Abstract

We interpret a suite of satellite, aircraft, and ground-based measurements over the North Pacific Ocean and western North America during April–May 2006 as part of the Intercontinental Chemical Transport Experiment Phase B (INTEX-B) campaign to understand the implications of long-range transport of East Asian emissions to North America. The Canadian component of INTEX-B included 33 vertical profiles from a Cessna 207 aircraft equipped with an aerosol mass spectrometer. Long-range transport of organic aerosols was insignificant. Measured sulfate plumes in the free troposphere over British Columbia exceeded 1 µg/m³. We update the global anthropogenic emission inventory in a chemical transport model (GEOS-Chem) and use it to interpret the observations. Trends in Aerosol Optical Depth (AOD) retrieved from two satellite instruments (MISR and MODIS) for 2000–2006 are analyzed with GEOS-Chem to estimate an annual growth in Chinese sulfur emissions of 6.2% and 9.6%, respectively. Analysis of aircraft sulfate measurements from the NASA DC-8 over the central Pacific, the NSF C-130 over the east Pacific and the Cessna over British Columbia indicates most Asian sulfate over the ocean is in the lower free troposphere (800–600 hPa), with a decrease in pressure toward land due to orographic effects. We calculate that 63% of the measured sulfate at 600 hPa over British Columbia is due to East Asian sources. Simulation of INTEX-B and May 1985 aircraft measurements off the northwest coast of the United States reveals a 2.4–3.4 fold increase in the relative contribution of East Asian sulfate to the total burden. Campaign-average simulations indicate anthropogenic East Asian sulfur emissions increase mean springtime sulfate in Western Canada at the surface by 0.14–0.19 µg/m³ (~30%) and account for 40% of the overall regional sulfate burden between 1 and 5 km. Mean measured daily surface sulfate concentrations taken in the Vancouver area increase by 0.27 µg/m³ per 10% increase in the simulated fraction of Asian sulfate, suggesting current East Asian emissions degrade local air quality.
1 Introduction

The transport of Asian emissions to North America has been well documented (e.g. Parrish et al., 1992; Jaffe et al., 1999; Bertschi et al., 2004; Liang et al., 2004; Park et al., 2004). Andreae et al. (1988) measured sulfate (SO$_4^{2-}$) concentrations off the northwest coast of the United States in May 1985, and attributed enhancements in the free troposphere to Asian sources. Asian emissions of sulfur oxides (SO$_x$≡SO$_2$+SO$_4^{2-}$) are dominated by SO$_2$ and have grown substantially over the last two decades (Streets and Waldhoff, 2000). They increasingly impact North America, affecting both regional air quality (Park et al., 2004; Heald et al., 2006) and climate (Ming et al., 2007). Additional analysis of in-situ and remote-sensed observations are needed to quantify this long-range transport and its implications.

Sirois and Barrie (1999) analyzed aerosol composition between 1980 and 1995 to infer the presence of Eurasian SO$_4^{2-}$ in the Canadian Arctic between those dates. During the Polar Sunrise Experiment in 1992 at Alert, Canada, concentrations of SO$_x$ were well correlated with long-range transport of fine anthropogenic aerosol (Barrie et al., 1994). Asian pesticides have been observed in the Yukon Territory, Canada, as a result of transpacific flow (Bailey et al., 2000). The influence of long-range transport to Canada is not limited to remote regions, and is especially relevant in populated areas. Asian pesticides have also been transported to the Fraser Valley, British Columbia (Harner et al., 2005). Dust transport to western Canada has been observed from as far as the Sahara Desert (McKendry et al., 2007) and Asian fine dust provides an estimated median 1.2 µg/m$^3$ in surface air over the western United States in spring (Fairlie et al., 2007). Chinese dust has also been observed in British Columbia’s Lower Fraser Valley (McKendry et al., 2001) and can be linked to SO$_4^{2-}$ transport through the uptake of sulfur dioxide (SO$_2$) on dust (Jordan et al., 2003; Song et al., 2007).

Satellite observations offer a top-down constraint on emissions. Previous work includes absolute emissions of nitrogen oxides (Leue et al., 2001; Martin et al., 2003a; Jaeglé et al., 2005; Müller and Stavrakou, 2005), volatile organic compounds (Palmer
et al., 2003; Fu et al., 2007), and carbon monoxide (Arellano et al., 2004; Heald et al., 2004; Pétron et al., 2004), as well as trends in nitrogen oxide (Richter et al., 2005; van der A et al., 2006; Zhang et al., 2007) emissions. The clearest signals in current SO$_2$ retrievals are of volcanic activity (Khokar et al., 2005), although anthropogenic activity has also been detected (Eisinger and Burrows, 1998; Krotkov et al., 2006; Carn et al., 2007). In some regions satellite-retrieved Aerosol Optical Depth (AOD) is closely related to SO$_2$ emissions through production of SO$_4^{2-}$ (Massie et al., 2004; Dubovik et al., 2007).

Although direct emission of Asian aerosol may be readily scavenged near its source due to wet deposition, SO$_2$ emissions can still escape to the free troposphere prior to SO$_4^{2-}$ conversion and then transported across the Pacific Ocean (Brock et al., 2004). Elevated aerosol concentrations, attributed to East Asian combustion sources, have been observed reaching North America near the Canadian border at Cheeka Peak (Jaffe et al., 1999).

