Abstract

We use the global three-dimensional Goddard Earth Observing System chemical transport model (GEOS-Chem) to examine the contribution of nitrate aerosol to aerosol concentrations in the upper troposphere and lower stratosphere (UTLS) over the Tibetan Plateau and the South Asian summer monsoon (TP/SASM) region during summertime of year 2005. Simulated surface-layer aerosol concentrations are compared with ground-based observations, and simulated aerosols in the UTLS are evaluated by using the Stratospheric Aerosol and Gas Experiment II satellite data. Simulations show elevated aerosol concentrations of sulfate, nitrate, ammonium, black carbon, organic carbon, and PM$_{2.5}$ (particles with diameter equal or less than 2.5 µm) in the UTLS over the TP/SASM region throughout the summer. Nitrate aerosol is simulated to be the second largest aerosol species in the surface-layer but the most dominant aerosol species in the UTLS over the studied region. Averaged over summertime and over the TP/SASM region, $C_{\text{Nit}}$ (the ratio of nitrate concentration to PM$_{2.5}$ concentration) values are 5–35% at the surface, 25–50% at 200 hPa, and exceed 60% at 100 hPa. The mechanisms for the accumulation of nitrate in the UTLS over the TP/SASM region include vertical transport and the gas-to-aerosol conversion of HNO$_3$ to form nitrate. The high relative humidity and low temperature associated with the deep convection over the TP/SASM region are favorable for the gas-to-aerosol conversion of HNO$_3$.

1 Introduction

Aerosols in the upper troposphere and lower stratosphere (UTLS) have much longer residence time than those in the lower troposphere, which influence atmospheric chemistry and the Earth’s climate with large spatial and temporal coverage (Rasch et al., 2008). Aerosols in the UTLS influence the concentrations of chemical species via changes in photolysis rates and heterogeneous reactions (Pitari et al., 2014). For example, heterogeneous reactions on sulfate aerosol can perturb the chemical parti-
tioning in the lower stratosphere, leading to significant O\textsubscript{3} depletion through enhanced chlorine, bromine, and odd-hydrogen catalytic cycle (Zhao et al., 1997; Considine et al., 2001; Talukdar et al., 2012; Tang et al., 2014; Pitari et al., 2014). Aerosols in the UTLS also influence climate by altering properties of cirrus clouds via homogeneous or heterogeneous ice nucleation (Li et al., 2005; Liu et al., 2009; Yin et al., 2012; Fadnavis et al., 2013). Injection of aerosols into the UTLS has been reported to induce complex responses in circulation, temperature, and water vapor (Liu et al., 2009; Wu et al., 2011; Su et al., 2011; Fadnavis et al., 2013).

Aerosols over the Tibetan Plateau (TP) and the Asian summer monsoon region are especially important. The TP is surrounded by countries with large anthropogenic emissions (Li et al., 2005; Lau et al., 2006). Aerosols from India, Southeast Asia, and southern China can be transported to the TP by prevailing winds in the premonsoon and monsoon seasons (Lawrence and Lelieveld, 2010; Xia et al., 2011). Observational and modeling studies have shown that persistent maxima of atmospheric constituents, such as water vapor (Gettelman et al., 2004; Randel and Park, 2006; Park et al., 2007), CO (Kar et al., 2004; Li et al., 2005; Park et al., 2007, 2008, 2009), CH\textsubscript{4} (M. Park et al., 2004; Xiong et al., 2009), NO\textsubscript{x} (M. Park et al., 2004), HCN (Park et al., 2008; Randel et al., 2010), C\textsubscript{2}H\textsubscript{6} and C\textsubscript{2}H\textsubscript{2} (Park et al., 2008), exist in the UTLS above the TP and the South Asian summer monsoon (SASM) region because of the deep convection during boreal summer. Satellite observations suggested that the convection associated with the SASM is a vital pathway to transport air mass from the lower troposphere into the stratosphere (Chen et al., 2006; Randel and Park, 2006; Randel et al., 2010; Bian et al., 2011a). The heating associated with the persistent deep convection during summertime leads to the formation of the Tibetan anticyclone in the UTLS, which acts to isolate air within the anticyclone and traps the uplifted pollutants at that altitude (Park et al., 2007; Vernier et al., 2011; Bourgeois et al., 2012; Fadnavis et al., 2013; He et al., 2014). The stratosphere–troposphere exchange (STE) over the TP contributes largely to the global STE (Chen et al., 2006).
Previous studies have reported that aerosols exist in the UTLS over the TP/SASM region. Kim et al. (2003) carried out optical measurements with a ground-based lidar in Lhasa from August to October of 1999, and found an enhancement in aerosol concentration near the local tropopause with scattering ratio (SR, the ratio of aerosol plus molecular backscatter to molecular backscatter alone) of 1.1–1.2. Tobo et al. (2007) reported an enhancement of sub-micron aerosols (effective radius $r = 0.15–0.6\mu m$) near the summertime tropopause (about 130 to 70 hPa), on the basis of in situ balloon measurements from an Optical Particle Counter at the same location in August of 1999. Vernier et al. (2009) examined satellite measurements from the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) onboard Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) and reported the presence of small depolarizing particles with high SR values (about 1.20 at 532 nm) at 16–17 km altitude over South Asia in July and August of 2007 and 2008. Bourgeois et al. (2012) found that an aerosol layer existed at 16–18 km altitude over the Asian continent and Indian Ocean ($20^\circ$S–$30^\circ$N, 5–105$^\circ$E) on the basis of the CALIOP observations. Recently, He et al. (2014) examined the vertical profiles of aerosol extinction coefficients measured with a Micro Pulse Lidar at Naqu, a meteorological station located in the central part of the TP, and also showed a maximum in aerosol extinction coefficient ($\sim 2.10^{-3}\text{km}^{-1}$) in the UTLS (18–19 km) during the summer of 2011.

