(1) Comments from the Referees

Comment from Referee 1:
GENERAL COMMENTS
The authors provide a validation study of reactive gases modelled by the MACC system using a variety of data sources. In particular they validate O3 using GAW and EMEP data, CO using GAW station data and MOPITT retrievals, and NO2 using SCIAMACHY and GOME-2 retrievals. Given the extensive current and expected future use of MACC/CAMS products, this is a highly welcome and important contribution. With MACC soon becoming operational as CAMS this is a very much needed study at this point and it fits reasonably well within the scope of ACP although GMD probably would be more appropriate. The manuscript in general is structured consistently and well written, although some comprehensive editing by a native English speaker would be beneficial.

My main concern stems from the validation of modelled NO2 columns using satellite data. Satellite data of NO2 are extremely useful for comparing overall spatial patterns and providing an approximate qualitative assessment of the data. When using longterm averages they can even be used in a somewhat quantitative fashion to some extent. However, the uncertainty in the NO2 retrievals (both in terms of systematic biases and random errors!) themselves is too high to allow a full quantitative validation of model results. You are essentially comparing two similarly uncertain parameters with each other! Furthermore, NO2 is primarily relevant close to the surface and within the PBL (and the NO2 output from MACC/CAMS will be primarily used for such applications), whereas satellite-based validation of NO2 can only be carried out for tropospheric columns (and in addition the satellite instruments tend to be least sensitive near the surface!). It is thus impossible to draw robust quantitative conclusions from this, particularly for hourly/daily sampling and at the individual grid cell level (and this is very important for a full validation of the model results). A comprehensive validation of modelled NO2 with satellite data alone is not sufficient to draw accurate conclusions about the model performance. This is particularly relevant for validating the results from such a highly visible, high-profile, and heavily funded project as MACC/CAMS, whose model output will be used operationally for a wide variety of applications worldwide in future. As such, the validation methodology should be as robust as possible. Therefore, in addition to the comparison against satellite data provided in the current manuscript, the authors really need to perform a solid quantitative validation of modelled surface NO2 against reliable station observations (and possibly a validation of modelled NO2 columns against ground-based MAX-DOAS data) before this manuscript can be published.

My second concern is related to the extensive use of the MNMB in this study. This is a highly non-standard statistical metric and is not readily understandable by a general audience. It is entirely unclear why the MNMB is arbitrarily multiplied by a factor of 2, for example, and how the percentage values of a bounded index should be interpreted.

Personally I think it would be preferable to stick to commonly used metrics such as for example the classic combination of mean bias and the standard deviation of the differences (representing systematic and random error, respectively) with RMSE as a measure of total error, possibly MAE, etc. I do realise that MNMB seems to have been adopted by the MACC validation team and is being used throughout several MACC related papers in order to make statistics between species comparable. However, the vast majority of readers of MACC-related papers will not be familiar
with this metric and will not know about its properties. If the authors insist on using this metric as intensively as in the given manuscript, I think they need to much better justify the use of such a non-standard validation metric and further should provide a detailed background regarding its statistical properties as compared to standard metrics.

SPECIFIC COMMENTS
P6279 L1: What about MACC-III? Wouldn’t it be more sensible to call it something along the lines of a "series of MACC projects" or similar?
P6280-6281: This reads more like a textbook section on atmospheric chemistry than an introduction to a validation paper. Please be concise and focus on what is relevant for this study. It would also be useful here to discuss why we actually care about these gases and why we model them, i.e. what are some potential health effects or other impacts of these gases. See the submitted MACC validation paper by Eskes et al. (2015) in GMDD for an example on this.
P6281-6282 etc: Sometimes you talk about MACC/MACC-II, sometimes about MACCIII and sometimes about MACC. Please be consistent. I recommend introducing the series of MACC projects (including MACC-III) once in the beginning and then referring to it simply as MACC in the remainder of the manuscript. Again, take a look at the submitted MACC validation paper by Eskes et al. (2015) in GMDD for finding out how to do this in a better way.
P6281 L19-20: This is worded a bit strangely. It is not the series of MACC projects that form the basis of CAMS, but rather the work that has been carried as part of MACC represents the preparatory activities that in the end are supposed to result in the operational CAMS.
P6281 L26: Are there more recent references on how data assimilation is being carried out within MACC/CAMS? If yes, cite them here. Maybe Inness et al. 2013 or similar?
P6282 L17-21: It is not clear how the availability of independent observations limits the period of this study to 2009-2012. For sure all the satellite datasets (MOPITT, SCIAMACHY, GOME-2) were available many years before 2009 and with exception of SCIAMACHY also continued after 2012. Surely GAW and EMEP data were available outside this period as well? Be precise about what is the limiting factor here.
P6282 L25: are -> is
P6282 L28: "encloses"? Better write something like "provides" or "contains"
P6283 L19: "MACC_osuite". Can you provide an explanation for this rather odd technical acronym?
P6283 L24: Be specific about the spatial resolution of the model. Is it 100 km x 100 km or irregular (and/or give it in degrees lat/lon)?
P6284 L9: What do you mean by "go back"? Do you mean the emissions are taken from or based on the RETRO-REAS inventory? Also, how exactly were the emissions merged?
P6284: Give more information about the spatial resolution of the various emission Inventories
P6284 L26: "lists up" -> "lists"
P6285 L20: Has this been studied (if yes, provide results) or is this just an assumption?
P6286 L5: WMO 2010 is not included in the list of references
P6286 L6: Why specify "tropospheric" here? These are surface observations, right?
P6286 L24: Why didn’t you use vertical interpolation between the two closest model levels. Discuss why the resulting error is negligible (or why not).
P6289 L1: The labels "Fires-Alaska" and "Fires-Siberia" look awkward compared to the other regions. Clarify why these specifically refer to fires and that they are only used for CO validation with MOPITT. Also in some of the Figures these labels are not used consistently. Please fix.

P6289 L11: "UV-VIS". Also I would recommend either writing "UV-VIS and NIR" or "ultraviolet-visible and near-infrared" and not mixed.

P6289: This section requires a discussion about the expected uncertainty of the satellite-based NO2 retrievals. Also, what is a reasonable minimum threshold of detection for the tropospheric NO2 column derived from SCIAMACHY and GOME-2?

P6290 L7: "linearly in time"

P6291 L8: Why does the MNMB used here range from -2 to 2 rather than -1 to 1? Why is this metric multiplied by 2? When using this metric in percent, as the authors do in this study you get a bounded range of -200% to 200%. How should this be interpreted? Please provide additional detail about the statistical properties of this non-standard evaluation metric.

P6291 L20: Keep the section headers consistent. Either spell out the species or not, but do not mix.

P6291 L23: It shows not one but two maps

P6291 L23: Figure 11? Figures 2-10 have not even been discussed yet. This also applies throughout the rest of the paper. Renumber Figures and Tables based on when they are introduced in the manuscript

P6292 L4: "far north" -> Better write "high latitudes in the northern hemisphere" or something similar to be specific

P6293 L6: better write "northern hemisphere winter months"

P6293 L24: This is not clear from Figure 14. It seems to show negative values of around -30% for Dec 2010?

P6293 L25-27: Can you provide an explanation for why Dec 2012 behaves so differently?

P6293 L27: "diurnal O3 cycle". This is misleading - Figure 15 does not really analyse the diurnal cycle but rather simply differentiates the result by day and night. Consider rewording this.

P6294 L21-23: Why do you need to refer to RMSEs and correlation coefficients in this sentence, when you are just talking about MNMBs? Please revise.

P6294 L24 "northern hemisphere"

P6295 L1: These correlation coefficients are indeed extremely low. A Pearson correlation coefficient of what is on average about 0.3 (Fig 2) translates to an $R^2$ of 0.09! And this is even for monthly averages and not hourly/daily observations - so the random error should already be reduced to a large extent. If a model can explain less than 10% of the variability in monthly averages, I think quite a bit of explanation about possible reasons for the poor performance is necessary. Please add a discussion on this here.

P6295 L3: How was the subset of stations in Figure 3 selected? Were only those stations selected at which the model performed well, or was some other selection process used? Please add information about this in the text.

P6295 L25 to P6296 L10: This section discusses solely differences between MOPITT and IASI but not the relevance of these differences with respect to the model. Please revise to better indicate how these differences affect the model performances? Is it due to assimilation of IASI CO products in the model?

P6296 L24: Be careful about interpreting too much into satellite-based NO2 columns
over the open oceans. The NO2 levels there tend to be below the detection limits of the instruments and the patterns observed there often represent no true geophysical signal.

P6298: Please clearly distinguish here between CO and NO2 here. These are intermixed in the discussion making it difficult to follow.
P6299: This section also requires a brief discussion of the potential uncertainties introduced by transitioning from SCIAMACHY to GOME-2 in 2012 and how it affects the validation of NO2.
P6300 L5: Again, you are not really studying/validating the diurnal cycle. Please reword.
P6316: The combined label/region field is a bit confusing. Do only the GAW stations have a label whereas the EMEP stations have a region acronym? For clarity please highlight this in the caption and list the region acronyms.
P6319: This table has unrealistically high number of significant digits. Please modify.
P6322: The panels in this plot are missing labels as a) b) c), yet the caption refers to them. Also, why does the caption only refer to a) and b) instead of all three. Please be consistent. Also the panels are very small, such that the legend is not readable.
P6324: The legend here does not list the region names as "Fires-Alaska" and "Fires-Siberia", as they were introduced previously. Please decide on a label for these regions and then stick to it consistently in text and Figures.
P6325: Same in this Figure.
P6326: It would be helpful to use different symbols/colours for SCIAMACHY and GOME-2 in this Figure.
P6328: Same in this Figure.
P6329: The caption says "daily" but the Figure shows monthly averages. Please correct.
P6331: This Figure has an unclear colour scale, making the interpretation of MNMBs close to zero challenging. Plots with divergent colour scale such as this should ideally have only one colour gradient for positive and negative values, respectively, with a neutral colour (white or grey) in between. I recommend shades of red for positive values and shades of blue for negative values with white or grey symmetrically around zero.
P6332: These plots are extremely busy and the legend is unreadable. Please consider ways of reducing the overplotting to increase the visual impact of the Figure. Also, once again, please consistently format and label the panels. Why does subplot a) consist of two panels and subplot b) of one panel. Why not have 3 separate subplots?
P6333: Describe either in the caption or in the text how this seemingly random subset of stations was selected.