Springtime weather patterns generally produce the strongest seasonal outflow from Asia (Jacob et al., 2003; Liu et al., 2005), and therefore a pronounced influence of Asian emissions upon the North American continent. During April and May 2006, the Intercontinental Chemical Transport Experiment, Phase B (INTEX-B) set out to assess this influence using a combination of aircraft and satellite measurements throughout the northeastern pacific (Singh et al. 1).

In this paper we investigate the long-range transport of East Asian SO$_4^{2-}$ to Canada. Section 2 presents the aircraft component of the Canadian contribution to INTEX-B and outlines the other instruments, platforms and the model used in this study. In

---

Sect. 3, we estimate the recent growth in East Asian SO\textsubscript{x} emissions based upon remote sensing measurements. Section 4 combines data from a chemical transport model with in-situ measurements to characterize the Asian sulfur transport to Canada. A case study of an Asian plume is presented in Sect. 5, along with the implications for Canadian air quality. Conclusions are in Sect. 6.

2 INTEX-B platforms

Here we introduce the aircraft, surface and satellite measurements, and the model used for interpretation.

2.1 In-situ measurements

Figure 1 provides an overview of the measurement platforms and regions examined throughout this manuscript. Several aircraft participated in INTEX-B, including the NASA DC-8, the NSF C-130 and a Canadian Cessna 207 described below. Throughout this manuscript, we limit the DC-8 and C-130 measurements to within the boxed regions of Fig. 1 to focus on long-range transport of Asian aerosol to Canada. The DC-8 aircraft utilized both a mist chamber (Cofer et al., 1985) and bulk aerosol filters to characterize the SO\textsubscript{4} aerosol load, during 10 flights between 17 April 2006 and 15 May 2006. The size cutoff of the onboard mist chamber system is $\sim1 \mu$m (based on estimated particle transmission efficiency through the inlet and sampler) while that of the bulk aerosol filters has been empirically determined to be $\sim4.5 \mu$m (McNaughton et al., 2007). Mist chamber sampling periods are less than two minutes and aerosol filters are not exposed longer than 10 to 20 min, depending upon altitude. Uncertainties in the reported SO\textsubscript{4} mixing ratios are $\sim20\%$ from the mist chamber and $\sim25$ pptv ($\sim110$ ng/m$^3$) from the filters. A chemical ionization mass spectrometer (CIMS) instrument (Huey et al., 2004; Kim et al., 2007) was also onboard the DC-8 and used for the measurement of SO\textsubscript{2} with a sampling frequency of approximately
3 s. The C-130 platform included a high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) (DeCarlo et al., 2006; Canagaratna et al., 2007; Dunlea et al.) with ∼12 s sampling frequency and a particle-into-liquid sampler (PILS) (Weber et al., 2001; Peltier et al., 2007) of one minute sampling frequency during its 11 flights between 21 April 2006 and 15 May 2006. AMS particle transmission is approximately PM$_1$ in vacuum aerodynamic diameter (Jayne et al., 2000) with particle transmission efficiency rapidly decreasing for aerosols larger than 0.7 μm (e.g. Rupakheti et al., 2005; Liu et al., 2007). PILS measurements were restricted to particles less than 1 μm (at 1 atm. pressure) aerodynamic diameter via a single-stage micro-orifice impactor (Model 100, MSP Corp.). AMS and PILS sulfate measurement uncertainties are estimated at 25% and 10%, respectively.

Whistler Peak Station (50.1° N, 122.9° W, 2182 m) is operated by Environment Canada and has provided continuous measurements of meteorological data, CO and O$_3$ since its establishment in 2002 (Macdonald et al., 2006). Inorganic filter packs of SO$_4^{2-}$, NO$_3^-$ and Ca$^+$ are also routinely collected and analyzed. In addition to these regular measurements, a HR-ToF-AMS (Sun et al.) and a Micro-Orifice Uniform Deposit Impactor (MOUDI) were operated at the site for the duration of INTEX-B. The MOUDI was operated with three stages to isolate particles into three nominal size bins of <1 μm, 1–3 μm and >3 μm.

A Cessna 207 aircraft (Leaitch et al.), supplied by Environment Canada during INTEX-B, contained a suite of instruments designed to capture both gaseous and aerosol pollutants. Aerosol instrumentation included number concentrations of ultra-

---

fine aerosol (PMS7610), aerosol size distribution (FSSP300: <18 µm and PCASP: <2.5 µm) and aerosol composition by way of a quadrupole aerosol mass spectrometer (Q-AMS) (Rupakheti et al., 2005; Jimenez et al., 2003; Jayne et al., 2000). The Q-AMS detection limits are 40 ng/m³ for SO₄²⁻ and nitrate and 600 ng/m³ for organic aerosol for each one-minute average measurement. Walker et al.⁵ describe and interpret O₃ and CO measurements on the Cessna.

All Cessna 207 flights, shown in Fig. 2, originated outside Pemberton, B. C., 35 km north of Whistler, with the exception of one inter-comparison flight with the C-130, conducted on 9 May 2006 along the Canada-US border and related transit. Most Cessna flight tracks consisted of an ascent and descent near Whistler Peak Station before returning to the takeoff site. Thirty-three flights occurred between 22 April 2006 and 17 May 2006, with most extending from the surface to approximately 5 km (550 hPa) altitude and those with valid Q-AMS data occurring mid-late morning to late afternoon. Q-AMS data from the 9 May inter-comparison and several other flights were lost due to radio frequency interference, resulting in a total twenty one flights with successful Q-AMS measurements.