A number of previous studies have attempted to understand the chemical composition of aerosols in the UTLS. Froyd et al. (2009) measured aerosol composition with the National Oceanic and Atmospheric Administration (NOAA) single-particle mass spectrometer aboard the National Aeronautics and Space Administration (NASA) WB-57 high altitude aircraft platform, and reported that particles in the tropical tropopause layer were rich in nitrogen. Vernier et al. (2011) suggested that aerosol layer at the tropopause of Asia could be sulfur and/or organics, considering that Asian pollutants consisted of black carbon, organic carbon, SO$_2$, and NO$_x$ (Park et al., 2009; Randel et al., 2010). Weigel et al. (2011) analyzed the volatility of aerosols obtained from in situ airborne measurements and reported that about 75–90% of the particles in the tropical
tropopause layer were volatile (> 75%), but this study did not give any detailed analyses of chemical composition of aerosols. Bourgeois et al. (2012) showed, by using the ECHAM5.5-HAM2 model, that sulfate, water, and OC contributed, respectively, 53, 29, and 11% to aerosol extinction in the vicinity of the tropical tropopause layer. The ECHAM5.5-HAM2 model used by Bourgeois et al. (2012) simulated all major aerosol species in the atmosphere except for nitrate.

Few previous studies have examined nitrate aerosol in the UTLS, although nitrate is expected to be important for the following reasons. First, emissions of precursors of nitrate, such as NO\textsubscript{x} and NH\textsubscript{3}, are high over India, Southeast Asia, and China (Streets et al., 2003; Datta et al., 2012; Huang et al., 2012). Second, simulated nitrate concentrations are high over those regions (Liao and Seinfeld, 2005; Mu and Liao, 2014; Lou et al., 2014). Third, measured concentrations of nitrate are comparable to or larger than those of sulfate at rural and urban sites in the SASM region. Shrestha et al. (2000) carried out measurements of aerosols at Phortse, Nepal, during September 1996–November 1997, and showed that the average concentration of nitrate during the monsoon season (June–September) was 0.34 µg m\textsuperscript{-3}, higher than that of sulfate (0.17 µg m\textsuperscript{-3}). Decesari et al. (2010) reported, on the basis of measurements at the Nepal Climate Observatory-Pyramid from 2006 to 2008, that the concentrations of nitrate and sulfate were 0.37 and 0.50 µg m\textsuperscript{-3}, respectively, during the monsoon season. Chatterjee et al. (2010) measured aerosols at a high altitude station in northeastern Himalayans during January–December 2005. They found that the average concentrations of fine-mode nitrate and sulfate were 3.31 ± 2.25 µg m\textsuperscript{-3} and 3.80 ± 2.9 µg m\textsuperscript{-3}, respectively. At Lahore, an urban site in Pakistan, the observed daytime nitrate concentration of 21.8 µg m\textsuperscript{-3} was also higher than sulfate concentration of 12.6 µg m\textsuperscript{-3} (Lodhi et al., 2009), as the observations were averaged over November 2005 to March 2006. Fourth, the low temperatures in the UTLS would favor nitrate formation (Seinfeld and Pandis, 2006). Therefore, it is of interest to take nitrate aerosol into consideration when we examine aerosols in the UTLS.
In this work we simulate nitrate aerosol and its contribution to aerosol concentrations in the UTLS over the TP (70–105° E, 25–40° N) and the SASM region (70–105° E, 10–25° N) by using the global chemical transport model GEOS-Chem driven by the assimilated meteorological fields. These regions of interest are shown in Fig. 1. Simulated surface-layer aerosol concentrations are compared with ground-based observations, and simulated aerosols in the UTLS are evaluated by using the Stratospheric Aerosol and Gas Experiment II (SAGE II) satellite data. Section 2 is a brief description of the GEOS-Chem model and numerical experiment. Section 3 presents the simulation and evaluation of distributions and concentrations of HNO₃ and O₃ to show model’s capability in simulating the NOₓ-O₃-HNO₃ cycle over the studied regions. Section 4 shows simulated aerosols and Sect. 5 presents the simulated contribution of nitrate to aerosol concentrations in the UTLS over the TP and the SASM region. Section 6 discusses the mechanisms for high concentrations of nitrate in the UTLS.

2 Model description and numerical experiment

2.1 GEOS-Chem model

We simulate gas-phase species and aerosols using the global chemical transport model GEOS-Chem (version 9-01-03, http://acmg.seas.harvard.edu/geos/index.html) driven by the GEOS-5 assimilated meteorological fields from the Goddard Earth Observing System of the NASA Global Modeling and Assimilation Office. The version of the model used here has a horizontal resolution of 2° latitude by 2.5° longitude and 47 vertical layers extending from the surface to 0.01 hPa. Over the TP and the SASM region, the model has about 34 layers in the troposphere and 12 layers in the stratosphere.

The GEOS-Chem model has a fully coupled treatment of tropospheric NOₓ-CO-hydrocarbon-aerosol chemistry and aerosols including sulfate (SO₄²⁻), nitrate (NO₃⁻), ammonium (NH₄⁺), organic carbon (OC), black carbon (BC) (R. J. Park et al., 2003,
2004; Pye et al., 2009), mineral dust (Fairlie et al., 2007), and sea salt (Alexander et al., 2005; Jaeglé et al., 2011). The gas-aerosol partitioning of nitric acid and ammonium is calculated using the ISORROPIA II thermodynamic equilibrium model (Fountoukis and Nenes, 2007). The two-way coupling between aerosols and gas phase chemistry provides consistent chemical fields for aerosol simulation and aerosol mass for heterogeneous processes and calculations of gas-phase photolysis rates. Heterogeneous reactions include hydrolysis of N$_2$O$_5$ (Evans and Jacob, 2005), irreversible absorption of NO$_3$ and NO$_2$ on wet aerosols (Jacob, 2000), and the uptake of HO$_2$ by aerosols (Liao and Seinfeld, 2005; Thornton et al., 2008).

