms are presented in the supplement for
C_{5}H_{12}O\cdot S_{1}, C_{10}H_{17}O\cdot N_{1}S_{1}, and C_{16}H_{32}O\cdot S_{1} (Figure S1). Two and four isomers were
detected for C_{5}H_{12}O\cdot S_{1} and C_{10}H_{17}O\cdot N_{1}S_{1}, respectively, whereas Surratt et al. (2008)
detected one and six isomers for these OSs, also from ambient samples. A thorough
analysis of UHPLC-Orbitrap MS data leads to the tentative determination of more
than 100 CHOS formulas and dozens of CHONS formulas, with various numbers of
isomers in each sample. The full list of the neutral mass, molecular formula, number
of isomers, retention times, and potential precursors for these assigned OSs is
tabulated in Table S3. Having access to the isomeric pattern of significant OSs could
be very helpful in the future for identifying possible OS sources. Thus, Table S3
provides one of the first data sets of OS isomers in ambient samples.

The full mass spectra in summer samples from the three megacities, including all
tentatively assigned OSs, have been reconstructed to present the samples’ general
characteristics. In Figure 3, the X-axis corresponds to the neutral molecular weight of
detected OSs, the Y-axis represents their arbitrary abundances, and the number of
isomers per detected mass is color-coded. Comparison of the reconstructed mass
spectra shows that the number of OSs with an identical formula and the same number
of isomers that could be observed in all three megacities accounted for only 17.6% of
all the tentatively assigned OS molecular formulas. Between WHS and NJSN, the proportion of OSs sharing identical formulas reached 50.3%, but only 27.9% also possessed the same number of isomers. Quite similarly, between NJSN and SHSD+SHSN, the proportion of OSs sharing identical formulas reached 62.8%, but only 39.4% also had the same number of isomers. Between WHS and SHSD+SHSN, this proportion reached 51.5%, with only 32.3% having the same number of isomers. Therefore, one can consider that the samples from NJ and SH showed greater similarity, especially from their isomeric patterns. This observation is in agreement with the proximity of the two megacities compared to the more distant megacity of WH.

As shown in Figure 3, OSs with two to four isomers accounted for about 50% of the total detected OSs. Those with more than six isomers accounted for the largest proportion, and OSs with one isomer were insignificant in WH. In contrast, in SH and NJ, OSs with one isomer only were preponderant, while those with more than six isomers were much less numerous. Clearly, the isomeric pattern differs significantly in WH compared to the other two megacities, probably due to the diversity in precursors and/or oxidation mechanism.

3.2 Tentative assignment and potential precursors of major OSs

The gaseous precursors of many OSs in Figure 3 can be tentatively assigned, since identical formulas of OSs have been observed in chamber studies. In Figure 3, OSs with strong arbitrary intensities have been labeled with a letter as follows: A: C_5H_8O_3SO_4; B: C_5H_12O_3SO_4; C: C_6H_10O_3SO_4; D: C_7H_12O_3SO_4; E: C_9H_18O_2SO_4; F: C_5H_11O_2NO_3SO_4; G: C_9H_16O_3SO_4; H: C_10H_17NO_3SO_4; I: C_5H_10O_1(NO_3)_2SO_4; J: C_16H_32O_2SO_4; and K: C_15H_25NO_3SO_4. Among these OSs, A, C, D, and G are a series of homologues, and so are E and J. A, B, F, and I could be derived from isoprene, whereas D and G could be derived from limonene, C from 3-Z-hexenal, K from β-caryophyllene, and H from various monoterpenes (i.e., α-pinene, β-pinene, α-terpinene and terpinolene) (Chan et al., 2011; Shalamzari et al., 2014; Surratt et al., 2008; Gomez-Gonzalez et al., 2008). E and J were characterized by high molecular
weights and degrees of saturation, presumably being long-chain aliphatic OSs. In
general, many abundant OSs could be derived from isoprene, monoterpenes, and
sesquiterpenes in these three megacities.

The relative abundance of J was the highest in WH but much lower in NJSN and
SHSD+SHSN samples. H was the highest in the SHSD+SHSN samples, while I was
the most abundant in the NJSN sample. It is doubtless that I bears two nitrate groups
(two nitrogen atoms in its formula that fulfill the \(4s+3n \leq 0\) rule) and is the most
abundant in the NJSN sample, likely due to active NO\(_3\) radical chemistry at night. F
and K, which bear one nitrate group, were also quite abundant in the NJSN sample,
underlying the role of NO\(_3\) chemistry at night. The isomer ratios vary from sample to
sample and therefore certainly carry information about their origin. These ratios and
possible VOC precursors for these most abundant OSs are summarized in Table S4.