The right panel of Fig. 2 shows the flight paths for the 3 May inter-comparison flight between the Cessna and the C-130. The inter-comparison zone is outlined in grey. The Cessna descent was not completed within the comparison region until approximately 50 min after the C-130 had left the inter-comparison zone. To minimize the effect of sampling time differences, we compare only measurements taken during the Cessna upward spiral against those from the C-130.

Figure 3 shows the speciated aerosol profiles from both aircraft during this intercomparison. All measurements are converted to concentrations at standard temperature and pressure of 1013 hPa and 0°C. Significant agreement is found between the AMS measurements, with respective Root Mean Square Differences (RMSD) and mean bias of, 0.9 and 0.3 µg/m³ for SO₄²⁻, 0.3 and 0.2 µg/m³ for organics, 0.03 and 0.003 µg/m³ for

nitrate, and 0.2 and $-0.0007 \, \mu g/m^3$ for ammonium. The largest disagreement is found in $SO_4^{\equiv}$ at approximately 625 hPa, likely representative of a change in air mass, as indicated by significant and abnormal disagreement ($\sim 30\%$) between the relative humidity measurements on the two aircraft. This particular pressure was sampled $\sim 35$ minutes apart. Removal of points between 600 and 650 hPa, decreases the RMSD and bias in $SO_4^{\equiv}$ to 0.6 and $-0.01 \, \mu g/m^3$ respectively, leaving other species largely unchanged. This is considered good agreement for these sampling conditions.

A collection efficiency (CE) of 0.5 is used for the AMS on the C-130 and is based on many previous intercomparisons (Canagaratna et al., 2007, and references therein), with a correction for increased CE under high acidity conditions (Quinn et al., 2006) and is discussed by Dunlea et al. (in preparation). The CE used with the Cessna AMS is discussed by Leaitch et al. (in preparation).

MOUDI Measurements of the $SO_4^{\equiv}$ size distribution at Whistler Peak during INTEX-B indicate a mean ratio of total $SO_4^{\equiv}$ aerosol to $SO_4^{\equiv}$ below 1 µm in aerodynamic diameter of 1.4. We scale the Cessna $SO_4^{\equiv}$ Q-AMS measurements by this correction factor, which is further justified in section 4, to better represent total $SO_4^{\equiv}$ mass. Airborne measurements off the west coast of Washington State and Oregon in May 1985 found that up to half of the non-seasalt $SO_4^{\equiv}$ mass was above 1.5 µm (Andreae et al., 1988) suggesting either a larger scale factor or a change in the $SO_4^{\equiv}$ size distribution. MOUDI measurements of the $NO_3^{-}$ size distribution indicate that total $NO_3^{-}$ aerosol is eight times larger than submicron $NO_3^{-}$. However, we do not apply a correction factor to nitrate measurements due to concerns about such a larger scale factor.

Figure 4 shows average vertical profiles of Cessna Q-AMS and water ($H_2O$) concentration data obtained during four separate enhancement periods. $SO_4^{\equiv}$ concentrations of 1–2 µg/m³ dominate in the free troposphere and tend to increase with altitude, implying long-range transport. In contrast, organic concentrations typically decrease with altitude and dominate at the surface, implying a local source. These opposing trends suggest that the amount of organics transported with $SO_4^{\equiv}$ is small and that long-range transport of organic aerosols is not a significant contributor to the organic concentration.
in the region studied. Leaitch et al. (in preparation) find a high level of mass closure with Cessna Q-AMS measurements, suggesting that the relatively high Q-AMS detection limit for organics (0.4–0.6 µg/m³) has not impacted this conclusion. They also show that the occurrence of increased sulfate usually accompanies an increase in the number and mass concentrations of coarse particles. Dunlea et al. (2007) find that SO₄²⁻ concentrations exceed those of organics for all Asian plume intercepts in the C-130, with older air masses being characterized by a larger SO₄²⁻/organics ratio than younger ones having undergone more rapid transport, presumably due to additional production of SO₄²⁻ during their extended transport time. The organic enhancement over 15 May–17 May is likely fuelled by an unusually high mixed layer depth, as indicated by the water concentration profile, and can be attributed to local sources. This period is further examined by Zhang et al. (in preparartion) and McKendry et al. The contribution of nitrate to particulate mass is relatively insignificant, in part reflecting AMS size restrictions. We focus on long-range transport of SO₄²⁻ for the remainder of the manuscript.

2.2 Model description

We use the GEOS-Chem chemical transport model v7-04-09 (Bey et al., 2001) (http://www-as.harvard.edu/chemistry/trop/geos/index.html) to interpret the aforementioned measurements. GEOS-Chem is driven by assimilated meteorological data from the Goddard Earth Observing System (GEOS-4) at the NASA Global Modeling Assimilation Office (GMAO), with 30 vertical levels and degraded to the model's horizontal resolution of 2° latitude by 2.5° longitude.