With respect to chemistry in the stratosphere, stratospheric O$_3$ concentrations are calculated using the linearized parameterization scheme (McLinden et al., 2000). The monthly mean production rates and loss frequencies of species other than O$_3$ use those from NASA Global Modeling Initiative (GMI) Combo simulations using MERRA met fields (Duncan et al., 2007; Considine et al., 2008; Murray et al., 2012).

Convective transport in GEOS-Chem mimics that in the parent GEOS general circulation model (GCM) (Hack, 1994; Zhang and McFarlane, 1995), which accounts for updraft, downdraft, and entrainment mass fluxes for deep and shallow convection (Wu et al., 2007). The aerosol wet deposition scheme in the GEOS-Chem follows that of Liu et al. (2001). For the scavenging of aerosols, SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, and hydrophilic OC and BC aerosols are assumed to be fully soluble. Dry deposition follows the standard resistance-in-series model of Wesely (1989).

Global emissions of aerosols and their precursors in the GEOS-Chem follow R. J. Park et al. (2003, 2004), with anthropogenic emissions of NO$_x$, CO, SO$_2$, and non-methane volatile organic compounds (NMVOC) in Asia overwritten by David Streets’ 2006 emission inventory (http://mic.greenresource.cn/intex-b2006). Emissions of NH$_3$ in Asia are taken from Streets et al. (2003). Since NH$_3$ emissions in China showed large uncertainties in previous studies (Streets et al., 2003; Kim et al., 2006; Y. Zhang et al., 2010; Huang et al., 2011, 2012), we use the most recent estimate of NH$_3$ emissions in China by Huang et al. (2012), which is 9.8 Tgyr$^{-1}$, instead of 13.5 Tgyr$^{-1}$ from
Streets et al. (2003). Table 1 summarizes the annual emissions of NO$_x$, SO$_2$, NH$_3$, OC, and BC in Asia domain (60–155° E, 10–55° N).

Natural NO$_x$ emissions from lightning are calculated using the scheme described by Sauvage et al. (2007) and Murray et al. (2012), and those from soil are simulated following Wang et al. (1998). Natural NH$_3$ emissions from soil, vegetation, and the oceans are taken from the Global Emissions Inventory Activity inventory (Bouwman et al., 1997). Biomass burning emissions are from the monthly Global Fire Emissions Database (GFED v3) driven by satellite observations of fire activity (van der Werf et al., 2010). Biogenic VOC (volatile organic compounds) emissions are calculated from the Model of Emissions of Gases and Aerosols from Nature (Guenther et al., 2006).

The monthly variations of emissions of SO$_2$ and NO$_x$ follow Wang et al. (2013) and those of BC and OC follow Lou et al. (2014). The monthly scaling factors for NH$_3$ emissions follow the global inventory compiled by Marcel Meinders and Lex Bouwman (Fisher et al., 2011). Monthly variations of emissions (anthropogenic plus natural emissions) of NO$_x$, SO$_2$, NH$_3$, OC, and BC over Asia are displayed in Fig. 2. The emissions of NH$_3$ are the highest in June as a result of the agriculture practice and high temperatures (Wang et al., 2013). Emissions of SO$_2$, OC and BC are the highest during wintertime as a result of the winter heating.

### 2.2 Numerical experiment

To examine the contribution of nitrate to aerosol concentrations in the UTLS over the TP/SASM region, we simulate year 2005 aerosol concentrations by using the GEOS-Chem model. Year 2005 is chosen so that we can use the observational datasets for this year from SAGE II and MLS, as described in Sects. 3 and 4. Following Rasch et al. (2008), we perform a 10 year spin-up run to generate the initial conditions (to allow the stratospheric species to reach quasi-steady state conditions).
3 Simulated concentrations of HNO$_3$ and O$_3$ and model evaluation

Nitrate aerosol forms when nitric acid (HNO$_3$) reacts with alkaline gases (for example, ammonia) in the atmosphere (Seinfeld and Pandis, 2006). HNO$_3$, as the important precursor of nitrate, is the major oxidation product of nitrogen oxides (NO$_x$ = NO + NO$_2$) (Seinfeld and Pandis, 2006). To show the model’s capability in simulating the NO$_x$-O$_3$-HNO$_3$ cycle over the studied regions, we present and evaluate the simulated HNO$_3$ and O$_3$ in this section.

Simulated mixing ratios of HNO$_3$ and O$_3$ in the UTLS are evaluated by using datasets from the limb viewing satellite instrument of Microwave Limb Sounder (MLS, version 4.2, level 2, ftp://acdisc.gsfc.nasa.gov/data/s4pa//Aura_MLS_Level2/). The MLS datasets provide valuable information on atmospheric compositions in the UTLS (Waters et al., 2006). For HNO$_3$, the MLS provides datasets for 316 to 68 hPa, with a vertical resolution of 3–4 km and a horizontal resolution of 400–500 km. Since further evaluations are needed for datasets at altitudes with pressures higher than 215 hPa (Livesey et al., 2015), we use only datasets for pressures lower than that. For O$_3$, the MLS provides datasets for 261 to 0.02 hPa, with a vertical resolution of 3–3.5 km and a horizontal resolution of 300–350 km in the UTLS (Santee et al., 2007; Livesey et al., 2015). The uncertainties of the MLS HNO$_3$ and O$_3$ datasets in the UTLS are about ±0.5–1 ppbv (±5–10%) and 0.02–0.03 ppmv, respectively (Livesey et al., 2015).