Comment from Referee 2:
GENERAL COMMENTS
In this paper an evaluation of the MACC operational forecast system is given with comparisons of the model with surface and satellite data of O3, NO2 and CO. The comparisons show deficiencies in the model or the model input that are pointed out. The paper gives the impression of hastily being put together leaving a lot of work to the reader. This should really be tidied up before publication. For example the number and choice of GAW stations shown should be motivated, or should be similar for the different comparisons (O3, CO and NO2). For NO2 ground based data is missing, FTIR or UV-VIS data could be used here. Figures and tables numbering need to be
tidied up. Figures with the lots of lines are illegible. Please try to be consistent with the analysis of the 3 different data sets.

page 6280:
line 4: Avoid one sentence paragraphs
line 19: better: "in their respective summer months" instead of just "in the summer months"

page 6282:
line 16: It is no the 'paper that investigates’, more something like this "In this paper we
describe the investigation of..."

page 6284:
line 24: "Table 2 lists the assimilated data products." instead of "...lists up...

O3

page 6291
line 23: The figure order needs to be checked. This should be Figure 2 and not Figure 11, the Figure order has to be changed.

Fig.1
Fig.11 should be 2
Fig.13 should be 3
Fig.12 should be 4
Fig.14 should be 5
Fig.15 should be 6
Fig.2-10 should be 7-15

page 6292:
line 8: Figure 13 (which should be plot 3) shows very large variability in the model
data,

compared to the observations. The agreement does not seem very good for the high latitude stations but there seems to be indeed an amelioration after Jul 2012.
line 15: O3 in tropical regions (30_S to 30_N) seem to have min 20% differences up to
40%
line 19: could you show the correlation coefficients on the plots?

Table 6 should be Table 4. Please change Table order.

Figure 12: Legends are not legible, there are too many lines. The plots should be numbered a, b, c. There are curves that stop, eg the pink line in plot a. in Dec 2011. Why? Or one starts in Jun 2010 (black?) Maybe the plots should be stacked on top of each other.

page 6293:
line 8: The correlation does not show a distinct seasonal behaviour in Fig 12, but the
MNMBs or the RMSEs not either on this plot! How do you know this?
line 15: There also seems to be a phase shift at KOS, KOV and CVO. TSU seems to have random observations, but the black points are not really visible behind the red line.
line 27: Figure 15 should have the panels stacked and numbered a, b, c.

CO

page 6294:
line 6: MNMBs have already been described. These descriptions (also for RMSEs)
could move to the O3 section.
line 20: Reference to Table 4 should come earlier (line 7).
line 24: Figure 2 could have the 3 plots stacked again.
Fig 3: Why do you use different stations for O3 and CO?

Why do you use the IASI product, when you know that it is not as good as the MOPITT product for higher latitudes?

NO2

Discussion

There is a stray 'to'

Discussion

lines 7-9: 'realistically reproduces': Isn’t this a bit of an exaggeration with up to 110% underestimations for NO2? Incidentally the values are all negative overall an range from 5% to 70% underestimation. The values for CO seem to be 15% to -23%, whereas the overall values of -50% to 28% do not really agree well...

It would be good to have a Table with the satellite results for CO, too.

Discussion

lines 27 to end of Discussion: O3 section should probably come first in the discussion.

Conclusion

line 8: 'however with a negative offset' should probably be 'however, with a large negative offset'

line 18: Wasn’t the impact of the fire emission error rather large!!

Tables:

Check order of tables with first occurance in the text being first.

Figures:

Check order of figures with first occurance in the text being first.

Better use a, b, c, d, e, f, etc for the sub-figures.

Figure 9 Caption, the latitudinal an longitudinal boundaries are defined in Figure 1 not in the text!

(2) Author’s response to the general comments:

Thank you very much for the comprehensive review of our paper!

We have tidied up the numbering of the figures and tables; we have changed the introduction and re-structured the discussion and conclusion and we included the requested changes.

Concerning the use of NO2 surface observations for the validation:

We absolutely agree with the referee that surface measurements of NO2 would indeed be very useful in addition to the satellite observations. However, for the global model validation this has not been implemented in MACC so far. For the validation of the global model, it was important for us to compare especially the spatial patterns of NO2 which can hardly be captured globally by the sparse amount of GAW station observations. In MACC-III, the validation with MAX-DOAS is tested, however, with regional models with higher spatial resolution.
Concerning the use of the MNMB:
We use the MNMB in the MACC and future CAMS evaluations because verifying chemical species concentration values significantly differs from verifying standard meteorological fields. For example, spatial or temporal variations can be much greater and the differences between model and observed values (“model errors”) are frequently much larger in magnitude. Most importantly, typical concentrations can vary quite widely between different pollutant types (e.g. O₃ and CO) and region (e.g. Europe vs. Antarctica), a given bias or error value can have a quite different significance. It is useful therefore to consider bias and error metrics which are normalized with respect to observed concentrations and hence can provide a consistent scale regardless of pollutant type (see e.g. Elguindi et al., 2010 or Savage et al., 2013). Moreover, the MNMB is robust to outliers, converges to the normal bias for biases approaching zero, while taking into account the representativeness issue when comparing coarse resolved global models versus site specific station observations. Though GAW stations prove regional representative in general, the experience is that local effects cannot always be ruled out reliably in long worldwide data sets, because transport, chemical processes and parameterizations are not selective for the super- to sub-grid-scale threshold. Referencing to the model/observation mean again constitutes a pragmatic workaround to avoid misleading bias tendencies, particularly in sensitive regions with sparse data coverage. Within MACC, the MNMB is used as an important standard score. It is used in the MACC quarterly evaluation reports and it appears in a lot of recent publications, e.g. Cuevas et al. (2015), Eskes et al. (2015), Sheel et al. (2014). As our paper is dedicated to the MACC special issue, we assume that most of the readers will be familiar with this metric and thus we would like to stick to the MNMB in our validations. In our paper, the MNMB is complemented with the commonly used standard metrics RMSE and R.

The specific comments of the referees have been addressed point-by-point in what follows:

Author’s response point-by-point:

Referee 1:
Specific comments:
P6279 L1: What about MACC-III? Wouldn’t it be more sensible to call it something along the lines of a "series of MACC projects" or similar?
-done

P6280-6281: This reads more like a textbook section on atmospheric chemistry than an introduction to a validation paper. Please be concise and focus on what is relevant for this study. It would also be useful here to discuss why we actually care about these gases and why we model them, i.e. what are some potential health effects or other impacts of these gases. See the submitted MACC validation paper by Eskes et al. (2015) in GMDD for an example on this.

-the introduction has been re-written to:
The impact of reactive gases on climate, human health and environment has gained increasing public and scientific interest in the last decade (Bell et al., 2006, Cape 2008, Mohnen et al., 2013, Seinfeld and Pandis 2006, Selin et al., 2009). As air pollutants, carbon monoxide (CO),
nitrogen oxides ($NO_x$) and ozone ($O_3$) are known to have acute and chronic effects on human health, ranging from minor upper respiratory irritation to chronic respiratory and heart disease, lung cancer, acute respiratory infections in children and chronic bronchitis in adults (Bell et al., 2006, Kampa and Castanas 2006). Tropospheric ozone, even in small concentrations, is also known to cause plant damage in reducing plant primary productivity and crop yields (e.g. Ashmore 2005). It is also contributing to global warming by direct and indirect radiative forcing (Forster et al., 2007, Sitch et al., 2007). Pollution events can be caused by local sources and processes but are also influenced by continental and intercontinental transport of air masses. Global models can provide the transport patterns of air masses and deliver the boundary conditions for regional models, facilitating the forecast and investigation of air pollutants.

The EU-funded research project MACC - Monitoring Atmospheric Composition and Climate, (consisting of a series of European projects, MACC to MACC-III), provides the preparatory work that will form the basis of the Copernicus Atmosphere Monitoring Service (CAMS). This service is established by the EU to provide a range of products of societal and environmental value with the aim to help European governments respond to climate change and air quality problems. MACC provides reanalysis, monitoring products of atmospheric key constituents (e.g. Inness et al., 2013), as well as operational daily forecasting of greenhouse gases, aerosols and reactive gases (Benedetti et al., 2011, Stein et al., 2012) on a global and on European-scale level, and derived products such as solar radiation. An important aim of the MACC system is to describe the occurrence, magnitude and transport pathways of disruptive events, e.g., volcanoes (Flemming and Inness, 2013), major fires (Huijnen et al., 2012, Kaiser et al., 2012) and dust storms (Cuevas et al., 2015). The product catalogue can be found on the MACC website, http://copernicus-atmosphere.eu. For the generation of atmospheric products, state-of-the-art atmospheric modelling is combined with assimilated satellite data (Hollingsworth et al., 2008, Inness et al., 2013, 2015, more general information about data assimilation can be found in e.g. Ballabrera-Poy et al., 2009 or Kalnay 2003). Within the MACC project there is a dedicated validation activity to provide up-to-date information on the quality of the reanalysis, daily analyses and forecasts. Validation reports are updated regularly and are available on the MACC websites.

The MACC global near-real-time (NRT) production model for reactive gases and aerosol has operated with data assimilation from September 2009 onwards, providing boundary conditions for the MACC regional air quality products (RAQ), and other downstream users. The model simulations also provide input for the stratospheric ozone analyses delivered in near-real-time by the MACC stratospheric ozone system (Lefever et al., 2014).

In this paper we describe the investigation of the potential and challenges of near-real-time modelling with the MACC analysis system between 2009 and 2012. We concentrate on this period because of the availability of validated independent observations (namely surface observations from the Global Atmosphere Watch Programme GAW, the European Monitoring and Evaluation Programme EMEP, as well as total column satellite data from the MOPITT, SCIAMACHY and GOME-2 sensors) that are used for comparison. In particular, we study the model’s ability to reproduce the seasonality and absolute values of CO and NO$_2$ in the troposphere as well as $O_3$ and CO at the surface. The impact of changes in model version, data assimilation and emission inventories on the model performance is examined and discussed. The paper is structured in the following way: Section 2 contains a description of the model and the validation data sets as well as the applied validation metrics. Section 3 presents the validation results for CO, NO$_2$ and $O_3$. Section 4 provides the discussion and section 5 the conclusions of the paper.
at the submitted MACC validation paper by Eskes et al. (2015) in GMDD for finding out how to do this in a better way.

P6281 L19-20: This is worded a bit strangely. It is not the series of MACC projects that form the basis of CAMS, but rather the work that has been carried as part of MACC represents the preparatory activities that in the end are supposed to result in the operational CAMS.

P6281 L26: Are there more recent references on how data assimilation is being carried out within MACC/CAMS? If yes, cite them here. Maybe Inness et al. 2013 or similar?

P6282 L17-21: It is not clear how the availability of independent observations limits the period of this study to 2009-2012. For sure all the satellite datasets (MOPITT, SCIAMACHY, GOME-2) were available many years before 2009 and with exception of SCIAMACHY also continued after 2012. Surely GAW and EMEP data were available outside this period as well? Be precise about what is the limiting factor here.

- The data availability is only limiting the end of the validation period. We chose 2009 as the beginning because the MACC_osuite model run with data assimilation was introduced in 09/2009.