The aerosol simulation in GEOS-Chem includes the sulfate-nitrate-ammonium system (Park et al., 2004; Park et al., 2006), carbonaceous aerosols (Park et al., 2003; Liao et al., 2007), mineral dust (Fairlie et al., 2007) and sea-salt (Alexander et al.,

---

The aerosol and oxidant simulations are coupled through formation of sulfate and nitrate (Park et al., 2004), heterogeneous chemistry (Jacob, 2000) and aerosol effects on photolysis rates (Martin et al., 2003b). Wet and dry deposition are based upon Liu et al. (2001), including both washout and rainout. GEOS-Chem simulations capture both the timing and distribution of Asian dust outbreaks during TRACE-P and ACE-Asia (Fairlie et al., 2007). It exhibits no significant bias in Asian SO\(_x\) (SO\(_2\)+SO\(_4^{2-}\)) outflow during spring 2001 as part of the TRACE-P campaign (Park et al., 2005), although modeled SO\(_4^{2-}\) concentrations were 50% high during ACE-Asia, which may suggest an error in SO\(_2\) oxidation rates (Heald et al., 2005).

The global emission inventory in the standard GEOS-Chem model is based on GEIA (Benkovitz et al., 1996) for the base year of 1985 with scale factors to 1998. We implement here the EDGAR 3.2FT2000 emission inventory based upon the year 2000 (Olivier et al., 2002) to provide a more current estimate of global emissions of NO\(_x\), SO\(_x\) and CO. The global inventory is replaced by regional inventories from NEI99 (http://www.epa.gov/ttn/chief/net/1999inventory.html) over the United States for 1999, BRAVO (Kuhns et al., 2005) over Mexico for 1999 and Streets et al. 2003; 2006) for 2000 (NO\(_x\) and SO\(_x\)) and 2001 (CO) for eastern Asia. EMEP emissions (http://www.emep.int) of NO\(_x\) and CO are used over Europe for up to 2000. We update the eastern Asia emissions to 2006 from Streets et al. (in preparation) and implement EMEP SO\(_x\) emissions (Vestreng et al., 2007) over Europe for the year 2004. We increase ship emissions by 4.1% per year (Corbett et al., 2007).

We scale all regional and global inventories from their respective base year to 2003, the last year of available statistics, unless its base year is after 2003. Our approach follows Bey et al. (2001) and Park et al. (2004). Emissions are scaled according to estimates provided by individual countries, where available. These countries/regions include the United States, Canada, Japan and Europe. NO\(_x\) emissions of remaining countries are scaled proportional to changes in total CO\(_2\) emissions. SO\(_x\) emissions are similarly scaled to solid fuel CO\(_2\) emissions and CO emissions to liquid fuel CO\(_2\) emissions. CO\(_2\) emission data are obtained from the Carbon Dioxide Information Anal-

4027
ysis Center (CDIAC).

In addition to annual scale factors, diurnal scale factors are also applied to NO\textsubscript{x} emissions. Here, the intra-day variation of each grid cell is based upon the diurnal variation of each source type, as provided with the EDGAR inventory, and its relative contribution to total NO\textsubscript{x} emissions within that cell.

2.3 Satellite instrumentation

Aerosol Optical Depth (AOD), a measure of light extinction, has been retrieved since 2000 from the Moderate Resolution Imaging Spectroradiometer (MODIS) and Multi-angle Imaging Spectroradiometer (MISR), onboard the NASA satellite Terra. The MODIS retrieval of AOD is based on scene brightness over dark surfaces, using empirical relationships in the spectral variation in surface reflectivity (Kaufmann et al., 1997; Remer et al., 2005). We use the MODIS collection 5 dataset (Levy et al., 2007). The MISR algorithm uses observed differences in the spatial variation of backscattered radiation with changing viewing angle to self-consistently retrieve surface reflectivity and AOD (Martonchik et al., 2002; Kahn et al., 2005). Global coverage in the absence of clouds is achieved daily from MODIS and in 6 to 9 days from MISR.

3 Estimate of sulfur emission growth from China

Significant increases in AOD retrieved from the Total Ozone Mapping Spectrometer (TOMS) over China between 1979–2000 and the Advanced Very High Resolution Radiometer (AVHRR) off the east coast of China between the periods 1988–1991 and 2002–2005 are attributed to increased aerosol sources (Massie et al., 2004; Mishchenko and Geogdzhayer, 2007). Here we investigate the recent trend using AOD from MODIS and MISR and assess its relationship with Chinese sulfur emissions growth. We first use GEOS-Chem, with East Asian emissions held at year 2000 levels, to investigate meteorologically induced changes to AOD.
The top row of Fig. 5 shows mean AOD for 2000–2006 over East Asia from MODIS, MISR and GEOS-Chem. Pronounced enhancements of mean AOD in excess of 0.4 are apparent in all three datasets. MODIS AOD exceeds MISR AOD by 12% over the outlined Region 1, consistent with comparisons by Abdou et al. (2005). Simulated AOD exhibits a smoother distribution than both retrievals and exceeds MISR AOD by 22%. The middle panel of Fig. 5 presents monthly average AOD within the Region 1. All three datasets contain a distinct seasonal variation with a spring maximum and a fall minimum that reflects the seasonal variation in dust as noted by Prospero et al. (2002). Simulated AOD generally captures the retrieved monthly variation and magnitude as compared to both instruments (MODIS: $r^2=0.46$, RMSD=0.09; MISR: $r^2=0.36$, RMSD=0.12), although the simulation tends to overestimate springtime AOD. Simulated AOD contributions from dust (green) and $\text{SO}_4^{\text{aq}}$ (magenta) indicate that dust comprises the largest fraction of springtime AOD, whereas $\text{SO}_4^{\text{aq}}$ dominates during other periods. We focus on the periods between July and December, as indicated by yellow bars, when non-sulfate aerosol species such as dust have smaller burdens.