3.1 HNO$_3$

Figure 3a shows the simulated global distribution of HNO$_3$ concentrations averaged over June–August of 2005. Concentrations of HNO$_3$ exceed 1 ppbv over the industrialized areas such as Europe, North America, central and eastern Asia, in agreement with the distributions and magnitudes reported in Liao et al. (2003). Over South Asia, simulated HNO$_3$ concentrations are high (0.3–1 ppbv) in the northern Indian subcontinent, because the emissions of NO$_x$ and NH$_3$ are high in this region (Streets et al., 2003; Zhang et al., 2009; Datta et al., 2012).
Figure 4a and b shows the simulated HNO$_3$ concentrations in the UTLS averaged over June–August of 2005. Since the tropopause is located at 70–150 hPa (12–15 km) over the TP/SASM region (Li et al., 2005; Bian et al., 2011b; Fadnavis et al., 2014), we choose the vertical layers of 200 and 100 hPa to represent the UTLS. At both 200 and 100 hPa, the highest HNO$_3$ concentrations are simulated to occur in the high latitude regions in the Northern Hemisphere (NH) (Fig. 3a and b). Simulated HNO$_3$ concentrations at 100 hPa are low over the region of 40–100° E and 10–30° N, which is part of the anticyclone region defined in Fig. 1. Figure 4c shows the latitude–altitude cross section of simulated seasonal mean HNO$_3$ mixing ratios averaged over 70–105° E. In boreal summer, the highest HNO$_3$ mixing ratios are simulated to occur at 30 hPa over the Polar Regions in both hemispheres. Over high latitudes, HNO$_3$ concentrations in the Southern Hemisphere (SH) are simulated to be higher than those in the NH.

To evaluate the simulated HNO$_3$, Fig. 4d–f shows HNO$_3$ concentrations in the UTLS from MLS that are averaged over June–August of 2005. At 200 and 100 hPa altitudes, the observed HNO$_3$ mixing ratios are high in the high latitudes in the NH, which are captured by the GEOS-Chem model. The observed HNO$_3$ at 100 hPa exhibits low values of less than 240 pptv over 30–100° E and 10–30° N in the Asian monsoon anticyclone region (Fig. 4e). At 100 hPa, the observed HNO$_3$ mixing ratio averaged over the TP/SASM region (70–105° E, 10–40° N) is 301.3 pptv, which is lower than the simulated values of 345.9 pptv. The difference between the simulated and observed HNO$_3$ mixing ratio lies within the confidence range of ±500–1000 pptv of the MLS instruments (Livesey et al., 2015). The observed pattern of the HNO$_3$ vertical distribution (Fig. 4f) is also captured by the GEOS-Chem model (Fig. 4c). The distributions of HNO$_3$ in the UTLS are associated with the Brewer–Dobson (BD) circulation proposed by Brewer (1949) and Dobson (1956), traveling upwards across the tropopause to the stratosphere at the equator and downwards to the troposphere near the Polar region.
3.2 O₃

Figure 3b shows the global distribution of simulated summertime surface-layer O₃ concentrations. Simulated O₃ concentrations are in a range of 40–70 ppbv over Europe, North America, China, and the biomass burning region of South Africa. Our model results agree closely with the simulated distributions and magnitudes reported in Mickley et al. (1999), Collins et al. (2000), Liao et al. (2003), Wu et al. (2008), Zeng et al. (2008), and Fadnavis et al. (2014). Fadnavis et al. (2014) also presented aircraft measurements over India in September of 2010 during the Cloud Aerosol Interaction and Precipitation Enhancement Experiment (CAIPEEX). Our simulated O₃ concentrations of 30–40 ppbv over India agree with the CAIPEEX measurements.

Figure 5a and b show the simulated O₃ concentrations in the UTLS averaged over June–August of 2005. The distributions of O₃ concentrations in the UTLS are similar to those of HNO₃, with elevated values in the high latitudes of the NH. Relatively low O₃ mixing ratios of less than 200 ppbv are simulated at 100 hPa over 10–30° N, 20–110° E, within the anticyclone region defined in Fig. 1. Our simulated distributions and magnitudes of O₃ agree with those reported in Bian et al. (2011b), which examined the summertime distributions of O₃ in the UTLS during 2005–2009 by using the MLS version 2.2 level 2 products (Livesey et al., 2008). Because the background O₃ concentrations are generally high in the UTLS and the stratosphere, the low O₃ concentrations in the UTLS over the TP/SASM region are caused by the deep convection that transports O₃-poor air upward (Fu et al., 2006; Randel and Park, 2006; Park et al., 2007; Bian et al., 2011b). Figure 5c displays the latitude-altitude cross section of seasonal mean O₃ mixing ratios averaged over 70–105° E. As a result of the BD circulation, O₃ concentrations in the UTLS are lower over the tropics than in the Polar Regions, even though the maximum O₃ concentrations are located around 10 hPa over the tropics (Brewer, 1949). Our simulated O₃ concentrations in the UTLS agree well with the measurements from MLS (Fig. 5d–f). Our simulated global STE of O₃ is 420 Tgyr⁻¹, which is within the range reported in previous studies (475 ± 120 Tgyr⁻¹ in McLinden...
In addition to the comparisons against MLS products, the simulated O$_3$ profiles are compared with balloon-borne sonde measurements in Fig. 6. The measurements were carried out at Kunming (KM, 102.7° E, 25.0° N) in August of 2009 and at Lhasa (LH, 91.1° E, 29.7° N) in August of 2010. The tropospheric air in LH was less polluted than in KM, and the uncertainties of the observed O$_3$ mixing ratios were estimated to be within 5–10% (Bian et al., 2012). In the troposphere, the model underestimates O$_3$ mixing ratios in KM, while it overestimates O$_3$ mixing ratios in LH. Since the model results represent the averages over 2° × 2.5° grid cells, the simulated O$_3$ mixing ratios may not capture well the local variations in emissions. At 100 hPa, the simulated and observed O$_3$ mixing ratios are, respectively, 112.6 and 124.2 ppbv at KM, and 152.6 and 142.4 ppbv at LH. The magnitudes of O$_3$ mixing ratios from these balloon-borne sonde measurements support those from MLS; O$_3$ mixing ratios in the UTLS are less than 200 ppbv over the TP/SASM region.