P6282 L25: are -> is

P6282 L28: "encloses"? Better write something like "provides" or "contains"

P6283 L19: "MACC_osuite". Can you provide an explanation for this rather odd technical acronym?

P6283 L24: Be specific about the spatial resolution of the model. Is it 100 km x 100 km or irregular (and/or give it in degrees lat/lon)?

P6284 L9: What do you mean by "go back"? Do you mean the emissions are taken from or based on the RETRO-REAS inventory? Also, how exactly were the emissions merged?

P6284: Give more information about the spatial resolution of the various emission Inventories

P6284 L26: "lists up" -> "lists"

P6285 L20: Has this been studied (if yes, provide results) or is this just an assumption?

-This is the experience (unpublished, however) of our validation work within MACC.

P6286 L5: WMO 2010 is not included in the list of references
The selection of the vertical model level is indeed a challenge. Within MACC, we initially did extensive sensitivity tests for level selection, but had to conclude that there is no clear optimal approach for all stations, terrains and species. At the lowest levels, the narrow spacing of the model levels is often not significantly resolved by model processes and parameterizations, at large model/real surface differences the missing surface influence (e.g. deposition) could introduce more problematic inconsistencies (e.g. in diurnal cycle) than a precisely chosen model altitude, be it w.r.t. altitude, pressure or temperature (which all has been applied in published studies but each has clear pros and cons).

The labels "Fires-Alaska" and "Fires-Siberia" look awkward compared to the other regions. Clarify why these specifically refer to fires and that they are only used for CO validation with MOPITT. Also in some of the Figures these labels are not used consistently. Please fix.

"UV-VIS". Also I would recommend either writing "UV-VIS and NIR" or "ultraviolet-visible and near-infrared" and not mixed.

This section requires a discussion about the expected uncertainty of the satellite-based NO2 retrievals. Also, what is a reasonable minimum threshold of detection for the tropospheric NO2 column derived from SCIAMACHY and GOME-2? We agree that a short section on uncertainties is needed and have added the following paragraph:

Satellite observations of tropospheric NO2 columns have relatively large uncertainties, mainly linked to incomplete stratospheric correction (important over clean regions and at high latitudes in winter and spring) and to uncertainties in air mass factors (mainly over polluted regions) (e.g. Boersma et al., 2004 and Richter et al., 2005). The uncertainty varies with geolocation and time but in first approximation can be separated into an absolute error of 5x1014 molec cm-2 and a relative error of about 30%, whichever is larger. As some of the contributions to this uncertainty are systematic, averaging over longer time periods does not reduce the errors as much as one would expect for random errors. Over polluted regions, the uncertainty from random noise in the spectra is small in comparison to other error sources, in particular for monthly averages.

The question of a detection limit for satellite NO2 observations is an interesting one. Averaging of large amounts of data will lower the random noise in the data significantly as has been demonstrated for many trace gases in studies looking at multi-annual averages. While the number of available measurements is limited in real world observations, it is not clear to us whether or not a detection limit in the sense of an absolute threshold exists for this type of absorption spectroscopy measurements. We therefore preferred not to give a "detection limit" but rather an absolute uncertainty which for practical applications has the same meaning.
Why does the MNMB used here range from -2 to 2 rather than -1 to 1? Why is this metric multiplied by 2? When using this metric in percent, as the authors do in this study you get a bounded range of -200% to 200%. How should this be interpreted? Please provide additional detail about the statistical properties of this non-standard evaluation metric.

The MNMB is a normalization based on the mean of the observed and forecast value. It is used as a standard score within MACC and been adopted in order to avoid asymmetry, which occurs in bias assessment when the mean observation is used as a reference, see also Elguindi et al. (2010). A detailed discussion on this has been added in the general part of the author’s answers above.

Keep the section headers consistent. Either spell out the species or not, but do not mix.

It shows not one but two maps

Better write "high latitudes in the northern hemisphere" or something similar to be specific

better write "norther hemisphere winter months"

This is not clear from Figure 14. It seems to show negative values of around -30% for Dec 2010?

Can you provide an explanation for why Dec 2012 behaves so differently?
-We suppose because of the limited data availability towards the end of the validation period.

"diurnal O3 cycle". This is misleading - Figure 15 does not really analyse the diurnal cycle but rather simply differentiates the result by day and night. Consider rewording this.

Why do you need to refer to RMSEs and correlation coefficients in this sentence, when you are just talking about MNMBs? Please revise.
These correlation coefficients are indeed extremely low. A Pearson correlation coefficient of what is on average about 0.3 (Fig 2) translates to an $R^2$ of 0.09! And this is even for monthly averages and not hourly/daily observations - so the random error should already be reduced to a large extent. If a model can explain less than 10% of the variability in monthly averages, I think quite a bit of explanation about possible reasons for the poor performance is necessary. Please add a discussion on this here.

The low values of 0.1 during the period January 2011 to October 2011 result from the reading error in the fire emissions. The generally only moderate correlation coefficient is related to mismatches in the strong short-term variability seen in both the model and the measurements. Data assimilation also presumably impacts this.

How was the subset of stations in Figure 3 selected? Were only those stations selected at which the model performed well, or was some other selection process used? Please add information about this in the text.

We chose representative examples for every region to underline the results in the text but certainly not only stations where the model performed well, as can be seen by the deviations between model and observations in the plots.

This section discusses solely differences between MOPITT and IASI but not the relevance of these differences with respect to the model. Please revise to better indicate how these differences affect the model performances? Is it due to assimilation of IASI CO products in the model?

Be careful about interpreting too much into satellite-based NO2 columns over the open oceans. The NO2 levels there tend to be below the detection limits of the instruments and the patterns observed there often represent no true geophysical signal.

We agree that NO2 columns, which are close to the uncertainty, should be interpreted with care. We do not think that this is limited to columns over the open oceans although there might be small problems with the spectral signature of vibrational Raman scattering and possibly also liquid water absorption.

The patterns seen in the satellite data, which are referred to in the text are clearly linked to outflow from the continents and we do not think they are artefacts. The enhanced values in the Southern Ocean close to Antarctica are a well-known artefact from incomplete removal of stratospheric variability.

In response to the comment by the reviewer we have changed the corresponding paragraph as follows:

In the northern hemisphere, background values of NO2 VCD over the ocean are lower in the simulations than in the satellite data. The same is true for the South Atlantic Ocean to the west of Africa (see Fig.15). This might suggest a model underestimation of NO2 export from continental sources or too rapid conversion of NO2 into its reservoirs. However, as the NO2 columns over the oceans are close to the uncertainties in the satellite data, care needs to be taken when interpreting these differences.
P6298: Please clearly distinguish here between CO and NO2 here. These are intermixed in the discussion making it difficult to follow.
-done

P6299: This section also requires a brief discussion of the potential uncertainties introduced by transitioning from SCIAMACHY to GOME-2 in 2012 and how it affects the validation of NO2.
-we have repeated the validation with GOME-2 data and the conclusions are the same as for the combined SCIAMACHY and GOME-2 validation. For the region plots, the daily mean values of SCIAMACHY show a stronger temporal variability compared to the daily mean values of GOME-2. This is due to the differences in the data sampling (GOME-2 has a better spatial coverage). Figures are attached below.

P6300 L5: Again, you are not really studying/validating the diurnal cycle. Please reword.
-done

P6316: The combined label/region field is a bit confusing. Do only the GAW stations have a label whereas the EMEP stations have a region acronym? For clarity please highlight this in the caption and list the region acronyms.
-done

P6319: This table has unrealistically high number of significant digits. Please modify.
-done

P6322: The panels in this plot are missing labels as a) b) c), yet the caption refers to them. Also, why does the caption only refer to a) and b) instead of all three. Please be consistent. Also the panels are very small, such that the legend is not readable.
-done

P6324: The legend here does not list the region names as "Fires-Alaska" and "Fires-Siberia", as they were introduced previously. Please decide on a label for these regions and then stick to it consistently in text and Figures.
-done

P6325: Same in this Figure.
-done

P6326: It would be helpful to use different symbols/colours for SCIAMACHY and GOME-2 in this Figure.
For the daily values, different symbols are not an option due to the dense plotting in the long time series. We could use different colours; however, this would not be in accordance to the other Figures, then. We could, if this helps, introduce a vertical dashed line in the x-axis.

P6328: Same in this Figure.
-see above

P6329: The caption says "daily" but the Figure shows monthly averages. Please correct.
This Figure has an unclear colour scale, making the interpretation of MNMBs close to zero challenging. Plots with divergent colour scale such as this should ideally have only one colour gradient for positive and negative values, respectively, with a neutral colour (white or grey) in between. I recommend shades of red for positive values and shades of blue for negative values with white or grey symmetrically around zero. This is the colour bar used in the MACC validation exercises. We would like to keep it, for in this case we wanted to especially highlight large biases.

These plots are extremely busy and the legend is unreadable. Please consider ways of reducing the overplotting to increase the visual impact of the Figure. Also, once again, please consistently format and label the panels. Why does subplot a) consist of two panels and subplot b) of one panel. Why not have 3 separate subplots?

Describe either in the caption or in the text how this seemingly random subset of stations was selected. We wanted to give some examples for every region to underline the findings in the text.

Referee 2:
Specific comments:

page 6280:
line 4: Avoid one sentence paragraphs
-done

line 19: better: "in their respective summer months" instead of just "in the summer months"
-done

page 6282:
line 16: It is no 'paper that investigates', more something like this "In this paper we describe the investigation of..."
-done

page 6284:
line 24: "Table 2 lists the assimilated data products." instead of "...lists up..."
-done

page 6291
line 23: The figure order needs to be checked. This should be Figure 2 and not Figure 11, the Figure order has to be changed.
-done

page 6292:
Figure 13 (which should be plot 3) shows very large variability in the model data, compared to the observations. The agreement does not seem very good for the high latitude stations but there seems to be indeed an amelioration after Jul 2012.
-Yes, as described in the text

O3 in tropical regions (30_S to 30_N) seem to have min 20% differences up to 40%
-yes, but the average of all stations is 20%

could you show the correlation coefficients on the plots?
- We initially had MNMBs and correlation coefficients in the plots, which turned out somewhat busy and unreadable. So we decided to list them in the tables (Table 4 and 5).

Table 6 should be Table 4. Please change Table order.
-done

The correlation does not show a distinct seasonal behaviour in Fig 12, but the MNMBs or the RMSEs not either on this plot! How do you know this?
-MNMBs and RMSE show higher (positive MNMBs) values during the summer months and lower values (negative MNMBs) during the winter months.