The bottom left panel of Figure 5 shows the annual mean difference over July–December between simulated and retrieved AOD for Region 1, expressed as a percentage of the mean retrieved AOD from each instrument over the six-year, low-dust period. We find a significant trend for both MODIS (+4.1%/year, $r^2=0.72$) and MISR (+3.4%/year, $r^2=0.54$). We associate this trend with increased $\text{SO}_x$ emissions, as $\text{SO}_4^{\text{aq}}$ dominates simulated AOD in this comparison, simulated $\text{SO}_x$ emissions are held at 2000 levels and interannual changes in other aerosols are accounted for in the simulation.

The quantitative relationship between AOD and $\text{SO}_2$ emissions depends on a number of factors including $\text{SO}_2$ oxidation rates, dynamics and aerosol deposition (Dubovik et al., 2007). We quantify the relationship by conducting sensitivity simulations with increased $\text{SO}_x$ emissions, and examining the change in simulated AOD. The bottom right panel of Fig. 5 shows the calculated relationship between $\text{SO}_x$ emissions and AOD over Region 1. The calculated ratio of $\Delta\text{AOD}(\%)/\Delta\text{SO}_x$ emissions (\%) is $4029$.\[\text{CC BY} \]
nearly linear over this region during July to December. The annual trend in AOD for MISR and MODIS correspond to simulations with an annual growth in SO\textsubscript{x} emissions of 6.2%/yr and 9.6%/yr, respectively. In agreement, a comparison of the two bottom-up SO\textsubscript{x} emission inventories for 2000 (Streets et al., 2003) and 2006 (http://www.cgrer.uiowa.edu/EMISSION\_DATA\_new/index_16.html) over Region 1 yields an annual growth of 9.9%. Beyond actual emission growth, changes between the 2000 and 2006 inventories include the addition of local inventories not present in, and improvement and corrections made to, the original 2000 inventory. These factors may account for the slight discrepancy between the growth estimates. We adopt the 2006 bottom-up inventory for our standard simulation, as it provides additional information on the spatial distribution of these SO\textsubscript{x} emissions.

4 Campaign average analysis of transpacific transport

The top row of Fig. 6 shows campaign average SO\textsubscript{4}\textsuperscript{\textendash} concentrations for the DC-8 over the domain in Fig. 1. Only filter pack and mist chamber measurements with corresponding CIMS SO\textsubscript{2} measurements have been included to allow subsequent SO\textsubscript{x} comparison. Both filter pack (4.5 \textmu m cutoff) and mist chamber (1 \textmu m cutoff) measurements show a maximum between 700–800 hPa. Heald et al. (2006) attribute the SO\textsubscript{4}\textsuperscript{\textendash}maximum in the lower free troposphere to preferential scavenging during transport either in the boundary layer or during lifting to the upper troposphere. Our standard simulation of total SO\textsubscript{4}\textsuperscript{\textendash}captures the relative vertical profile for both the mist chamber and filter pack measurements over the domain of the DC-8, but overestimates their magnitude by a RMSD of 0.43 \textmu g/m\textsuperscript{3} (mean bias=49%) and 0.54 \textmu g/m\textsuperscript{3} (mean bias=81%), respectively. We attribute the bias versus the filter pack measurements to an underestimate in wet deposition. Comparison of the GEOS-4 rainfall rates used in GEOS-Chem with data from the Tropical Rainfall Measuring Mission (TRMM) (Bowman, 2005) reveals a 40% underestimate in modeled rainfall rates over the North Pacific (25–45° N, 120° E–130° W) during INTEX-B. An overestimate in the SO\textsubscript{2} oxidation rate may also
play a role (Heald et al., 2005). Comparison of simulated $SO_x$ with the sum of CIMS $SO_2$ measurements (converted to $\mu g/m^3$) with mist chamber and filter pack $SO_4^{\text{aq}}$ data between 500-900 hPa reduces the mean bias to 39% and 70% for the filter pack and mist chamber, respectively. However, the bias in $SO_4^{\text{aq}}$ found here for the East Pacific is lower than found by Heald et al. (2005) for the West Pacific, suggesting a decrease with air mass age as continued $SO_4^{\text{aq}}$ production during transport decreases the ratio of $SO_2$ to $SO_x$.

The campaign average filter pack measurements are 25% higher than the mist chamber measurements between 500–900 hPa, an altitude range inclusive of the C-130 and Cessna measurements. Over the altitude of the C-130 and Cessna measurements a higher bias is found between simulated values and the mist chamber (RMSD=0.75 $\mu g/m^3$, mean bias=98%) versus the filter pack (RMSD=0.49 $\mu g/m^3$, mean bias=45%). This comparison provides additional evidence for scaling the AMS and PILS measurements to reflect total $SO_4^{\text{aq}}$ mass.
concentrations at lower altitudes.