4 Simulated aerosols and model evaluation

4.1 Simulated aerosols

Figure 7a shows the simulated surface-layer concentrations of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, OC, BC, and PM$_{2.5}$ (the sum of the mass of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, BC, and OC aerosols) averaged over June–August of year 2005. As expected, simulated aerosol concentrations are high over polluted regions such as India and eastern China as a result of the high anthropogenic emissions of aerosol precursors and aerosols (Streets et al., 2003; Huang et al., 2012). Over the TP/SASM region (70–105° E, 10–40° N), the average concentrations of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, BC, and OC are 1.69, 0.94, 0.85, 0.30, and 0.94 µgm$^{-3}$, respectively. NO$_3^-$ is simulated to be the second largest aerosol species...
over the region of our interest. The simulated distributions and magnitudes of these aerosol species are similar to those reported in Wang et al. (2013) and Mu and Liao (2014).

Figure 7b and c also show the simulated concentrations of $\text{SO}_4^{2-}$, $\text{NO}_3^-$, $\text{NH}_4^+$, OC, BC, and $\text{PM}_{2.5}$ in the UTLS. Elevated concentrations of $\text{SO}_4^{2-}$, $\text{NO}_3^-$, $\text{NH}_4^+$, OC, BC and $\text{PM}_{2.5}$ are simulated over the TP and Plateau south slope at 200 hPa altitude, and extend from eastern Mediterranean to western China at 100 hPa. The simulated enhanced concentrations of $\text{SO}_4^{2-}$, OC, and BC at 100 hPa over the anticyclone region (20–120° E, 10–40° N) agree with previous observational and modeling studies (Lelieveld et al., 2002; Li et al., 2005; Fadnavis et al., 2013). Li et al. (2005) reported elevated CO concentrations in the upper troposphere over the TP, on the basis of both MLS measurements and the GEOS-Chem simulation for September 2004. Fadnavis et al. (2013) also simulated maximum concentrations of $\text{SO}_4^{2-}$, OC, BC, and mineral dust aerosols in the UTLS during the Asian summer monsoon season owing to convective uplifting of the boundary layer pollutants. With $\text{NO}_3^-$ aerosol accounted for in our simulation, $\text{NO}_3^-$ is simulated to be the most dominant aerosol species in the UTLS over the TP/SASM region, followed by $\text{SO}_4^{2-}$, $\text{NH}_4^+$, OC, and BC. At 100 hPa, the averaged concentrations of $\text{SO}_4^{2-}$, $\text{NO}_3^-$, $\text{NH}_4^+$, OC, and BC over the TP/SASM region (70–105° E, 10–40° N) region are 0.026, 0.069, 0.014, 0.011, and 0.002 µgm$^{-3}$, respectively.

4.2 Comparisons of simulated aerosol concentrations with in-situ observations

The simulated aerosol concentrations in East Asia in the GEOS-Chem model have been evaluated in previous studies (L. Zhang et al., 2010; Fu et al., 2012; Jeong and Park, 2013; Jiang et al., 2013; Wang et al., 2013; Lou et al., 2014). Here we are focused on the evaluation of aerosols in the South Asian monsoon region. For lack of publicly accessible in situ measurements of summertime aerosols in South Asia monsoon area, we compiled monthly or seasonal mean measured concentrations of each
aerosol species based on measurements reported in the literature (see Table S1 in the Supplement). These measurements were carried out over years of 1992–2010. The locations of sites with measurements available are shown in Fig. 8a. Most sites are located in the upwind directions of the TP, with pollutants that can be transported to the UTLS during the South Asian summer monsoon season. The observed PM$_{10}$ concentrations listed in Table S1 are multiplied by 0.6 to convert to PM$_{2.5}$ for model evaluation, following the suggestions in Zhang et al. (2002).

Figure 8b–j shows the scatterplots of simulated vs. observed seasonal mean aerosol concentrations. Compared with measurements, simulated SO$_2^-$, NO$_3^-$, NH$_4^+$, OC and BC have normalized mean biases (NMB) of $-17.0$, $+38.8$, $+42.0$, $-69.7$ and $-41.0\%$, respectively, as the concentrations of all seasons are considered. The correlations between model results and observations have $R$ values of $0.49$–$0.85$ for all aerosol species, indicating that the model is capable of capturing the spatial distributions and seasonal variations of each aerosol species in the South Asian monsoon region despite the biases in concentrations. If we consider simulated and measured concentrations for JJA alone, the simulated concentrations of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, OC and BC exhibit seasonal NMB of $-15.3$, $+51.5$, $+74.9$, $-57.2$ and $-32.2\%$, respectively, and the values of $R$ are in the range of $0.24$–$0.85$. Note that the measurements of NO$_3^-$ and NH$_4^+$ are quite limited in terms of the number of samples, and the discrepancies between model results and measurements may also arise from the mismatch of the model year 2005 with the years of 1992–2010 with observations available.

4.3 Comparisons of simulated aerosol extinction coefficients with SAGE II datasets

Satellite datasets from the Stratospheric Aerosol and Gas Experiment II (SAGE II, http://sage.nasa.gov/SAGE2/) are used to evaluate the simulated aerosol extinction in the UTLS. The SAGE II instrument was launched in October 1984 aboard the Earth Radiation Budget Satellite (ERBS) and terminated on 8 September 2005 (McCormick et al., 1987; Chu et al., 1989). The datasets used here are aerosol extinction coeffi-
coefficients at 525 nm from the version 6.20 SAGE retrievals, covering from 0.5 to 40 km with a vertical resolution of 0.5 km. Many validation studies have been conducted on the SAGE II aerosol data (Russell and McCormick, 1989; Oberbeck et al., 1989; Wang et al., 1989), which indicated that extinction coefficients have uncertainties of 20–30%. The extinction coefficients of aerosols in the GEOS-Chem model are calculated using aerosol mass concentration, extinction efficiency, effective radius, particle mass density, and the assumed aerosol size distribution (Drury et al., 2010). The hygroscopic growth of each aerosol species with relative humidity is accounted for, using the hygroscopic growth factors listed in Martin et al. (2003).