There also seems to be a phase shift at KOS, KOV and CVO. TSU seems to have random observations, but the black points are not really visible behind the red line.
-done

Figure 15 should have the panels stacked and numbered a, b, c.
-done

MNMBs have already been described. These descriptions (also for RMSEs) could move to the O3 section.
-done

Reference to Table 4 should come earlier (line 7).
-done

Figure 2 could have the 3 plots stacked again.
-done

Why do you use different stations for O3 and CO?
-the observational validation data sets are different for CO and O3. Some stations provide measurements only for either CO or O3.
line 1: Why do you use the IASI product, when you know that it is not as good as the MOPiTT product for higher latitudes?
- In the course of the validation work, it has become clear that these differences exist between the two data sets. Now, both data sets are assimilated in the MACC operational suite.

line 27: There is a stray 'to'
-done

lines 7-9: 'realistically reproduces': Isn’t this a bit of an exaggeration with up to 110% underestimations for NO2? Incidentally the values are all negative overall and range from 5% to 70% underestimation. The values for CO seem to be 15% to -23%, whereas the overall values of -50% to 28% do not really agree well...
-done

line 9: It would be good to have a Table with the satellite results for CO, too.
-done

lines 27 to end of Discussion: O3 section should probably come first in the discussion.
-done

line 8: 'however with a negative offset' should probably be 'however, with a large negative offset'
-done

line 18: Wasn’t the impact of the fire emission error rather large!!
-done

General: Be consistent, sometimes it is Fig. in the text other times it is Figure.
-It was recommended by a referee to use “Figure”, when starting a sentence, apart from that we use “Fig”.

Figure 9 Caption, the latitudinal and longitudinal boundaries are defined in Figure 1 not in the text!

Abstract

Monitoring Atmospheric Composition and Climate (MACC) currently represents the European Union’s Copernicus Atmosphere Monitoring Service (CAMS) (http://www.copernicus.eu/), which will become fully operational in the course of 2015. The global near-real-time MACC model production run for aerosol and reactive gases provides daily analyses and 5-day forecasts of atmospheric composition fields. It is the only assimilation system world-wide that is operational to produce global analyses and forecasts of reactive gases and aerosol fields. We have investigated the ability of the MACC analysis system to simulate tropospheric concentrations of reactive gases (CO, O₃, and NO₂) covering the period between 2009 and 2012. A validation was performed based on CO and O₃ surface observations from the Global Atmosphere Watch (GAW) network, O₃ surface observations from the European Monitoring and Evaluation Programme (EMEP) and furthermore, NO₂ tropospheric columns derived from the satellite sensors SCIAMACHY and GOME-2, and CO total columns derived from the satellite sensor MOPITT. The MACC system proved capable of reproducing reactive gas concentrations in consistent quality, however, with a seasonally dependent bias compared to surface and satellite observations: For northern hemisphere surface O₃ mixing ratios, positive biases appear during the warm seasons and negative biases during the cold parts of the years, with monthly Modified Normalised Mean Biases (MNMBs) ranging between -30% and 30% at the surface. Model biases are likely to result from difficulties in the simulation of vertical mixing at night and deficiencies in the model’s dry deposition parameterization. Observed tropospheric columns of NO₂ and CO could be reproduced correctly during the warm seasons, but are mostly underestimated by the model during the cold seasons, when anthropogenic emissions are at a highest, especially over the US, Europe and Asia. Monthly MNMBs of the satellite data evaluation range between -110% and 40% for NO₂ and at most -20% for CO, over the investigated regions. The underestimation is likely to result from a combination of errors concerning the dry deposition...
parameterization and certain limitations in the current emission inventories, together with an insufficiently established seasonality in the emissions.

1. Introduction

The impact of reactive gases on climate, human health and environment has gained increasing public and scientific interest in the last decade (Bell et al., 2006, Cape 2008, Mohnen et al., 2013, Seinfeld and Pandis 2006, Selin et al., 2009). As air pollutants, carbon monoxide (CO), nitrogen oxides (NO\textsubscript{x}) and ozone (O\textsubscript{3}) are known to have acute and chronic effects on human health, ranging from minor upper respiratory irritation to chronic respiratory and heart disease, lung cancer, acute respiratory infections in children and chronic bronchitis in adults (Bell et al., 2006, Kampa and Castanas 2006). Tropospheric ozone, even in small concentrations, is also known to cause plant damage in reducing plant primary productivity and crop yields (e.g. Ashmore 2005). It is also contributing to global warming by direct and indirect radiative forcing (Forster et al., 2007, Sitch et al., 2007). Pollution events can be caused by local sources and processes but are also influenced by continental and intercontinental transport of air masses. Global models can provide the transport patterns of air masses and deliver the boundary conditions for regional models, facilitating the forecast and investigation of air pollutants.

The EU-funded research project MACC - Monitoring Atmospheric Composition and Climate, (consisting of a series of European projects, MACC to MACC-III), provides the preparatory work that will form the basis of the Copernicus Atmosphere Monitoring Service (CAMS). This service is established by the EU to provide a range of products of societal and environmental value with the aim to help European governments respond to climate change and air quality problems. MACC provides reanalysis, monitoring products of atmospheric key constituents (e.g. Inness et al., 2013), as well as operational daily forecasting of greenhouse gases, aerosols and reactive gases (Benedetti et al., 2011, Stein et al., 2012) on a global and on European-scale level, and derived products such as solar radiation. An important aim of the MACC system is to describe the occurrence, magnitude and transport pathways of disruptive events, e.g., volcanoes (Flemming and Inness, 2013), major fires (Huijnen et al., 2012, Kaiser et al., 2012) and dust storms (Cuevas et al., 2015). The product catalogue can be found on the MACC website, http://copernicus-atmosphere.eu. For the generation of atmospheric products, state-of-the-art atmospheric modelling is
combined with assimilated satellite data (Hollingsworth et al., 2008, Inness et al., 2013, 2015. more general information about data assimilation can be found in e.g. Ballabera-Poy et al., 2009 or Kalnay 2003). Within the MACC project there is a dedicated validation activity to provide up-to-date information on the quality of the reanalysis, daily analyses and forecasts. Validation reports are updated regularly and are available on the MACC websites.

The MACC global near-real-time (NRT) production model for reactive gases and aerosol has operated with data assimilation from September 2009 onwards, providing boundary conditions for the MACC regional air quality products (RAQ), and other downstream users. The model simulations also provide input for the stratospheric ozone analyses delivered in near-real-time by the MACC stratospheric ozone system (Lefever et al., 2014).

In this paper we describe the investigation of the potential and challenges of near-real-time modelling with the MACC analysis system between 2009 and 2012. We concentrate on this period because of the availability of validated independent observations (namely surface observations from the Global Atmosphere Watch Programme GAW, the European Monitoring and Evaluation Programme EMEP, as well as total column satellite data from the MOPITT, SCIAMACHY and GOME-2 sensors) that are used for comparison. In particular, we study the model’s ability to reproduce the seasonality and absolute values of CO and NO2 in the troposphere as well as O3 and CO at the surface. The impact of changes in model version, data assimilation and emission inventories on the model performance is examined and discussed. The paper is structured in the following way: Section 2 contains a description of the model and the validation data sets as well as the applied validation metrics. Section 3 presents the validation results for CO, NO2 and O3. Section 4 provides the discussion and section 5 the conclusions of the paper.

2. Data and Methods

2.1 The MACC model system in the 2009-2012 period

The MACC global products for reactive gases consist of a reanalysis performed for the years 2003-2012 (Inness et al., 2013) and the near-real-time analysis and forecast, largely based on the same assimilation and forecasting system, but targeting different user groups. The MOZART chemical transport model (CTM) is coupled to the
Integrated Forecast System (IFS) of the European Centre for Medium-Range Weather forecast (ECMWF), which together represent the MOZART-IFS model system (Flemming et al., 2009 and Stein et al. 2012). An alternative analysis system has been set up based on the global CTM TM5 (Huijnen et al., 2010). Details of the MOZART version used in the MACC global products can be found in Kinnison et al., 2007 and Stein et al. (2011, 2012). In the simulation, the IFS and the MOZART model run in parallel and exchange several two- and three-dimensional fields every model hour using the OASIS4 coupling software (Valcke and Redler 2006), thereby producing three-dimensional IFS fields for O₃, CO, SO₂, NOₓ, HCHO, sea salt aerosol, desert dust, black carbon, organic matter, and total aerosol. The IFS provides meteorological data to MOZART. Data assimilation and transport of the MACC species takes place in IFS, while the whole chemical reaction system is calculated in MOZART. The MACC_osuite (operational suite) is the global near-real-time MACC model production run for aerosol and reactive gases. Here, we have investigated only the MACC analysis. In contrast to the reanalysis, the MACC_osuite is a near-real-time run, which implies that it is only run once in near-real-time and may thus contain inconsistencies in e.g. the assimilated data. The MACC_osuite was based on the IFS cycle CY36R1 with IFS model resolution of approximately 100 km by 100 km at 60 levels (T159L60) from September 2009 until July 2012. The gas-phase chemistry module in this cycle is based on MOZART-3 (Kinnison et al., 2007). The model has been upgraded, following updates of the ECMWF meteorological model and MACC-specific updates, i.e. in chemical data assimilation and with respect to the chemical model itself. Thus, from July 2012 onwards, the MACC_osuite has run with a change of the meteorological model to a new IFS cycle (version CY37R3), with an IFS model resolution of approximately 80 km at 60 levels (T255L60) and an upgrade of the MOZART version 3.5 (Kinnison et al., 2007; Emmons et al., 2011, Stein et al. 2013). This includes, amongst others, updated velocity fields for the dry deposition of O₃ over ice, as described in Stein et al. (2013). A detailed documentation of system changes can be found at:

http://www.copernicus-atmosphere.eu/oper_info/nrt_info_for_users/

2.1.1 Emission inventories and assimilated data sets

In the MACC_osuite, anthropogenic emissions are based on emissions out of the EU project RETRO merged with updated emissions for East Asia from the REAS.
inventory, (Schultz et al. 2007) in the following referred to as RETRO-REAS. The horizontal resolution is 0.5° in latitude and longitude and it contains a monthly temporal resolution. Biogenic emissions are taken from GEIA, fire emissions are based on a climatology derived from GFEDv2 (van der Werf et al., 2006) until April 2010, when fire emissions change to GFAS fire emissions (Kaiser et al., 2012). Between January 2011 and October 2011 there has been a fire emission reading error in the model, where, instead of adjusting emissions to the appropriate month, the same set of emissions have been read throughout this period.

After the model upgrade to the new cycle version CY37R3, in July 2012, the emission inventories changed from the merged RETRO-REAS and GEIA inventories, used in the previous cycle, to the MACCity anthropogenic and biogenic emissions (Granier et al., 2011) and (climatological) MEGAN-v2 (Guenther et al., 2006) emission inventories. Wintertime anthropogenic CO emissions are scaled up over Europe and North America (see Stein et al., 2014). Near-real-time fire emissions are taken from GFASv1.0 (Kaiser et al. 2012), for both gas-phase and aerosol.