The sampling strategy for the Cessna was to conduct frequent profiles over Whistler Peak. Such a sampling strategy facilitated comparison with simulated results, provided context for the measurements at Whistler summit, and accommodated the range and duration of the Cessna. Cessna measurements indicate a fairly uniform vertical profile, with a large standard deviation in the free troposphere that reflects an oscillation between clean conditions and plumes. The simulation agrees significantly with size-correction scaled measured $\text{SO}_4^{\text{aq}}$ (RMSD=0.20 $\mu$g/m$^3$, mean bias=20%). The largest model-Cessna bias is observed nearer to the surface, suggesting an overestimate in local emissions which dominate at this altitude. Variability of the Cessna measurements, as represented by the mean standard deviation, exceed model variability by 86%, perhaps reflective of model resolution and thereby its suitability for large-scale events over small ones. While recognizing the potential influence of both measurement uncertainty and the limitation of applying a constant size-correction factor across both altitude and aircrafts, the eastward decrease in the bias between the three aircraft may indicate an increasing $\text{SO}_4^{\text{aq}}/\text{SO}_2$ ratio in the measurements.

Figure 6 also shows simulation without anthropogenic East Asian and all anthropogenic sources for all three aircraft flight tracks. Anthropogenic East Asian $\text{SO}_4^{\text{aq}}$ dominates throughout the DC-8 profiles, comprising 60% of the simulated mass between 500–900 hPa, with the largest contribution in the lower free troposphere. Other anthropogenic $\text{SO}_4^{\text{aq}}$ sources comprise an additional 17%. For the C-130 flight track, closer to North America, simulation results attribute 67% of $\text{SO}_4^{\text{aq}}$ to be of Asian origin, with a peak at 600 hPa. For the Cessna profiles over Whistler, local sources dominate below 700 hPa, while higher altitude concentrations reflect Asian anthropogenic emissions. We calculate that 63% of the measured $\text{SO}_4^{\text{aq}}$ at 600 hPa is from East Asia. Model analysis indicates the influence of Asian sources at higher altitudes in both C-130 and Cessna versus the DC-8 measurements. This orographic effect is induced by rising air masses on approach to North American mountain ranges.

Of interest is the evolution of Asian sulfate over the last two decades. Figure 7 shows
the mean non-seasalt sulfate profile observed by Andreae et al. (1988) during 4 flights in May 1985, covering a similar domain to the C-130 INTEX-B flights. Concentrations of 0.3–0.8 \( \mu g/m^3 \) (adjusted to STP at 273 K, sum of coarse and fine fractions) were observed between 500–900 hPa. \( \text{SO}_4^{2-} \) concentrations increased with altitude below 5 km, from 0.3–0.6 \( \mu g/m^3 \) in the marine boundary layer to 0.6–0.8 \( \mu g/m^3 \) in the cloud convection layer and free troposphere. The 1985 measurements thus showed lower concentrations, but a similar trend with increased altitude as was seen in the C-130 measurements. Mean measurements between 500–900 hPa are higher than the 1985 data by 60% from C-130 PILS and by 90% from HR-ToF-AMS. We further interpret these observations by conducting a GEOS-Chem simulation using 1985 GEIA emissions and meteorology and sampling along the 1985 flights tracks. The simulation reproduces the measurements with an RMSD of 0.25 \( \mu g/m^3 \) (mean bias=21%) over 500–900 hPa. A sensitivity simulation without anthropogenic East Asian emissions reveals that this source contributes 0.14 \( \mu g/m^3 \) (20%) to the measured values in 1985, greatly reduced compared to the 67% along the C-130 flights in 2006. Comparison of simulations along the 1985 and INTEX-B flight tracks indicate a 3.4 fold increase in the relative contribution of east Asian sulfate between 1985–2006. Simulation of complete temporal and spatial coverage within the C-130 area (April–May, 34–55 N, 123.75–141.25 W, 500–900 hPa) indicates a 2.4 fold increase between these two time periods, while a simulation over the 1985 flight region (April–May, 45–49 N, 123.75–126.25 W, 500–900 hPa) experiences an increase of 2.8 fold, suggesting a substantial increase in the influence of East Asian emissions to the free troposphere over the western coast of North America.

5 Asian plume development and influence

Figure 8 examines the development of an Asian plume from 18 April 2006 to 25 April 2006. MODIS AOD retrievals are used from both the Aqua (01:30 overpass) and Terra (10:30 overpass) satellites and plotted with simulation results from the same
period. The GEOS-Chem simulation successfully captures many of the trends associated with the influx event. Both retrieval and simulation show this plume beginning from China on 18 April and stretching across the Pacific Ocean through 21 April, and finally aligning to the north while moving eastward over the North American coast. Many simulated features, however, are spatially shifted after several days transport primarily due to differences in the simulated and real meteorology. This is typical of simulations of all individual events, complicating individual flight comparisons.

Figure 9 shows individual Cessna $SO_4^{\infty}$ profiles taken between 22 and 25 April with GEOS-Chem profiles during the same flights. The first three Cessna profiles show enhancements of 0.2–0.8 $\mu g/m^3$ above 800 hPa relative to surface concentrations, indicative of a transported plume and in agreement with simulated enhancements of 0.6–0.8 $\mu g/m^3$. In the final profile, however, Cessna measurements show an enhancement of 1.6 $\mu g/m^3$ which the model fails to represent. Simulations can fail to produce accurate plumes (e.g. Dunlea et al., in preparation), but in this case the simulated plume has advanced beyond the Cessna’s flight path, where in fact the physical plume still resides. During long range transport events, small errors in the meteorological fields used by chemical transport models can compound to create offsets in time and space, making average comparisons more robust.