Figure 9a presents the simulated monthly mean distribution of aerosol extinction coefficients at 100 hPa for July of 2005. The region with relatively high aerosol extinction coefficients corresponds to that with high PM$_{2.5}$ concentrations at 100 hPa (Fig. 7). Aerosol extinction coefficients are simulated to be $1.2-2 \times 10^{-3}$ km$^{-1}$ at 100 hPa over the Asian continent and Indian Ocean (20° S–30° N, 30–105° E). These values agree closely with aerosol extinction coefficients measured at Naqu during August of 2011 for the same altitude, the maximum of which was $2.4 \times 10^{-3}$ km$^{-1}$ (He et al., 2014). Vernier et al. (2011) also identified this Asian aerosol layer with high SR at 100 hPa by observations of CALIPSO for JJA of 2006–2008.

Figure 9b displays the monthly mean vertical profiles of aerosol extinction coefficients averaged over the Asian monsoon anticyclone region (20–120° E, 10–40° N) (Fig. 1) for July of 2005. The SAGE II datasets are available for July only in 2005. The profiles from SAGE II and the GEOS-Chem simulation are all shown. Accounting for all aerosol species, the GEOS-Chem model reproduces well the aerosol extinction coefficients above 10 km, but the discrepancies are rather large in altitudes less than 10 km. Note that the uncertainties in satellite datasets increase as the altitude decreases (Vanhellemont et al., 2008; Kulkarni and Ramachandran, 2015), and the missing data in the lower troposphere along the satellite trajectories over the region of our interest also contribute to the discrepancies.
Comparisons of profiles of aerosol extinction coefficients with and without nitrate aerosol indicate that the profiles show small differences in altitudes less than 6 km but large discrepancies from 6 km to the tropopause. With nitrate aerosol accounted for, the simulated aerosol extinction coefficients agree closely with SAGE II datasets in the UTLS (averaged over 14–16 km, the simulated value is $8.6 \times 10^{-4} \text{ km}^{-1}$ while the observed value is $8.0 \times 10^{-4} \text{ km}^{-1}$). Without nitrate aerosol, the simulated aerosol extinction coefficient at 14–16 km altitude is $1.5 \times 10^{-4} \text{ km}^{-1}$, which underestimates the aerosol extinction coefficient by 82.6% compared to that calculated with all the aerosol species. These comparisons of extinction coefficients with and without nitrate aerosol suggest that nitrate aerosol plays an important role in aerosol extinction in the UTLS over the region of our interest.

5 Contribution of nitrate to aerosol concentrations in the UTLS

Since nitrate aerosol is simulated to be the most abundant aerosol species in the UTLS over the TP/SASM region, we analyze the contribution of nitrate to PM$_{2.5}$ concentration ($C_{\text{NIT}} =$ nitrate concentration/PM$_{2.5}$ concentration) in this section. Figure 10 shows the simulated seasonal mean distributions of $C_{\text{NIT}}$ for June–August of year 2005. At the surface layer (Fig. 10a), simulated high $C_{\text{NIT}}$ values are located over the areas with high nitrate concentrations (India and eastern China) as well as the oceans where NO$_3^-$ also forms on sea salt and mineral dust particles (Arimoto et al., 1996; Nakamura et al., 2005; George and Nair, 2008). Over the TP/SASM region, the $C_{\text{NIT}}$ values in JJA are 5–35% at the surface, 25–50% at 200 hPa (Fig. 10b), and exceed 60% at 100 hPa (Fig. 10c). The latitude–altitude cross section of $C_{\text{NIT}}$ (Fig. 10d) shows that $C_{\text{NIT}}$ over 20–40° N increases with altitude and reaches maximum values around the extratropical tropopause.

Table 2 lists the mean concentrations of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, BC and OC, and their contributions to PM$_{2.5}$ during summertime of 2005 over the TP/SASM, TP, and SASM regions. Over the TP/SASM region, SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, BC and OC are simulated to...
contribute 35.9, 19.8, 18.1, 6.4, and 19.8 %, respectively, to PM$_{2.5}$ mass concentration at the surface layer. The contributions increase significantly in the UTLS. The largest $C_{\text{NIT}}$ is simulated in the SASM region at 100 hPa, where NO$_3^-$ accounts for 60.5 % of PM$_{2.5}$ mass concentration. The high $C_{\text{NIT}}$ values indicate that NO$_3^-$ plays an important role in the aerosol layer in the UTLS over the TP/SASM region.

6 Mechanisms for high nitrate concentrations in the UTLS

6.1 Upward transport of nitrate from the lower troposphere

The intense convective transport of chemical species into the UTLS over the TP/SASM region during summertime has been widely discussed in previous studies (Randel et al., 2010; Bian et al., 2011a; Fadnavis et al., 2013, 2014; Qie et al., 2014; He et al., 2014). Since nitrate aerosol is simulated to be the second abundant aerosol species in the surface layer over the TP/SASM region (Fig. 7), the vertical mass transport through the deep convection in this region contributes to the accumulation of NO$_3^-$ in the UTLS. Figure 11 shows the latitude–altitude cross sections of simulated concentrations of SO$_4^{2-}$ and NO$_3^-$ averaged over 70–105° E in June–August of 2005, together with the wind vectors obtained from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-Interim Reanalysis data. High values of aerosol concentrations are found on the south slope of the Himalayas, where the deep convection exists. Although both SO$_4^{2-}$ and NO$_3^-$ are transported upward to the extratropical tropopause, the details of the vertical distributions are different. At altitudes higher than 8 km, the concentrations of NO$_3^-$ do not decrease with altitude as quickly as those of SO$_4^{2-}$, and the concentrations of NO$_3^-$ over 10–40° N are higher than those of SO$_4^{2-}$, suggesting that the different chemical mechanisms for NO$_3^-$ and SO$_4^{2-}$ have contributed to these differences in vertical distributions.
6.2 The gas-to-aerosol conversion of HNO₃ to form nitrate