In the MACC_osuite, the initial conditions for some of the chemical species are provided by data assimilation of atmospheric composition observations from satellites (see Benedetti et al., 2009; Inness et al., 2009, 2013; Massart et al., 2014). Table 1 lists the assimilated data products. From September 2009 to June 2012, O$_3$ total columns of the MLS and SBUV-2 instruments are assimilated, as well as OMI and SCIAMACHY total columns (the latter only until March 2012, when the European Space Agency lost contact with the ENVIRONMENTAL SATELLITE ENVIROSAT). CO total columns are assimilated from the IASI sensor and aerosol total optical depth is assimilated from the MODIS instrument. After the model cycle update in July 2012, data assimilation also contains OMI tropospheric columns of NO$_2$ and SO$_2$, as well as CO MOPITT total columns. The CO total columns retrieved by MOPITT and IASI instruments have a relatively similar seasonality, but there is a systematic difference with MOPITT CO being higher over most regions in the northern hemisphere, especially during winter and spring. George et al. (“An examination of the long-term CO records from MOPITT and IASI and comparison of retrieval methodology”, AMTD, 2015 submitted) investigated the differences between MOPITT and IASI, and showed the impact of a priori information on the retrieved measurements.

Table 1 and 2 summarize the data assimilation and setup of the MACC_osuite.
2.2 Validation data and methodology

In this study, mainly the same evaluation data sets have been used as during the MACC near-real-time validation exercise. This implies some discontinuities in the evaluations, e.g. the substitution of SCIAMACHY data with GOME-2 data after the loss of the ENVISAT sensor or an exclusion of MOPITT satellite data after the start of its assimilation into the model. The continuous process of updating and complementation of data sets in databases requires the selection and definition of an evaluation data set at some point. The comparatively small inconsistencies between our data sets are considered to have a negligible impact on the overall evaluation results.

2.2.1 GAW Surface O$_3$ and CO Observations

The Global Atmosphere Watch (GAW) programme of the World Meteorological Organization (WMO) has been established to provide reliable long-term observations of the chemical composition and physical properties of the atmosphere, which are relevant for understanding atmospheric chemistry and climate change (WMO, 2013). GAW tropospheric O$_3$ measurements are performed in a way to be suitable for the detection of long-term regional and global changes. Furthermore, the GAW measurement programme focuses on observations, which are regionally representative and should be free from influence of significant local pollution sources and suited for the validation of global chemistry climate models (WMO 2007). Detailed information on GAW and GAW related O$_3$ and CO measurements can be found in WMO (2010, 2013).

Hourly O$_3$ and CO data have been downloaded from the WMO/GAW World Data Centre for Greenhouse Gases (WDCGG) for the period between 09/2009 and 12/2012 (status of download: 07/2013). Our evaluation includes 29 stations with surface observations for CO and 50 stations with surface observations for O$_3$. Table 3 lists the geographic coordinates and altitudes of the individual stations. Being a long-term data network, the data in the database is provided with a temporal delay of approximately 2 years. As the data in the database becomes sparse towards the end of the validation period, near-real-time observations, as used in the MACC-project for near-real-time validation, presented on the MACC website, have been included to complement the validation data sets. For the detection of long-term trends and year-to-year variability,
the data quality objectives (DQOs) for CO in GAW measurements are set to a maximum uncertainty of ± 2 ppb and to ± 5 ppb for marine boundary layer sites and continental sites that are influenced by regional pollution and to ± 1 ppb for ozone (WMO, 2012, 2013).

For the evaluation with GAW station data, 6-hourly values (0, 6, 12, 18 UTC) of the analysis mode have been extracted from the model and are matched with hourly observational GAW station data. Model mixing ratios at the stations’ location have been linearly interpolated from the model data in the horizontal. In the vertical, modelled gas mixing ratios have been extracted at the model level, which is closest to the GAW stations’ altitude. Validation scores (see section 2.3) have been calculated for each station between the 6-hourly model analysis data and the corresponding observational data for the entire period (09/2009-12/2012) and as monthly averages.

2.2.2 EMEP Surface $O_3$ Observations

The European Monitoring and Evaluation Programme (EMEP) is a scientifically based and policy driven programme under the Convention on Long-Range Transboundary Air Pollution (CLRTAP) for international co-operation to solve transboundary air pollution problems. Measurements of air quality in Europe have been carried out under the EMEP since 1977. A detailed description of the EMEP measurement programme can be found in Tørseth et al. (2012). The surface hourly ozone data between 09/2009 and 12/2012 have been downloaded from the EMEP data web-page (http://www.nilu.no/projects/ccc/emepdata.html). For the validation, only stations meeting the 75% availability threshold per day and per month are taken into account. The precision is close to 1.5 ppb for a 10s measurement. More information about the ozone data quality, calibration and maintenance procedures can be found in Aas et al. (2000).

For comparison with EMEP data, 3-hourly model values (0, 3, 6, 12, 15, 18, 21 UTC) of the analysis mode have been chosen, in order to be able to evaluate day and night time performance of the model separately. Gas mixing ratios have been extracted from the model and are matched with hourly observational surface ozone data at 124 EMEP stations in the same way as for the GAW station data. The EMEP surface ozone values and the interpolated surface modeled values are compared on a monthly
basis for the latitude bands of 30°N – 40°N (southern Europe), 40°N – 50°N (central Europe) and 50°N – 70°N (northern Europe). For the identification of differences in the MACC_ouite performance between day and night time, the MACC_ouite simulations and the EMEP observations for the three latitude bands have been additionally separated into day-time (12:00–15:00 Local Time LT) and night-time (00:00–03:00 LT) intervals.

2.2.3 MOPITT CO total column retrievals

The MOPITT (Measurement Of Pollution In The Troposphere) instrument is mounted on board the NASA EOS Terra satellite and provides CO distributions at the global scale (Deeter et al., 2004). MOPITT has a horizontal resolution of 22 km x 22 km and allows global coverage within 3 days. The data used in this study corresponds to CO total columns from version 5 (V5) of the MOPITT thermal infrared (TIR) product level 3. This product is available via the following web server: [http://www2.acd.ucar.edu/mopitt/products](http://www2.acd.ucar.edu/mopitt/products). Validation of the MOPITT V5 product against in-situ CO observations showed a mean bias of 0.06x10^{18} molecules cm^{-2} (Deeter et al., 2013). Following the recommendation in the users’ guide, [www.acd.ucar.edu/mopitt/v5_users_guide_beta.pdf](http://www.acd.ucar.edu/mopitt/v5_users_guide_beta.pdf), the MOPITT data were averaged by taking into account their relative errors provided by the Observation Quality Index (OQI).

Also, in order for better data quality we used only daytime CO data since retrieval sensitivity is greater for daytime rather than nighttime overpasses. A further description of the V5 data is presented in Deeter et al. (2013) and Worden et al. (2014).

For the validation, the model CO profiles (X) were transformed by applying the MOPITT averaging kernels (A) and the a priori CO profile (X_a) according to the following equation (Rodgers, 2000) to derive the smoothed profiles X* appropriate for comparison with MOPITT data:

\[ X^* = X_a + A(X - X_a) \]

Details on the method of calculation are referred to in Deeter et al. (2004) and Rodgers (2000). The averaging kernels indicate the sensitivity of the MOPITT measurement and retrieval system to the true CO profile, with the remainder of the information set by the a priori profile and retrieval constraints (Emmons, 2009; Deeter
et al., 2010). The model CO total columns used in the comparison with MOPITT observations, have been calculated using the averaging kernel smoothed profiles $X^*$ which have the same vertical resolution and a priori dependence as the MOPITT retrievals. For the evaluation, 8 regions are defined (see Fig. 1): Europe, Alaska, Siberia, North Africa, South Africa, South Asia, East Asia and the United States. The model update in July 2012 includes an integration of MOPITT CO total columns in the model’s data assimilation system. With this, the MOPITT validation data has lost its independency for the rest of the validation period and MOPITT validation data has thus only been used until June 2012 for validation purposes.

### 2.2.4 SCIAMACHY and GOME-2 NO$_2$ Satellite Observations

The SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY (SCIAMACHY; Bovensmann et al., 1999) onboard the ENVISAT and the Global Ozone Monitoring Experiment-2 (GOME-2; Callies et al., 2000) onboard the Meteorological Operational Satellite-A (MetOp-A) comprise UV–VIS and NIR sensors designed to provide global observations of atmospheric trace gases. In this study, the tropospheric NO$_2$ column data set described in Hilboll et al. (2013a) has been used. In short, the measured radiances are analysed using Differential Optical Absorption Spectroscopy (DOAS), (Platt and Stutz, 2008) in the 425–450 nm wavelength window (Richter and Burrows, 2002). The influence of stratospheric NO$_2$ air masses has been accounted for using the algorithm detailed by Hilboll et al. (2013b), using stratospheric NO$_2$ fields from the B3dCTM model (Sinnhuber at al., 2003a; Sinnhuber et al., 2003b; Winkler et al., 2008). Tropospheric air mass factors have been calculated with the radiative transfer model SCIATRAN (Rozanov et al., 2005). Only measurements with FRESCO+ algorithm (Wang et al., 2008) cloud fractions of less than 20% are used.

Tropospheric NO$_2$ vertical column density (VCD) from the MACC_osuite is compared to tropospheric NO$_2$ VCD from GOME-2 and SCIAMACHY. As the European Space Agency lost contact with ENVISAT in April 2012, GOME-2 data is used for model validation from 1 April 2012 onwards, while SCIAMACHY data is used for the remaining time period (September 2009 to March 2012). Satellite observations are gridded to the horizontal model resolution, i.e. 1.875° for IFS cycle CY36R1 (09/2009 - 06/2012) and 1.125° for cycle CY37R3 (07/2012 - 12/2012).
A few processing steps are applied to the MACC_osuite data to account for differences to the satellite data such as observation time. Firstly, model data are vertically integrated to tropospheric NO$_2$ VCDs by applying National Centers for Environmental Prediction (NCEP) reanalysis (Kalnay et al., 1996) climatological tropopause pressure shown in Fig 1 of Santer et al. (2003). Secondly, simulations are interpolated linearly in time to the SCIAMACHY equator crossing time (roughly 10:00 LT). This most likely leads to some minor overestimation of model NO$_2$ VCDs compared to GOME-2 data, as the equator crossing time for GOME-2 is about 9:30 LT. Moreover, only model data for which corresponding satellite observations exist are considered. For the evaluation, the same regions have been used as for MOPITT (Fig.1), except for Siberia and Alaska. In contrast to MOPITT data, no averaging kernel is applied.