Figure 10 shows simulated average conditions during April and May 2006. The top panel shows mean concentrations at 2 km, where DC-8 $SO_4^{\infty}$ enhancements were observed. Simulated $SO_4^{\infty}$ enhancements occur along the entire western Pacific Canadian border, extending to the northwestern United States. A pronounced enhancement covers the eastern United States and Canada, related to major regional anthropogenic sources. The middle and bottom panels show vertical cross-sections of $SO_4^{\infty}$ and percentage of $SO_4^{\infty}$ originating from East Asia, respectively, averaged between the blue lines of the top panel. The highest overall magnitude (>1 $\mu g/m^3$) is again simulated in eastern North America and is predominately from regional emissions. Nonetheless, a narrow band of Asian influence in excess of 40% prevails over the continent at 4.5 km, where overall concentrations are $\sim$0.3 $\mu g/m^3$. Along coastal regions, the largest East
Asian influence is found between 1 and 5 km, where 40% of the overall SO$_4^{\text{-}}$ burden originated in Southeast Asia. We calculate that surface concentrations of SO$_4^{\text{-}}$ along the southern Pacific Canadian coast are increased by 0.14–0.19 µg/m$^3$ (~30%) as a result of Asian emissions in spring. Heald et al. (2006) found a 0.16 µg/m$^3$ enhancement in SO$_4^{\text{-}}$ over the northwest United States during periods of Asian influence.

We go on to explore the surface SO$_4^{\text{-}}$ measurements from the National Air Pollution Surveillance (NAPS) Network in the Vancouver area for evidence of Asian influence. Figure 11 shows surface SO$_4^{\text{-}}$ concentrations between April and May 2006 in the Vancouver area as a function of the modeled percent SO$_4^{\text{-}}$ originating in Asia. The two measurement sites in the Vancouver area, Abbotsford and Vancouver, reside in the same model grid box. Black circles correspond to measurement averages, binned at intervals of 5% simulated East Asian influence. Individual measurements show substantial scatter, but linear regression of the binned measurements show a significant correlation ($r^2=0.64$). Binned measurements indicate that an additional 0.27 µg/m$^3$ reaches the surface with each 10% increase in modeled Asian SO$_4^{\text{-}}$, corroborating that current levels of Asian sulfur emissions are impacting surface SO$_4^{\text{-}}$ concentrations in Canada.

6 Conclusions

We interpret a suite of satellite (MODIS and MISR), aircraft (DC-8, C-130 and Cessna 207) and ground-based measurements (Whistler Peak, NAPS) over the North Pacific Ocean and western North America in April-May 2006 as part of the INTEX-B campaign to understand the implications of long-range transport of Asian aerosol to Canada.

The Canadian component of INTEX-B included 33 flights from a Cessna 207 aircraft. We compare the Cessna quadrupole Aerodyne Mass Spectrometer (Q-AMS) measurements with a high resolution time of flight AMS (HR-ToF-AMS) onboard the C-130 during an intercomparison flight, yielding an overall bias of −0.01 µg/m$^3$ with appreciable scatter (RMSD=0.6 µg/m$^3$) for sulfate (SO$_4^{\text{-}}$) and similar agreement for...
organics (bias=0.2µg/m³, RMSD=0.3µg/m³). However, there was a small systematic difference (<20%) between the C-130 HR-ToF-AMS sulfate and a co-located PILS measurement of SO$_4$\(^{=}\) (Dunlea et al., in preparation). We use ground-based measurements (MOUDI) of the SO$_4$\(^{=}\) size distribution at Whistler Peak to estimate that a correction factor of 1.4 should be applied to Cessna Q-AMS SO$_4$\(^{=}\) mass to compensate for mass lost due to instrument size restrictions. Cessna profiles over Whistler, B. C. show SO$_4$\(^{=}\) enhancements of 1–2µg/m³ over 600–700 hPa, indicative of long-range transport, whereas organic enhancements are largest near the surface, suggesting a local emission source. We did not detect long-range transport of significant organic aerosol from the Cessna data.

We interpret these observations with a global chemical transport model, GEOS-Chem, to simulate the implications of anthropogenic activity. We develop updated scale factors, bringing global anthropogenic emissions from 1998 to at least the year 2003. We also implement a recent bottom-up inventory for East Asia for 2006 (http://www.cgrer.uiowa.edu/EMISSION\_DATA\_new/index\_16.html).

Trends in retrieved Aerosol Optical Depth (AOD) from MISR and MODIS during low dust periods (July–Dec) over 2000–2006 are used to evaluate growth in SO$_x$ emissions from the year 2000 (Streets et al., 2003) to the 2006 values. We find a trend in retrieved AOD of 3.4%/yr (MISR) and 4.1%/yr (MODIS) after accounting for interannual variability in transport and natural sources as represented by GEOS-Chem. GEOS-Chem calculations of the change in AOD for a change in SO$_x$ emissions indicate a near-linear relationship with a ratio of 0.4 over East Asia. We estimate the average annual growth in East Asian SO$_x$ emissions to be between 6.2% for MISR and 9.6% for MODIS, supporting the bottom-up estimate of an annual increase of 9.9% from 2000 (Streets et al., 2003) to 2006.