3.3 Comparison of OS characteristics

Table 1 summarizes the average characteristics (molecular weight, DBE, and
elemental ratios) of tentatively assigned CHOS and CHONS compounds. These
CHOS and CHONS compounds were here tentatively regarded as organosulfates and
nitrooxy-organosulfates respectively, but other S- and N-containing functional groups
could be involved as well in small amount (Lin et al., 2012b). In addition, \((o-3s)/c\)
(Tao et al., 2014) and \((o-3s-2n)/c\) have been calculated to illustrate the number of
oxygen-containing functional groups per carbon atom. These two values are derived
from the fact that each sulfate and nitrate group respectively contains three and two
oxygen atoms more than do common oxygen-containing groups, such as a hydroxyl
or a carbonyl moiety. \((o-3s)/c\) and \((o-3s-2n)/c\) can therefore be regarded as measures
of the degree of oxidation of CHOSs and CHONS compounds, respectively.

The average molecular weight and DBE value of CHONS species were generally
larger than those of CHOS analogues, because CHONS contains one or two more
nitrate groups (the presence of one nitrate group adding one DBE unit). Measurement
of the O/C ratio of OSs in Bakersfield (CA, USA) indicated that the degree of
oxidation of CHONS was larger than that of CHOS throughout the day (O’Brien et al.
A similar trend has been observed for CHONS$_1$ and CHOS$_1$ in SH and Los Angeles aerosol samples but using the (o-3)/c ratio to measure the degree of oxidation (Tao et al., 2014). In this study, however, the average degree of oxidation of CHONS was only slightly larger than that of CHOS during the daytime and slightly smaller at night. The use of the (o-3s)/c and (o-3s-2n)/c ratios to evaluate the degrees of oxidation of the CHOS and CHONS carbon chain, respectively, allows for precise comparison of the oxidation states of these two classes of compounds. The values of the oxidation states for OSs and nitrooxy-OSs on a same sample (0.01 to 0.14 units of difference) suggest that the presence of the sulfate and/or nitrate groups is not determinant.

The OSs with (DBE-n) < 4 accounted for 86.2, 78.5, and 78.3% of total OSs in WH, NJ, and SH, respectively, suggesting tentatively assigned OSs were mainly aliphatic OSs. Also, the number of OSs with (DBE-n) ≥ 4 can be regarded as the maximum number of aromatic OSs. This value appears to be slightly higher in SH (21.7%) and NJ (21.5%) compared to WH (13.8%), possibly indicating a slightly more significant anthropogenic influence for the first two cities.

The number of OSs with DBE/C > 0.67 accounted for 2.2, 5.2, and 7.1% of total OSs, and their abundance accounted for 0.6, 1.4, and 8.0% of total abundances of OSs in WHS, NJSD+NJSN, and SHSD+SHSN, respectively. Only a few aromatic OSs with AI > 0.5 were detected, but it could be due to the fact that this value takes into account carbon-bounded S and N but not sulfate and nitrate groups (and the related oxygen atoms), underestimating the aromatic ring content. BS and its analogues were nevertheless detected in most of the samples of the three megacities.