The gas-to-aerosol conversion of HNO₃ to form nitrate is important in nitrate budget (Liao et al., 2004; Feng and Penner, 2007) and this process is very sensitive to relative humidity (RH) and temperature (Fountoukis and Nenes, 2007; Dawson et al., 2007). High RH is favorable for NO₃⁻ formation. As the temperature falls, the gas-phase oxidation of SO₂ decreases (Yao et al., 2002; Seinfeld and Pandis, 2006; X. Y. Zhang et al., 2012), while the gas-to-aerosol partition of HNO₃ (the formation of nitrate aerosol) is promoted (Ansari and Pandis, 2000; Dawson et al., 2007). Figure 12 shows the seasonal mean horizontal distributions of RH and temperature at 100 hPa and the latitude–altitude cross sections of these two parameters averaged over 70–105° E. RH exhibits high values in the TP/SASM region, which are consistent with the high H₂O mixing ratios in this area reported in Gettelman et al. (2004), M. Park et al. (2004), and Fu et al. (2006). At 100 hPa, the locations with high RH of exceeding 45% correspond well with those with high C_NIT values (Fig. 10c). The latitude–altitude cross section of RH (Fig. 13c) shows that RH has high values over the places with intense upward transport (Fig. 11). For temperature, as Fig. 12b and d shows, summertime temperatures are cold (190–200 K) at 100 hPa in the TP/SASM region, in consistent with the distribution and magnitude reported for August 2011, in He et al. (2014) on the basis of the NCEP Reanalysis data. The low temperatures over the TP/SASM region are associated with the adiabatic expansion of ascending air mass of the deep convections (Yanai et al., 1992; Park et al., 2007; He et al., 2014). Besides being the dynamic responses to enhanced convection, the low temperatures at the tropopause reinforce the upwelling activities.

Because of the favorable conditions of RH and temperature, the gas-to-aerosol conversion of HNO₃ to form nitrate can occur during the upward transport and in the UTLS. Figure 13 shows the mass budget for nitrate aerosol within the selected box of (70–105° E, 10–40° N, 8–16 km) to see the role of nitrate formation over the TP/SASM region. The horizontal mass fluxes have a net negative value of 0.10 Tg season⁻¹,
reducing nitrate aerosol in the selected box. The vertical transport and the gas-to-
aerosol conversion of HNO₃ increase nitrate mass in the selected box, with values of
0.09 Tg season⁻¹ and 0.11 Tg season⁻¹, respectively, indicating that the gas-to-aerosol
conversion plays an important role in the enhancement of nitrate in the UTLS over the
TP/SASM region.

Although relatively high RH exists near the tropopause of the TP/SASM region, the
air near the tropopause is still dryer compared to that in the lower altitudes. Model
results show that the gas-to-aerosol partition of HNO₃ decreases with altitude over
8–16 km, indicating that the gas to aerosol conversion contributes to nitrate accumula-
tion in the UTLS mainly during the process of upward transport. HNO₃ can be absorbed
onto ice particles at low temperatures and lead to the formation of nitric acid trihydrates
(NAT, HNO₃·(H₂O)₃) in polar and tropical stratosphere (Hofmann et al., 1989; Carslaw
et al., 1998; Voigt et al., 2000; Popp et al., 2006). The NAT condensation tempera-
ture is approximately 193 K (Kirner et al., 2011). As shown in Fig. 12, the temperatures
around 100 hPa over the TP/SASM region are in the range of 190–200 K, which are low
enough to produce some NAT particles. However, balloon-borne measurements of de-
polarization ratio and backscattering ratio of aerosols at Lhasa during August–October
of 1999 by Kim et al. (2003) and Tobo et al. (2007) suggested that particles in the UTLS
of the TP/SASM region scarcely composed of coarse and aspherical particles such as
NAT.

7 Conclusions

In this work we simulate nitrate aerosol and its contribution to aerosol concentrations in
the UTLS over the TP/SASM region (70–105° E, 10–40° N) by simulation for summer-
time of year 2005, using the global chemical transport model GEOS-Chem driven by
the assimilated meteorological fields.

Simulated HNO₃ and O₃ are evaluated to show the model’s capability in simulating
the NOₓ-O₃-HNO₃ cycle over the studied region. In the UTLS, both the horizontal and
vertical distributions of simulated HNO$_3$ and O$_3$ agree well with the MLS observations. At 100 hPa, the simulated and observed HNO$_3$ mixing ratios averaged over the ASM/TP region are 345.9 and 301.3 pptv, respectively, and the difference lies within the confidence range of the MLS instruments. Both simulated and observed O$_3$ concentrations show relatively low values of less than 200 ppbv at 100 hPa over the TP/SASM region.

Averaged over the TP/SASM region, the surface-layer concentrations of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, BC, and OC are simulated to be 1.69, 0.94, 0.85, 0.30, and 0.94 µg m$^{-3}$, respectively. Nitrate is simulated to be the second largest aerosol species over the region of our interest. Comparisons of simulated aerosol concentrations with ground-based observations show that simulated summertime concentrations of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, OC and BC have NMB of $-15.3$, $+51.5$, $+74.9$, $-57.2$ and $-32.2\%$, respectively. Note that the measurements of NO$_3^-$ and NH$_4^+$ are quite limited in terms of the number of samples.

Model results show elevated concentrations of SO$_4^{2-}$, NO$_3^-$, NH$_4^+$, OC, BC and PM$_{2.5}$ in the UTLS over the TP/SASM region throughout the summer. NO$_3^-$ is simulated to be the most dominant aerosol species in the UTLS of the TP/SASM region. Accounting for NO$_3^-$ aerosol, the GEOS-Chem model reproduces well the magnitude of aerosol extinctions above 10 km, as model results are compared with the SAGE II measurements. Simulated vertical profiles of aerosol extinction coefficients with and without nitrate aerosol show large discrepancies from 6 km to tropopause, indicating the important role of nitrate in aerosol layer in the UTLS over the TP/SASM region.