We use this simulation to understand the characteristics of East Asian outflow as measured by the INTEX-B aircraft. Over the Pacific Ocean, Asian outflow of SO$_x$ is strongest in the lower troposphere, with enhanced SO$_4$\(^{=}\) concentrations of 1–1.5µg/m³ observed by the DC-8 between 700–800 hPa. The C-130 and Cessna aircraft SO$_4$\(^{=}\)
measurements of 1–1.5 µg/m³ over 600–800 hPa indicate that Asian plumes are often elevated by orographic effects along coastal North America. The simulation generally captures the campaign mean profile shape of DC-8, C-130 and Cessna measurements, but overestimate total SO₄²⁻ concentrations with RMSD of 0.20–0.56 µg/m³ (mean bias of 20–62%), likely due to biases in precipitation and SO₂ oxidation. Simulations without Asian emissions reveal that long-range transport of SO₄²⁻ dominates campaign-mean aircraft measurements in the free troposphere.

We compare the INTEX-B measurements with aircraft measurements in May 1985 over a similar domain as the C-130. Measured free tropospheric SO₄²⁻ concentrations increase by 60–90% from 1985 to 2006. Simulations without East Asian emissions indicate that their relative contribution to SO₄²⁻ concentrations during April and May, between 500–900 hPa and over the two aircraft domains, have increased by a factor of 2.4–3.4 since 1985 depending on the specific region.

Comparison of individual plumes with aircraft profiles and MODIS AOD reveals a general consistency, but offsets in time and space. Campaign-mean simulations show that 40% of the SO₄²⁻ burden between 1 and 5 km over Whistler is of anthropogenic Asian origin. These emissions increase surface concentrations along the western Canadian coast by 0.14–0.19 µg/m³ (~30%) in spring. This effect is corroborated with surface measurements, where we find an increase of 0.27 µg/m³ with each 10% increase in simulated fraction of Asian SO₄²⁻ during INTEX-B.

A better understanding of SO₂ oxidation and wet scavenging is still needed. Previous work (Heald et al., 2006) and our analysis indicate an overestimate in the simulated SO₂ oxidation rate. Development of size-resolved aerosol simulations and SO₄²⁻ instruments that sample larger particles with high time resolution would facilitate model-measurement comparison. Improved understanding of inter-instrument SO₄²⁻ measurements would be valuable.

Fig. 1. Spatial domain of observations used to characterize Asian SO$_2$ emissions and their impact. The domains and flightpaths of the DC-8, C-130 and Cessna aircraft are shown in blue, red and green, respectively. The domain of the MODIS and MISR satellite observations used to estimate emissions is shown in yellow. Figure 2 shows a detailed plot of the Cessna flight tracks.
Fig. 2. Flight paths of the Cessna 207 aircraft during the INTEX-B campaign over 22 April 2006 to 17 May 2006. The left panel shows all Cessna 207 flights, with colors representing individual flights. The right panel highlights the 3 May 2006 inter-comparison flight between the Cessna and C-130 aircraft. The flight track of the Cessna is shown in red, and of the C-130 in blue. The grey box defines the inter-comparison region.
Fig. 3. Aerosol Mass Spectrometer (AMS) measurements from the 3 May 2006 inter-comparison flight over Whistler Peak Station (50.1° N, 122.9° W). Cessna data are shown in red. C-130 data are shown in blue. All data at STP. No scaling for the upper size cut of the AMS has been applied to these data.
Fig. 4. Cessna Q-AMS vertical profiles of sulfate, organics and nitrate during four enhancement periods. Sulfate (SO$_4^{2-}$) data have been scaled by multiplying with a factor of 1.4 to account for particle size restrictions as inferred from MOUDI measurements at Whistler summit. Aerosol data are at STP. Water (H$_2$O) concentration profiles are in cyan. Date ranges are indicated in the bottom right of each plot. Error bars represent one standard deviation of the data.
Fig. 5. Aerosol Optical Depth (AOD) from the MODIS and MISR satellite instruments and a GEOS-Chem simulation. The top row shows mean AOD over 2000–2006 and defines Region 1 as used in the lower panels. The middle panel shows monthly mean for Region 1 retrieved and simulated AOD with simulated SO\textsubscript{x} emissions held at 2000 levels. Simulated contributions of dust and SO\textsubscript{4}\textsuperscript{2-} to total AOD are also shown. Highlighted areas indicate time periods used in the lower panels. The bottom left panel shows the Region 1 difference between retrieved and simulated AOD averaged between July and December of each year expressed as a percentage of mean retrieved AOD. Dashed line indicates best linear fit, error bars represent the 20th and 80th percentile. The bottom right panel shows the simulated relationship in Region 1 between total AOD and SO\textsubscript{x} emissions over July–December 2000–2006 as calculated with 5 simulations with SO\textsubscript{x} emissions increased by 0%, 5%, 10%, 15% and 20%. The red and blue stars respectively indicate the observed change in difference of simulated AOD between MISR and MODIS. Error bars denote one standard deviation of the data.