Figure 4 shows the CH$_2$-Kendrick diagrams and Van Krevelen (VK) diagrams for CHOS species for the WHS, NJSD+NJSN, and SHSD+SHSN samples, respectively, and the variation in DBE is color-coded. In the CH$_2$-Kendrick diagram, compounds in a homologue series of compounds with identical KMD$_{CH2}$ values form a horizontal line. The molecular formula of the homologue series 1 and 2, which have DBE values equal to zero, can be written as C$_n$H$_{2n+2}$SO$_4$ and C$_n$H$_{2n+2}$O$_1$SO$_4$ (n>4), respectively. Hence, the OS in the homologue series 2 contained one more hydroxyl group or ether.
group than the corresponding one in the homologue series 1. Similarly, molecular
formula of the homologue series 3, 4, and 7 with DBE=1 can be written as
$C_{n}H_{2n}O_{1}SO_{4}$, $C_{n}H_{2n}O_{2}SO_{4}$, and $C_{n}H_{2n}O_{3}SO_{4}$; those for series 6, 9, 11, and 13 with
DBE=2 can be written as $C_{n}H_{2n-2}O_{2}SO_{4}$, $C_{n}H_{2n-2}O_{3}SO_{4}$, $C_{n}H_{2n-2}O_{4}SO_{4}$, and
$C_{n}H_{2n-2}O_{5}SO_{4}$; and those for series 5, 8, 10, 12, 14, and 15 with DBE=3 can be written
as $C_{n}H_{2n-4}O_{1}SO_{4}$, $C_{n}H_{2n-4}O_{2}SO_{4}$, $C_{n}H_{2n-4}O_{3}SO_{4}$, $C_{n}H_{2n-4}O_{4}SO_{4}$, $C_{n}H_{2n-4}O_{5}SO_{4}$, and
$C_{n}H_{2n-4}O_{6}SO_{4}$, respectively. For the homologue series with DBE=2 or 3, the oxygen
atoms other than those in the sulfate group probably belonged to hydroxyl, carbonyl,
or carboxylic groups, because it is unlikely that a compound in this range of
molecular weight would contain so many ether groups. CHOS with DBE=4 or 5
represented 9.9, 12.2, and 9.5% of the total CHOS species in the WHS, NJSD+NJSN,
and SHSD+SHSN samples, respectively.

The region of the CH$_2$-Kendrick diagrams where KM$_{CH2}$ is between 350 and 750
and KMD$_{CH2}$ is larger than 0.38 appears to be of particular interest. No CHOS was
observed in this region in WHS, whereas up to 6.5 and 9.5% of the total CHOS were
detected there in the NJSD+NJSN and SHSD+SHSN samples, respectively. The
CHOS species in this region were characterized by a high molecular weight, high
degrees of unsaturation and oxidation (DBE $> 5$ and (o-3s)/c $> 0.5$), and a minimum
amount of isomers (one isomer for 79% of CHOS in this region). Moreover, these
CHOS are located in the lower right region of the VK diagrams that plot H/C versus
(o-3s)/c ratios (Figure 4, Wu et al. 2004; Kim et al, 2003). They are thus likely to
contain one or more aromatic rings (DBE/C $> 0.67$, but AI$<0.5$) and come most
certainly from anthropogenic precursors.

Fewer CHONS than CHOS species were observed (Figure 5). In the CH$_2$-Kendrick
diagram, the KMD$_{CH2}$ values of CHONS were generally larger than those of CHOS
because of the presence of one or two additional nitrate group contributing to these
KMD$_{CH2}$ values. Similarly to CHOS species, CHONS species in a homologue series
with identical KMD$_{CH2}$ values form a horizontal line. Molecular formula of the
homologue series 1 and 3 with DBE=1 can be written as $C_{n}H_{2n+1}NO_{3}SO_{4}$ and
$C_{n}H_{2n+1}ONO_{3}SO_{4}$; those for homologue series 2, 4, 5, and 8 with DBE=2 can be
written as $C_{n}H_{2n-1}NO_{3}SO_{4}$, $C_{n}H_{2n-1}ONO_{3}SO_{4}$, $C_{n}H_{2n-1}O_{2}NO_{3}SO_{4}$, and $C_{n}H_{2n-1}O_{3}NO_{3}SO_{4}$; those for series 7, 9, and 10 with DBE=3 can be written as $C_{n}H_{2n-3}O_{2}NO_{3}SO_{4}$, $C_{n}H_{2n-3}O_{3}NO_{3}SO_{4}$, and $C_{n}H_{2n-3}O_{4}NO_{3}SO_{4}$; and those series 6 with DBE=4 can be written as $C_{n}H_{2n-5}ONO_{3}SO_{4}$ (n>4). By comparing the molecular formulas of CHOS and CHONS species, it appears that most of CHONS could correspond to the addition of nitrate groups on the detected CHOS. In the VK diagrams, the homologue series 1 and 3 constitute upward lines and the other ones constitute downward lines. In the region where $K_{MCH_2}$ is between 500 and 700 and $K_{MDCH_2}$ is larger than 0.6, CHONS species with DBE values larger than 5, a high molecular weight and a high degree of oxidation ($(o-3s-2n)/c > 0.5$) were detected in NJSD+NJSN and SHSD+SHSN, but not in WHS. According to the formulas of those CHONS species, their precursors were different from those for any CHOS species. On the other hand, a few additional CHONS species with DBE values also larger than 5, relatively low molecular weight and low degrees of saturation and oxidation ($(o-3s-2n)/c < 0.3$) were present in the three megacities.