The contribution of NO$_3^-$ to aerosols in the TP/SASM region is quantified by $C_{NIT}$ (the ratio of nitrate concentration to PM$_{2.5}$ concentration). Over the TP/SASM region, the $C_{NIT}$ values in summer are 5–35% at the surface, 25–50% at 200 hPa, and exceed 60% at 100 hPa. The mechanisms for the accumulation of nitrate in the UTLS over the TP/SASM region include vertical transport and the gas-to-aerosol conversion of HNO$_3$ to form nitrate. Such gas-to-aerosol conversion occurs during the upward transport and in the UTLS. The high relative humidity and low temperature associated with the deep convections over the TP/SASM region are favorable for nitrate formation.
Results from the present study indicate that nitrate is an important aerosol species in the UTLS over the ASM/TP region. Considering the scarce measurements of nitrate in the UTLS and the model uncertainties, more observational and modeling studies are needed to further explore the aerosol composition in the Asian tropopause aerosol layer.

Figure 1. Regions examined in this study: the Tibetan Plateau region (TP, 70–105° E, 25–40° N), the SASM region (SASM, 70–105° E, 10–25° N), and the anticyclone region of (20–120° E, 10–40° N).
Figure 2. Monthly variations in emissions of $\text{NO}_x$ (Tg N month$^{-1}$), $\text{SO}_2$ (Tg S month$^{-1}$), $\text{NH}_3$ (Tg N month$^{-1}$), OC (Tg C month$^{-1}$), and BC (Tg C month$^{-1}$) over Asia. Values shown are the total emissions (anthropogenic plus natural emissions listed in Table 1).
Figure 3. Simulated global distributions of surface-layer HNO$_3$ (pptv) and O$_3$ (ppbv) averaged over June–August 2005.
Figure 4. Comparisons of simulated HNO₃ concentrations (pptv) with observations (pptv) from MLS. (a) and (b) are simulated concentrations at 200 and 100 hPa, respectively. (c) is the latitude–altitude cross section of simulated HNO₃ concentrations averaged over 70–105° E. (d)–(f) are the same as (a)–(c), except that (d)–(f) are observations from MLS. The white areas in (d) and (f) have no datasets available from MLS. All the datasets are averaged over June–August of 2005.
Figure 5. Comparisons of simulated O$_3$ concentrations (ppbv) with observations (ppbv) from MLS. (a) and (b) are simulated concentrations at 200 and 100 hPa, respectively. (c) is the latitude–altitude cross section of simulated O$_3$ concentrations averaged over 70–105° E. (d)–(f) are the same as (a)–(c), except that (d)–(f) are observations from MLS. All the datasets are averaged over June–August of 2005.
Figure 6. The simulated and observed vertical profiles of monthly mean O₃ mixing ratios at (a) Kunming and (b) Lhasa in August 2005. The measurements are shown in black, and the simulated profiles are shown in red.
Figure 7. Simulated seasonal mean concentrations (µgm$^{-3}$) of sulfate, nitrate, ammonium, organic carbon, black carbon, and PM$_{2.5}$ at (a) the surface layer, (b) 200 hPa, and (c) 100 hPa, during summer (June–August) of year 2005. Note that color bars are different for concentrations at the surface, 200 hPa, and 100 hPa.
Figure 8. (a) Locations with measured aerosol concentrations from previous studies. Also shown are surface winds during summertime. (b)–(f) show the comparisons of simulated seasonal mean concentrations of sulfate, nitrate, ammonium, OC, and BC with measured values, respectively. Also shown in (b)–(f) are the 1:1 line (dashed), linear fit (solid line and equation), correlation coefficient between simulated and measured concentrations ($R$), and normalized mean bias (NMB) (defined as $\text{NMB} = \frac{\sum_{i=1}^{n}(P_i - O_i)}{\sum_{i=1}^{n}O_i} \times 100\%$, where $P_i$ and $O_i$ are predicted and observed concentrations at station $i$ for each aerosol species).
Figure 9. (a) Monthly mean distribution of aerosol extinction coefficients (km$^{-1}$) at 100 hPa for July of 2005. (b) Monthly mean vertical distributions of aerosol extinction coefficients (at 525 nm for SAGE II and 550 nm for GEOS-Chem) (km$^{-1}$) averaged over the Asian monsoon anticyclone region (20–120°E, 10–40°N) for July of 2005. The horizontal dashed line represents the tropopause averaged over the Asian monsoon anticyclone region simulated by the GEOS-Chem model.
Figure 10. Simulated contributions of nitrate to PM$_{2.5}$ ($C_{\text{NIT}} = \frac{[\text{NIT}]}{[\text{PM}_{2.5}]} \times 100\%$) averaged over summer (June–August) of year 2005 at (a) surface-layer, (b) 200 hPa, and (c) 100 hPa. (d) The latitude–altitude cross section of simulated $C_{\text{NIT}}$ (%) averaged over 70–105°E.
Figure 11. Latitude–altitude cross sections of simulated concentrations (color shades, \(\mu g m^{-3}\)) of \(SO_4^{2-}\) and \(NO_3^-\) averaged over 70–105°E in June–August of 2005, together with the wind vectors obtained from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-Interim Reanalysis data. The black line is the tropopause simulated by the GEOS-Chem model.
Figure 12. (a)–(b) Distributions of RH (%) and temperature (K) at 100 hPa. (c)–(d) The latitude–altitude cross sections of RH (%) and temperature (K) averaged over 70–105° E. RH and temperature are from the GEOS5 assimilated meteorological fields, and all the values are the averages over June–August of year 2005.
Figure 13. Mass budget for nitrate aerosol within the selected box of (70–105° E, 10–40° N, 8–16 km). E/W transport indicates net mass flux through the east and west lateral boundaries, N/S transport indicates net mass flux through the north and south lateral boundaries, and upward transport is the net mass flux through the top and bottom sides of the box. The mass flux is positive if it increases nitrate mass within the box. Unit of fluxes is Tg season$^{-1}$. All the values are the averages over June–August of 2005.