Satellite observations of tropospheric NO$_2$ columns have relatively large uncertainties, mainly linked to incomplete stratospheric correction (important over clean regions and at high latitudes in winter and spring) and to uncertainties in air mass factors (mainly over polluted regions) (e.g. Boersma et al., 2004 and Richter et al., 2005). The uncertainty varies with geolocation and time but in first approximation can be separated into an absolute error of 5x10$^{14}$ molec cm$^{-2}$ and a relative error of about 30%, whichever is larger. As some of the contributions to this uncertainty are systematic, averaging over longer time periods does not reduce the errors as much as one would expect for random errors. Over polluted regions, the uncertainty from random noise in the spectra is small in comparison to other error sources, in particular for monthly averages.

2.3 Validation metrics

A comprehensive model evaluation requires the selection of validation metrics that provide complementary aspects of model performance. The following metrics have been used in the evaluation:

**Modified Normalized Mean Bias MNMB**

$$MNMB = \frac{2}{N} \sum \frac{f_i - o_i}{f_i + o_i}$$

(1)

**Root Mean Square Error RMSE**

$$RMSE = \sqrt{\frac{1}{N} \sum (f_i - o_i)^2}$$

(2)
Correlation Coefficient

\[ R = \frac{1}{N} \sum \left( f_i - \bar{f} \right) \left( o_i - \bar{o} \right) \]

\[ \sigma_f \sigma_o \]  

(3)

where: \( N \) is the number of observations, \( f \) are the modelled analysis and \( o \) the observed values, \( \bar{f} \) and \( \bar{o} \) are the mean values of the analysis and observed values and \( \sigma_f \) and \( \sigma_o \) are the corresponding standard deviations.

The validation metrics above have been chosen to provide complementary aspects of model performance. The modified normalized mean bias is a normalization based on the mean of the observed and forecast value (e.g. Elguindi et al. 2010). It ranges between -2 and 2 and is very useful to check whether there is a negative or positive deviation between model and observations. When multiplied by 100%, it can be interpreted as a percentage bias. The advantage of the MNMB is that it varies symmetrically with respect to under- and overestimation and is robust with respect to outliers. However, when calculated over longer time periods, a balance in model error, with model over- and underestimation compensating each other, can lead to a small MNMB for the overall period. For this reason, it is important to additionally consider an absolute measure, such as the RMSE. However, it has to be noted that the RMSE is strongly influenced by larger values and outliers, due to squaring. The correlation coefficient \( R \) can vary between 1 (perfect correlation) and -1 (negative correlation) and is an important measure to check the linearity between model and observations.

### 3. Results

#### 3.1 Evaluation of Ozone

The evaluation of the MACC_osuite run with \( O_3 \) from GAW surface observations (described in section 2.2.1) demonstrates good agreement in absolute values and seasonality for most regions. Figure 2 shows maps with Modified Normalized Mean Bias (MNMB, see section 2.3) evaluations for 50 GAW stations globally (top) and in Europe (below). Figure 3 presents selected time series plots representing the results for high latitudes, low latitudes and Europe. Large negative MNMBs over the whole period 09/2009 to 12/2012 (-30 to -82%) are observed for stations located in Antarctica (Neumayer-NEU, South Pole-SPO, Syowa-SYO and Concordia- CON) whereby \( O_3 \) surface mixing ratios are strongly underestimated by the model. For
stations located in high latitudes in the northern hemisphere (Barrow-BAR, Alaska and Summit-SUM, Denmark), the MACC_osuite exhibits similar underestimated values of up to -35% for the whole evaluation period. The time series plots for Arctic and Antarctic stations (e.g. Summit-SUM, Neumayer-NEU and South Pole-SPO) in Fig. 3 show that an underestimation visible in these regions has been remedied and model performance improved with an updated dry deposition parameterization over ice, which has been introduced with the new model cycle in July 2012 (see section 2.1).

Large positive MNMBs (up to 50 to 70%, Fig. 2) are observed for stations that are located in or nearby cities and thus exposed to regional sources of contamination (Iskrba-ISK Slovenia, Tsukuba- TSU, Japan, Cairo-CAI, Egypt). In tropical and subtropical regions, O₃ surface mixing ratios are systematically overestimated (by about 20% on average) during the evaluation period. The time series plots for tropical and subtropical stations (e.g. for Ragged Point-RAG, Barbados and Cape Verde Observatory, Cape Verde –CVO, Fig. 3) reveal a slight systematic positive offset throughout the year, however with high correlation coefficients (0.6 on average). For GAW stations in Europe, the evaluation of the MACC_osuite for the whole period shows MNMBs between -80 and 67%. Large biases appear only for 2 GAW stations located in Europe: Rigi- RIG, Switzerland (-80%), located near mountainous terrain and Iskrba- ISK, Slovenia (67%). For the rest of the stations MNMBs lie between 22 and -30%. Root Mean Square Errors (RMSEs, see section 2.3) range between 7 and 35 ppb (15 ppb on average). Again, results for Iskrba-ISK and Rigi-RIG show the largest errors. All other stations show RMSEs between 7 and 20 ppb.

Correlation coefficients here range between 0.1 and 0.7 (with 0.5 on average). Table 4 summarizes the results for all stations individually.

Monthly MNMBs (see Fig. 4) show a seasonally varying bias, with positive MNMBs occurring during the northern summer months (with global average ranging between 5 and 29% during the months June and October), and negative MNMBs during the northern winter months (between -2 and -33% during the months December to March). These deviations partly cancel each other out in MNMB for the whole evaluation period. For the RMSEs, maximum values also occur during the northern summer months with global average ranging between 11 and 16 ppb for June to September. The smallest errors appear during the northern hemisphere winter.
months (global average falling between 8 and 10 ppb for December and January). The correlation does not show a distinct seasonal behaviour (see Fig. 6).

The time series plots in Fig. 3 show that the seasonal cycle of $O_3$ mixing ratios with maximum concentrations during the summer months and minimum values occurring during winter times for European stations (e.g. Monte Cimone-MCI, Italy, Kosetice-KOS, Czech Republic, and Kovk- KOV, Slovenia), could well be reproduced by the model, although there is some overestimation in summer resulting mostly from observed minimum concentrations that are not captured correctly by the MACC_osuite, (Kosetice-KOS, Czech Republic, and Kovk-KOV, Slovenia).

The validation with EMEP surface ozone observations (described in section 2.2.2) in three different regions in Europe for the period 09/2009 to 12/2012 likewise confirms the behaviour of the model to overestimate $O_3$ mixing ratios during the warm period and underestimate $O_3$ concentrations during the cold period of the year (see Fig. 7). The positive bias (May-November) is between -9 and 56% for northern Europe and Central Europe and between 8% and 48% for Southern Europe. Negative MNMBs appear, in accordance with GAW validation results, during the winter-spring period (December-April) ranging between -48 and -7% for EMEP stations in northern Europe (exception: December 2012 with 25%), between -1 and -39% in central Europe (exception: December 2012 with 31%), whereas in southern Europe, deviations are smaller and remain mostly positive (between -8 and 9%) in winter (exception: December 2012 with 37%). The different behaviour for December 2012 likely results from the limited availability of observations towards the end of the validation period. The separate evaluation of day and night-time $O_3$ mixing ratios (Fig. 8) shows that for northern Europe larger biases appear during night time. For central Europe and southern Europe night-time biases are larger during cold periods (December-April), whereas during warm periods (May-November) larger biases appear during day time.

### 3.2 Evaluation of Carbon Monoxide

The evaluation of the MACC_osuite with surface observations of 29 GAW stations (described in section 2.2.1) shows that over the whole period September 2009 to December 2012, CO mixing ratios could be reproduced with an average MNMB of -10%. The MNMBs for all stations range between -50 and +30%. Results are listed in...
Table 5, a selection of time series plots shows the results for stations in Europe, Asia and Canada in Fig. 9. MNMBs exceeding ± 30% appear for stations that are either located in or nearby cities and thus exposed to regional sources of contamination (Kosetice- KOS, Czech Republic) or are located in or near complex mountainous terrain (Rigi-RIG, Switzerland, BEO Moussala- BEO, Bulgaria) which is not resolved by the topography of the global model. RMSEs fall between 12 and 143 ppb (on average 48 ppb) for all stations during the validation period, but for only four stations (Rigi-RIG, Kosetice- KOS, Payerne-PAY, Switzerland and BEO Moussala-BEO, all located in Europe) do the RMSEs exceed 70 ppb. Correlation coefficients from the comparison with GAW station data calculated over the whole time period range between 0 and 0.8 (on average 0.4), with only four stations showing values smaller than 0.2 (Rigi-RIG, Moussala-BEO, East Trout Lake-ETL and Lac la Biche-LAC (the latter two located in Canada).

Considering the monthly MNMBs and RMSEs, it can be seen that during the northern hemisphere summer months, June to September, both are small (absolute differences less than 5%), see Fig. 10 and Fig. 11. Negative MNMBs (up to -35%) and larger RMSEs (up to 72 ppb) appear during the northern hemisphere winter months, November to March, when anthropogenic emissions are at a highest, especially for the US, northern latitudes and Europe. Monthly correlation coefficients are between 0.1 and 0.5 and do not show a distinct seasonal behaviour (see Fig. 12). The generally only moderate correlation coefficient is related to mismatches in the strong short-term variability seen in both the model and the measurements.

The time series plots for stations in Europe, Asia and Canada in Fig. 9 demonstrate that the annual CO cycle could to a large degree be reproduced correctly by the model with maximum values occurring during the winter period and minimum values appearing during the summer season. However, the model shows a negative offset during the winter period. Seasonal air mass transport patterns that lead to regular annual re-occurring CO variations could be reproduced for GAW stations in East Asia: The time series plots for Yonagunijima- YON and Minamitorishima- MNM station, Japan (Fig. 9) show that the drop of CO, associated with the air mass change from continental to cleaner marine air masses after the onset of the monsoon season during the early summer months, is captured by the MACC_osuite. Deterioration in
all scores is visible during December 2010 in the time series plots of several stations (e.g. Jungfraujoch-JFJ, and Sonnblick-SBL, Fig. 9). This is likely a result of changes in the processing of the L2 IASI data and a temporary blacklisting of IASI data (to avoid model failure) in the assimilation.