Figure S2 shows the numbers of CHOS and CHONS species in different mass ranges. Generally, OSs in the mass range of 250–300 Da showed the greatest variety. The number of OSs in the mass range of 200–400 Da accounted for 90.5, 83.1, and 85.4% of determined OSs in WHS, NJSD+NJSN, and SHSD+SHSN, respectively. OSs with molecular weights larger than 500 Da characterized by high degrees of unsaturation in the KMD diagrams existed in the NJ and SH samples, whereas the molecular weight of all OSs in the WH sample was less than 500 Da. In summary, the molecular characteristics of tentatively assigned OSs between NJSD+NJSN and SHSD+SHSN shared better similarity, probably because NJ and SH are geographically closer at the lower reach of the Yangtze River, whereas WH is at the middle reach of the Yangtze River.

3.4 Formation pathways of isoprene-derived OSs in three megacities

Isoprene has been shown to be an important precursor of OSs in the three megacities. Previous studies suggest that IEPOX ($C_5H_{10}O_3$) and MAE ($C_4H_6O_3$) are
two key reactive intermediates that are formed during isoprene oxidation under low-
and high-NOx conditions, respectively. Subsequent acid catalyzed-reactions of IEPOX
and MAE in the presence of sulfates lead to the formation of C$_{3}$H$_{12}$O$_{3}$SO$_{4}$ and
C$_{4}$H$_{8}$O$_{3}$SO$_{4}$, respectively (Surratt et al., 2010; Worton et al., 2013), with the C$_{4}$ OS
being promoted under high-NOx conditions compared to the C$_{5}$ OS. C$_{5}$ and C$_{4}$ OSs
could also be formed from sulfate/sulfite radical-induced oxidation reactions with
isoprene and its oxidation products (i.e., methyl vinyl ketone, and methacrolein) in the
aqueous phase, respectively (Schone et al., 2014; Noziere et al., 2010). Since the
liquid water content is not available for our ambient samples, these aqueous reaction
pathways are not considered here.

In this study, the S/C ratio has been limited to 0–0.2 to assure that the obtained
compound exists in nature (Lin et al., 2012a; Tao et al., 2014; Wozniak et al., 2008).
As a result, C$_{4}$H$_{8}$O$_{3}$SO$_{4}$ has been eliminated by this criterion. Manually extracted
ratios of the abundances of C$_{4}$H$_{8}$O$_{3}$SO$_{4}$ to C$_{5}$H$_{12}$O$_{3}$SO$_{4}$ (denoted hereafter as C$_{4}$/C$_{5}$
ratios) were used to elucidate the major formation pathway of isoprene-derived OSs in
the three megacities.

In SH winter daytime samples, the C$_{4}$/C$_{5}$ ratio was 8.9 and decreased to 0.20
during summer. In WH, the C$_{4}$/C$_{5}$ ratio was equal to 0.22 in winter and 0.13 in
summer. In both cases, these observations are consistent with the C$_{4}$ OS being
promoted with higher winter NOx levels but also suggest that even in winter, isoprene
OSs are formed under low-NOx conditions. In the NJSD sample, the C$_{4}$/C$_{5}$ ratio was
about 2.5, suggesting that the high-NOx pathway might dominate in summer in NJ
(Dong et al., 2013).

3.5 Comparison of OSs in the SH samples

For a more accurate comparison, the abundance of C$_{16}$H$_{17}$NO$_{3}$SO$_{4}$ in the SHSN
sample (the highest one from all the SH samples) was set arbitrarily to 100%, and an
abundance limit corresponding to 0.5% of this value was used to include or exclude
the OSs from the four SH samples in the following comparison. Figure 6 shows that
the number of OSs in the SHSD and SHSN samples was much larger than those in the
SHWD and SHWN samples, respectively, consistent with a higher photochemical activity and/or higher precursor emissions in summer than in winter. The number of OSs in the SHSN and SHWN samples, especially the number of CHONS, was much larger than that in the SHSD and SHWD samples, respectively, consistent with the previous observation in Figure 3 (see section 3.2) that much more CHONS is present during nighttime.

As shown in Figure 7, the total arbitrary abundances of OSs in the SHSD and SHSN samples were 2.1 and 3.0 times higher than in the SHWD and SHWN samples. The total arbitrary abundances of CHOS did not display significant differences between SHSD and SHSN or between SHWD and SHWN. However, the arbitrary abundances of CHONS in these SHSN and SHWN samples were 5.0 times and 2.2 times higher than in the SHSD and SHWD samples. This is consistent with an expected nighttime chemistry of NO3. Moreover, the variety (Figure 6) and the abundance (Figure 7) of CHONS in both SHWN and SHSN samples were far larger than those in SHWD and SHSD.

The fact that the SHSN sample showed higher abundance and variety of CHONS than the SHWD sample seems to point toward a CHONS formation driven by both daytime photochemistry (and/or precursor emission) and subsequent nighttime NO3 chemistry. Similar trends of higher CHONS abundance during nighttime than during daytime were observed in Beijing, China (van Pinxteren et al., 2009), Atlanta, GA (Hatch et al., 2011), and Bakersfield, CA, USA (O’Brien et al., 2014). However, He et al. (2014) observed a reverse trend at a regional background site in the Pearl River Delta region (concentrations of nitrooxy-OSs were higher during daytime), concluding that photochemical reactions could also lead to the formation of a significant amount of nitrooxy-OSs. This photochemical pathway could contribute to the formation of the nitrooxy-OSs detected during daytime, even if they showed only relatively low abundances in this study.

Figure 7 shows the carbon number-based arbitrary abundance of CHOS and CHONS. In all four samples, more than 60% of the OSs were characterized by 5 to 10 carbon atom chains. In the SHSD and SHSN samples, C5 and C10 were the most
abundant. Isoprene and monoterpenes could be the main precursors for most of the C5 and C10 OSs (Riva et al., 2015a; Surratt et al., 2008). On the other hand, a recent work (Riva et al., 2015b) suggests that a number of observed C10 OSs (e.g., C_{10}H_{12}O_{3}S_{1}) might be derived from PAHs. In addition to C5 and C10, the relative abundances of C8, C9, and C_{14+} were also high in the SHWD and SHWN samples, hinting at additional precursors. In contrast, C10 derived from monoterpenes always represented the dominant category in spring, autumn, and winter in the Pearl River Delta, South China, and in Taiwan (Lin et al., 2012b), underlying a lesser anthropogenic influence in these two regions than in the Yangtze River region.

The VK diagrams of CHOS and CHONS in the SH samples are presented in Figure S3, which represents a combination of Figure 4 and Figure 5 (with a lesser number of OSs accounted for). OSs in the four samples were characterized by similar degrees of saturation. OSs with a low degree of saturation and a high molecular weight existed in all four samples. Table 1 and Figure S3 show that the average degree of oxidation of OSs in the SHSD and SHSN samples was higher than those in the SHWD and SHWN samples, which is consistent with a promoted photochemical activity in summer.

4. Conclusions

In this study, atmospheric PM_{2.5} samples in WH, NJ, and SH were analyzed using an UHPLC-Orbitrap MS. More than 100 formulas of CHOS and dozens of formulas of CHONS with various numbers of isomers were tentatively determined in each sample. These CHOS and CHONS compounds were here tentatively regarded as organosulfates and nitrooxy-organosulfates respectively.

Aliphatic OSs represented at least 78% of the tentatively determined OSs in the three megacity summer samples, while there was much less aromatic OSs. Comparison of the molecular formula, number of isomers, average molecular weight, and degrees of saturation and oxidation suggests that OSs in aerosol samples from NJ and SH shared more similarities.

Major OSs in these ambient samples could be derived from biogenic precursors
(isoprene, monoterpenes, and sesquiterpenes), but also from PAHs. Isoprene appeared to be most likely one of the important precursors in the three megacities, and the influence of NO\textsubscript{x} level on the nature of isoprene-derived OSs is consistent with the literature. Clearly, the identity, precursors, and formation mechanisms of many OSs have yet to be positively elucidated. The systematic use of chromatographic separation prior to MS detection appears essential given the variety of the precursors and the resulting isomers.