The comparison with MOPITT satellite CO total columns between October 2009 and June 2012 (described in section 2.2.3) shows a good qualitative agreement of spatial patterns and seasonality, see Table 6. The MNMBs for 8 regions are listed in Fig. 13 and range between 14% and -22%. The seasonality of the satellite observations is captured well by the MACC_osuite over Asia and Africa, with MNMBs between -6% and 9% (North Africa), -12% and 8% (South Africa), -11% and 12% (East Asia), and -3% and 14% (South Asia). The largest negative MNMBs appear during the winter periods, especially from December 2010 to May 2011 and from September 2011 to April 2012, for Alaska and Siberia and for the US and Europe (MNMBs up to -22%), which coincides with large differences between MOPITT and IASI satellite data (see Fig. 14). On the global scale the average difference between the IASI and MOPITT total columns is less than 10% (George et al., 2009), and there is a close agreement of MOPITT and IASI for S. Asia and Africa (see Fig. 14). However, larger differences between MOPITT and IASI data appear during the northern winter months over Alaska, Siberia, Europe and the US, which result in lower CO concentrations in the model, due to the assimilation of IASI CO data in the MACC_osuite. The differences between MOPITT and IASI data can be mainly explained by the use of different a priori assumptions in the IASI and MOPITT retrieval algorithms (George et al., 2015). Indeed, the Fast Optimal Retrievals on Layers for IASI (FORLI) software (IASI) is using a single a priori CO profile (with an associated variance-covariance matrix) whereas the MOPITT retrieval algorithm is using a variable a priori, depending on time and location. George et al., 2015 (submitted) show that differences above Europe and the US in January and December (for a 5 year study) decrease by a factor of 2 when comparing IASI with a modified MOPITT product using the IASI single a priori. Between January 2011 and October 2011 there has also been a reading error in the fire emissions that contributes to larger MNMBs during this period (see section 2.1.1).
3.3 Evaluation of Tropospheric Nitrogen Dioxide

Figure 15 shows global maps of daily tropospheric NO$_2$ VCD averaged from September 2009 to March 2012. Overall, spatial distribution and magnitude of tropospheric NO$_2$ observed by SCIAMACHY are well reproduced by the model. This indicates that emission patterns and NO$_x$ photochemistry are reasonably well represented by the model. However, the model underestimates tropospheric NO$_2$ VCDs over industrial areas in Europe, East China, Russia, and South East Africa compared to satellite data. This could imply that anthropogenic emissions from RETRO-REAS are underestimated in these regions, or that the lifetime in the model is too short. The model simulates larger NO$_2$ VCD maxima over Central Africa, which mainly originate from wild fires. It remains unclear if GFEDv2/GFAS fire emissions are too high here or if NO$_2$ fire plumes closer to the ground cannot be seen by the satellites due to light scattering by biomass burning aerosols (Leitao et al., 2010). In the northern hemisphere, background values of NO$_2$ VCD over the ocean are lower in the simulations than in the satellite data. The same is true for the South Atlantic Ocean to the west of Africa (see Fig. 15). This might suggest a model underestimation of NO$_2$ export from continental sources or too rapid conversion of NO$_2$ into its reservoirs. However, as the NO$_2$ columns over the oceans are close to the uncertainties in the satellite data, care needs to be taken when interpreting these differences.

Time series of daily tropospheric NO$_2$ VCD averaged over different regions and corresponding monthly means are presented in Figs. 16 and 17, respectively. Time series of the MNMB and RMSE are shown in Figs. 18 and 19, respectively. Table 7 summarizes the statistical values derived over the whole time period. High anthropogenic emissions occur over the United States, Europe, South Asia and East Asia compared to other regions on the globe (e.g., Richter et al., 2005). In principle, the MACC_osuite catches the pattern of satellite NO$_2$ VCD over these regions.

However, the model tends to underestimate NO$_2$ VCDs throughout the whole time period investigated here. The negative bias is most pronounced over East Asia with a modelled mean NO$_2$ VCD for September 2009 to December 2012 of about 3.8 x 10$^{15}$ molec cm$^{-2}$ lower than that derived from satellite measurements (see Table 7). Considering monthly values, the MACC_osuite strongly underestimates magnitude and seasonal variation of satellite NO$_2$ VCD over East Asia (MNMBs between about -
40% and -110% and RMSE between 1 x 10^{15} \text{ molec cm}^{-2} and 14 x 10^{15} \text{ molec cm}^{-2}
throughout the whole time period). A change in the modelled NO\textsubscript{2} values is apparent
in July 2012 when the emission inventories changed and the agreement with the
satellite data improved for South and East Asia but deteriorated for the US and
Europe. This results in a drop of MNMBs (Fig. 18) for Europe and the US with values
approaching around -70% by the end of 2012. Nevertheless, correlations between
daily satellite and model data derived for the whole time period (see Table 7) are high
for East Asia (0.8), South Asia (0.8), Europe (0.8), and lower, but still rather high, for
the US (0.6).

The North African and South African regions are strongly affected by biomass
burning (Schreier et al., 2013). Magnitude and seasonality of daily and monthly
tropospheric NO\textsubscript{2} VCDs (Figs. 16 and 17, respectively) are rather well represented by
the model, apart from January 2011 to October 2011, due to difficulties in reading fire
emissions for this time period (see section 2.1.1). The latter results in large absolute
values of the MNMB (Fig. 18) and large RMSEs (Fig. 19) between January 2011 and
October 2011 compared to the rest of the time period. As for other regions
investigated in this section, mean values of simulated daily tropospheric NO\textsubscript{2} VCDs
over North Africa and South Africa between September 2009 and December 2012
tend to be lower than the corresponding satellite mean values (see Table 7). The
correlation between daily model and satellite data over the whole time period is about
0.6 for South Africa and 0.5 for North Africa. It should be investigated in future
studies if this difference in model performance for the African regions is due to
meteorology, chemistry or emissions.

4. Discussion

The validation of global \textit{O}_3 mixing ratios with GAW observations at the surface
levels showed that the MACC\_suite could generally reproduce the observed annual
cycle of ozone mixing ratios. Model validation with surface data shows global
average monthly MNMBs between -30% and 30% (GAW) and for Europe between -
50% and 60% (EMEP). The bias between measured \textit{O}_3 surface mixing ratios and the
MACC\_suite is seasonally dependent, with an underestimation of the observed \textit{O}_3
mixing ratios during the northern winter season and an overestimation during the
summer months.
The validation of day-time versus night-time concentrations for Northern and Central Europe shows larger negative MNMBs in the winter months during night time than day time (Fig. 8), so that the negative bias in winter could be attributed to the simulation of vertical mixing at night, also described by Ordoñez (2010) and Schaap (2008), which remains a challenge in the model. The systematic underestimation of O₃ mixing ratios throughout the year for high latitude northern regions and Antarctica has its origin in an overestimation of the O₃ dry deposition velocities over ice. With the implementation of the new model cycle and MOZART model version, which includes updated velocity fields for the dry deposition of O₃, as described in Stein et al. (2013), the negative offset in the MACC_osuite model has been remedied for high latitude regions from July 2012 onwards (see the time series plots for the South Pole station- SPO and Neumayer- NEU in Fig. 3). The overestimation of O₃ mixing ratios for the northern hemisphere summer months is a well-known issue and has been described by various model validation studies (e.g., Brunner et al., 2003, Schaap et al., 2008, Ordoñez et al., 2010, Val Martin et al., 2014). Inadequate ozone precursor concentrations and aerosol induced radiative effects (photolysis) have been frequently identified as being the main factors. The time series plots in Fig. 3, however, demonstrate that the minimum concentrations in particular are not captured by the model during summer. Possible explanations include a general underestimation of NO titration which especially applies to stations with urban surroundings and strong sub-grid scale emissions (e.g. Tsukuba-TSU Fig. 3), including difficulties by the global model to resolve NO titration in urban plumes. It also seems likely that dry deposition at wet surfaces in combination with the large surface sink gradient due to nocturnal stability cannot be resolved with the model’s vertical resolution. In regions such as Central and Southern Europe (Fig. 8) where day time biases exceed night time biases, the overestimation of O₃ might be related to an underestimation of day-time dry deposition velocities: Val Martin et al., (2014) describe a reduction of the summertime O₃ model bias for surface ozone after the implementation of adjustments in stomatal resistances in the MOZART model’s dry deposition parameterization. The MACC_osuite model realistically reproduces CO total columns over most of the evaluated regions with monthly MNMBs falling between 10% and -20% (Table 6). There is a close agreement of modelled CO total columns and satellite observations for Africa and South Asia throughout the evaluation period. However, there is a negative offset compared to the observational CO data over Europe and North ...
America, The largest deviations occur during the winter season when the observed CO concentrations are at a highest. The evaluation with GAW surface CO data accordingly shows a wintertime negative bias of up to -35% at the surface for stations in Europe and the US. A general underestimation of CO from global models in the northern hemisphere has been described by various authors (e.g., Shindell et al., 2006, Naik et al., 2013). According to Stein et al. (2014) this underestimation likely results from a combination of errors in the dry deposition parameterization and certain limitations in the current emission inventories. The latter include too low anthropogenic CO emissions from traffic or other combustion processes and missing anthropogenic VOC emissions in the inventories together with an insufficiently established seasonality in the emissions. An additional reason for the apparent underestimation of emissions in MACCity may be an exaggerated downward trend in the RCP8.5 (Representative Concentration Pathways) scenario in North America and Europe between 2000 and 2010, as this scenario was used to extrapolate the MACCity emissions from their benchmark year, i.e. 2000. For CO, uncertainties in the evaluation also include the retrieved amount of CO total columns between IASI and MOPITT. These vary with region, with IASI showing lower CO concentrations in several regions (Alaska, Siberia, Europe and the US) during the northern winter months, which possibly contribute to the deviations observed between the modelled data and MOPITT satellite data, as only IASI data has been assimilated in the model. The differences can primarily be explained by the use of different a priori assumptions in the IASI and MOPITT retrieval algorithms (George et al., 2015 submitted). On a global scale however, the average difference between the IASI and MOPITT total columns is less than 10% (George et al., 2009). From July 2012 onwards, MOPITT CO total columns are also assimilated in the MACC_0suite.

Modelled NO₂ total columns agree well with satellite observations over the United States, South Asia and North Africa. However, there is also a negative offset for NO₂ over Europe and East Asia. Again, the largest deviations are occurring during the winter season. The quality of the emission inventory is even more crucial for short lived reactive species such as NO₂, where model results depend to a large extent on emission inventories incorporated in the simulations. This is highlighted by the deterioration of agreement between model results and satellite data for the US in July 2012 when anthropogenic emissions were changed from RETRO-REAS to MACCity.
This change led to an increasing negative bias in NO$_2$ over Europe and North America and to an improvement for South and East Asia (see Fig. 18). A deterioration in MNMBs associated with the fire emissions is visible between January 2011 and October 2011 over regions with heavy fire activity (Africa and East Asia), and goes back to a temporary error in the model regarding the reading of fire emissions (see Figs. 17 and 18). Particular challenges for an operational forecast system are regions with rapid changes in emissions such as China, where inventories need to be extrapolated to obtain reasonable trends. A large underestimation of NO$_2$ in China especially in winter has been reported for other CTMs in previous publications (He et al., 2007, Itahashi et al., 2014). The latter has been linked to an underestimation of NO$_x$ and VOC emissions, unresolved seasonality in the emissions and expected non-linearity of NO$_x$ chemistry. The change in validation data sets from SCIAMACHY to GOME-2 has shown to have negligible impact on the validation results and conclusions.

5. Conclusion

The MACC_osuite model realistically reproduces CO and NO$_2$ total columns over most of the evaluated regions with monthly MNMBs falling between 10% and 20% (CO) and between 40% and 110% for NO$_2$. There is a close agreement of modelled CO total columns and satellite observations for Africa and South Asia throughout the evaluation period. NO$_2$ total columns agree well with satellite observations over the United States, South Asia and between January 2011 and October 2011.

The validation of NO$_2$ total columns agree well with satellite observations over the United States, South Asia and between January 2011 and October 2011. This change led to an increasing negative bias in NO$_2$ over Europe and North America and to an improvement for South and East Asia (see Fig. 18). A deterioration in MNMBs associated with the fire emissions is visible between January 2011 and October 2011 over regions with heavy fire activity (Africa and East Asia), and goes back to a temporary error in the model regarding the reading of fire emissions (see Figs. 17 and 18). Particular challenges for an operational forecast system are regions with rapid changes in emissions such as China, where inventories need to be extrapolated to obtain reasonable trends. A large underestimation of NO$_2$ in China especially in winter has been reported for other CTMs in previous publications (He et al., 2007, Itahashi et al., 2014). The latter has been linked to an underestimation of NO$_x$ and VOC emissions, unresolved seasonality in the emissions and expected non-linearity of NO$_x$ chemistry. The change in validation data sets from SCIAMACHY to GOME-2 has shown to have negligible impact on the validation results and conclusions.

5. Conclusion

The MACC_osuite model realistically reproduces CO and NO$_2$ total columns over most of the evaluated regions with monthly MNMBs falling between 10% and 20% (CO) and between 40% and 110% for NO$_2$. There is a close agreement of modelled CO total columns and satellite observations for Africa and South Asia throughout the evaluation period. NO$_2$ total columns agree well with satellite observations over the United States, South Asia and...
assimilated satellite data and fire emissions showed only a temporary impact on the quality of model results.

The MACC NRT system is constantly evolving. A promising step in model development is the on-line integration of modules for atmospheric chemistry in the IFS, currently being tested for implementation in the MACC_osuite. In contrast to the coupled model configuration as used in this paper, the on-line integration in the Composition IFS (C-IFS) provides major advantages; apart from an enhanced computational efficiency, C-IFS promises an optimization of the implementation of feedback processes between gas-phase/aerosol chemical processes and atmospheric composition and meteorology, which is expected to improve the modelling results for reactive gases. Additionally, C-IFS will be available in combination with different CTMs, (MOZART and TM5), which will help to explain whether deviations between model and observations go back to deficiencies in the chemistry scheme of a model.

Acknowledgements

This work has been carried out in the framework of the MACC projects, funded under the EU Seventh Research Framework Programme for research and technological development. The authors thank the MACC validation and reactive gas subproject teams for the fruitful discussions. Model simulations were carried out using the ECMWF supercomputer. We wish to acknowledge the provision of GAW hourly station data from the World Data Centre of Greenhouse Gases (WDCGG) and hourly EMEP station data from the NILU database. Specifically, we like to thank: the CSIRO Oceans and Atmosphere Flagship for making the data freely available and the Australian Bureau of Meteorology for continued operation and support of the Cape Grim station. We also like to thank Izaña Atmospheric Research Center (AEMET) for providing CO and O₃ data. Special thanks to the providers of NRT data to the MACC project, namely: Institute of Atmospheric Sciences and Climate (ISAC) of the Italian National Research Council (CNR), South African Weather Service, The University of York and National Centre for Atmospheric Science (NCAS (AMF)) (UK), and the Instituto Nacional de Meteorología e Geofísica (INMG) (Cape Verde), National Air Pollution Monitoring Network (NABEL) (Federal Office for the Environment FOEN and Swiss Federal Laboratories for Materials Testing and Research EMPA), Japan Meteorological Agency (JMA), Alfred Wegener Institute, Umweltbundesamt (Austria), National Meteorological Service (Argentina), Umweltbundesamt (UBA,
We thank the National Center for Atmospheric Research (NCAR) MOPITT science team and the NASA Langley Research Center, Atmospheric Science Data Center (ASDC), for producing and archiving the MOPITT CO product. IASI has been developed and built under the responsibility of the Centre National D’Etudes Spatiales (CNES, France). We are grateful to Juliette Hadji-Lazaro and the UBL/ LATMOS IASI team for establishing the IASI-MACC near real time processing chain. We wish to acknowledge that SCIAMACHY lv1 (level 1) radiances were provided to the Institute of Environmental Physics, University of Bremen by ESA through DLR/DFD.

Figure 1: Regions used for regional data stratification in the troposphere for the comparison with satellite data. The following regions are defined: 1 Europe (15W–35E, 35N–70N), 2 Alaska (150W–105W, 55N–70N), 3 Siberia (100E–140E, 40N–65N), 4 North Africa (15W–45E, 0N–20N), 5 South Africa (15E–45E, 20S–0S), 6 South Asia (50E–95E, 5N–35N), 7 East Asia (100E–142E, 20N–45N), 8 United States (120W–65W, 30N–45N).
Figure 2: Modified normalized mean biases (MNMBs) [%] derived from the evaluation of the MACC osuite with GAW O₃ surface observations during the period 09/2009 to 12/2012 globally (top), and for Europe (below). Blue colours represent large negative values; red/brown colours represent large positive values.
Figure 3: Time series plots of the MACC_osuite 6-hourly O₃ mixing ratios (red) and GAW surface observations (black) for South Pole-SPO (Antarctica), Neumayer-NEU (Antarctica), Summit-SUM (Denmark), Tsukuba-TSU (Japan), Ragged Point-RAG, (Barbados), Cape Verde Observatory-CVO (Cape Verde), Monte Cimone-MCI (Italy), Kosetice-KOS (Czech Republic), Kovk- KOV(Slovenia) during the period 09/2009 to 12/2012. Unit: ppb
Figure 4: Modified normalized mean bias (MNMB) in % derived from the evaluation of the MACC osuite with GAW O₃ surface observations during the period September 2009 to December 2012 (black line: global average of 50 GAW stations. Multi-coloured lines: individual station results, see legend to the right).
Figure 5: Root mean square error (RMSE) in ppb derived from the evaluation of the MACC_osuite with GAW O$_3$ surface observations during the period September 2009 to December 2012 (black line: global average of 50 GAW stations. Multi-coloured lines: individual station results, see legend to the right).
Figure 6: Correlation coefficient (R), derived from the evaluation of the MACC_oses suite with GAW O₃ surface observations during the period September 2009 to December 2012 (black line: global average of 50 GAW stations. Multi-coloured lines: individual station results, see legend to the right).
Figure 7: Modified normalized mean biases (MNMBs) derived from the evaluation of the MACC_osuite with EMEP O\textsubscript{3} surface observations in three different parts in Europe (blue: Northern Europe, orange: Central Europe, red: Southern Europe) during the period September 2009 to December 2012.
Figure 8: Modified normalized mean biases (MNMBs) derived from the evaluation of the MACC_osuite with EMEP O₃ surface observations during day-time (yellow color), and night-time (blue color) over northern Europe (a), central Europe (b) and southern Europe (c) during the period September 2009 to December 2012.
Figure 9: Time series plots of the MACC_ouesite 6-hourly CO mixing ratios (red) and GAW surface observations (black) for Jungfraujoch- JFJ (Switzerland), Sonnblick- SBL (Austria), Izana Observatory- IZO (Tenerife), Minamitorishima- MNM (Japan), Yonagunijima- YON (Japan), Estevan Point- EVP (Canada) during the period 09/2009 to 12/2012. Unit: ppb.
Figure 10: Modified normalized mean bias (MNMB) in % derived from the evaluation of the MACC_osuite with GAW CO surface observations over the period September 2009 to December 2012 (black line: global average of 29 GAW stations, Multi-coloured lines: individual station results, see legend to the right).
Figure 11: Root mean square error (RMSE) in ppb derived from the evaluation of the MACC osuite with GAW CO surface observations over the period September 2009 to December 2012 (black line: global average of 29 GAW stations multi-coloured lines: individual station results, see legend to the right).
Figure 1: Correlation coefficient (R), derived from the evaluation of the MACC_osuite with GAW CO surface observations over the period September 2009 to December 2012 (black line: global average of 29 GAW stations. Multi-coloured lines: individual station results, see legend to the right).

Figure 2b: Root mean square error (RMSE) in ppb derived from the evaluation of the MACC_osuite with GAW CO surface observations over the period September 2009 to December 2012 (black line: global average of 29 GAW stations multi-coloured lines: individual station results, see legend to the right).
Figure 13: Monthly average of modified normalized mean biases (MNMBs) derived from the comparison of the MACC_osuite with MOPITT CO total columns for 8 different regions during the period 09/2009 to 06/2012 (see legend on the right).
Figure 14: Time series plots of MOPITT CO total columns (black line) compared to IASI CO total columns (black dashed line) and the MACC_osuite CO total columns (red line) for 8 different regions (defined in Figure 1) during the period 09/2009 to 06/2012. Top: Siberia (left), Alaska (right), second row: United States (left), Europe (right), third row: South Asia (left), East Asia (right) bottom: South Africa (left), North Africa (right).
Figure 15: Long-term average of daily tropospheric NO$_2$ VCD \(10^{15} \text{molec cm}^{-2}\) from September 2009 to March 2012 for (left) MACC_osuite simulations and (right) SCIAMACHY satellite observations. Blue colours represent low values; red/brown colours represent high values.
Figure 16: Time series of daily tropospheric NO$_2$ VCD [$10^{15}$ molec cm$^{-2}$] averaged over different regions. Top: United States (left), Europe (right), second row: South Asia (left), East Asia (right), bottom: South Africa (left), North Africa (right). Black lines show satellite observations (SCIAMACHY up to 03/2012, GOME-2 from 04/2012 to 12/2012), red lines correspond to the MACC_osuite simulations.
Figure 17: As in Fig. 16 but for monthly means of daily tropospheric NO₂ VCD \(10^{15} \text{ molec cm}^{-2}\) averaged over different regions. Top: United States (left), Europe (right), second row: South Asia (left), East Asia (right), bottom: South Africa (left), North Africa (right).
Figure 18: Modified normalized mean bias [%] for monthly means of daily tropospheric NO$_2$ VCD averaged over different regions (see Fig. 1 for latitudinal and longitudinal boundaries) derived from the MACC_osuite simulations and satellite observations (SCIAMACHY up to 03/2012, GOME-2 from 04/2012 to 12/2012). Top: United States (left), Europe (right), second row: South Asia (left), East Asia (right), bottom: South Africa (left), North Africa (right). Values have been calculated separately for each month.
Figure 19: As in Fig. 18 but for the root mean square error \([10^{15} \text{ molec cm}^{-2}]\).
