Abstract

This paper presents a complete characterization of a very deep stratospheric intrusion which occurred over the British Isles on 15 August 2007. The signature of this event is diagnosed using ozonesonde measurements over Lerwick, UK (60.14° N, 1.19° W) and is also well characterized using meteorological analyses from the global operational weather prediction model of Météo-France, ARPEGE. Modelled as well as assimilated fields of both ozone (O₃) and carbon monoxide (CO) have been used in order to better document this event. The paper also presents a demonstration of the capability of O₃ and CO assimilated fields to better describe a stratosphere-troposphere exchange (STE) event in comparison with the free run modelled O₃ and CO fields. O₃ and CO from Aura/MLS and Terra/MOPITT instruments, respectively, are assimilated into the three-dimensional chemical transport model MOCAGE of Météo-France using a variational 3-D-FGAT (First Guess at Appropriate Time) method within the MOCAGE-PALM assimilation system. The usefulness of assimilated MOPITT CO data in a STE study is demonstrated in this novel result. The study shows that the use of the model MOCAGE gives consistent 3-D fields capable of describing the synoptic evolution of the event. However, modelled O₃ and CO vertical distributions do not provide a quantitative evaluation of the intrusion. Although the assimilation of MLS data improves the distribution of O₃ above the tropopause compared to the free model run, it is not sufficient to reproduce the stratospheric intrusion event well. Conversely, assimilated MOPITT CO allows a better description of the stratospheric intrusion event. Indeed, the horizontal distribution of the CO assimilated field is consistent with meteorological analyses. Moreover, the vertical distribution of the CO assimilated field is in accordance with the potential vorticity distribution and reveals a deeper intrusion from the lower stratosphere downward to the mid-troposphere compared to the O₃ assimilated field. This study clearly demonstrates the capability of the assimilation of MOPITT CO to improve the CO distribution in the upper troposphere and lower stratosphere region. In addition, the behaviour of CO assimilated field is consistent with the synoptic evo-
olution of the meteorological conditions. Therefore, the results of this study open the perspectives for using MOPITT CO in the STE studies.

1 Introduction

The troposphere and the stratosphere are characterized by different dynamical and chemical properties, involving strong gradients of potential vorticity (PV), relative humidity (RH) and chemical species such as ozone (O_3) and carbon monoxide (CO) at the tropopause. Dynamical, chemical and radiative coupling between the stratosphere and the troposphere are among the most important processes that must be understood for prediction of climate change (Holton et al., 1995). The stratosphere-troposphere exchange (STE) events across the tropopause play a key role in controlling the ozone and water vapour budgets of the upper troposphere and lower stratosphere (UTLS) region. STE events can have a significant role in the radiative forcing of climate change in relation to the increase of the anthropogenic influences (e.g. Santer et al., 2003). In this context, Stohl et al. (2003) reported that modifications in STE events in a changing climate may significantly affect stratospheric ozone depletion and the oxidizing capacity of the troposphere.

STE events have been reviewed by e.g., WMO (1986); Davies and Schuepbach (1994); Holton et al. (1995); Stohl et al. (2003). The exchange of mass across the tropopause is bidirectional, with a return flow transporting tropospheric air into the lowermost stratosphere (Danielsen, 1968; Hoor et al., 2002). It occurs via a variety of processes on different scales which include both Troposphere to Stratosphere Transport (TST) (e.g. Zahn et al., 2000; Hoor et al., 2002) and Stratosphere to Troposphere Transport (STT) (e.g. Danielsen, 1968; Shapiro, 1980) events. In the TST events, the isentropic transport into the lowermost stratosphere takes place across the extratropical tropopause (Dessler et al., 1995). The transport of tropospheric air into the stratosphere is irreversible (Hintsa et al., 1998). In the STT events, the deep descent of stratospheric air into the troposphere leads to irreversible transport as the stratospheric
Stratospheric intrusions are the most important manifestations of STT events in the extratropics and they are associated with tropopause folds (Danielsen, 1968; Kentarchos et al., 1999). These events, characterized by tongues of anomalously high potential vorticity, are considered as the main sources of ozone into the troposphere. Stratospheric intrusions form in the baroclinic zone beneath a jet stream, as a result of an ageostrophic circulation forced by convergence at the jet entrance (Keyser and Shapiro, 1986). They mainly depend on small-scale near-tropopause processes and they are more frequent in the extratropical regions than further poleward (e.g. Sprenger et al., 2003; Rao and Kirkwood, 2005). The intruding stratospheric air typically forms filamentary structures, which appear as laminae in ozone profiles and can reveal mesoscale features on water vapour satellite images especially if they are stretched into streamers and subsequently roll up (Holton et al., 1995; Stohl et al., 2003).

Knowledge of the frequency and global geographical distributions of stratospheric intrusions is important for the climatological understanding of extratropical synoptic-scale and mesoscale weather systems, and of irreversible mixing between stratospheric and tropospheric air (Sprenger et al., 2003). For these reasons, they have been widely studied using in-situ aircraft measurements (e.g. Hoor et al., 2002; Brioude et al., 2006), ground-based lidar sounding data (e.g. Eisele et al., 1999), airborne lidar systems (e.g. Browell et al., 1987), in-situ ozonesonde stations (e.g. Seidel and Randel, 2006), meteorological analyses (e.g. Wernli and Bourqui, 2002; Sprenger et al., 2003), and modelling studies (e.g. Kentarchos et al., 1999; Hsu et al., 2005). Most of the studies dealing with tropopause folds focused on the detection of the stratospheric signature in the troposphere based on low RH, high $O_3$, PV, radioactivity ($^7$Be, $^{10}$Be/$^7$Be) or static stability. Relationships between tracers have also been used in order to characterize mixing processes in the tropopause region (e.g. Zahn et al., 2000; Pan et al., 2007; Brioude et al., 2008).

Satellite measurements based on the analysis of satellite imagery from water vapour channels (e.g. Appenzeller, 1996; Wimmers et al., 2003) or the analysis of ozone to-
tal columns (e.g. Shapiro et al., 1987; Wimmers and Moody, 2004) have also been used in order to diagnose and document stratospheric intrusions into the troposphere. Generally, satellite measurements have the advantage that they provide global coverage which offers the opportunity to investigate the mixing processes between the stratosphere and the troposphere in the UTLS region. However, these measurements are not able to resolve the synoptic-scale variabilities in the tropopause region, neither from limb-viewing sensors because of their sparse horizontal sampling, nor from nadir-viewing sensors because of their poor vertical resolutions. Moreover, the UTLS region is characterized by very high vertical gradients, which is a well-known limitation of most of the global chemical transport models (CTM) as described by Law et al. (2000) in their comparison between global CTM results and Measurement of OZone and wA- ter vapour by alrbus in-service airCraft (MOZAIC) in-situ data (Marenco et al., 1998). Therefore, the use of chemical data assimilation, which allows for an optimal combination of model results and measurements, can be very useful to better resolve the UTLS region. In this context, Clark et al. (2007) and Semane et al. (2007) have used O$_3$ assimilated fields from MOZAIC in-situ measurements and stratospheric profiles from the Michelson Interferometer for Passive Atmospheric Sounding (MIPAS) instrument onboard ENVISAT, respectively, in order to better describe the exchange between the troposphere and the stratosphere across the tropopause region.

The main objectives of this paper are: firstly, to document a deep stratospheric intrusion event, which has occurred over the British Isles on 15 August 2007, using ozonesonde measurements, meteorological analyses, as well as modelled and assimilated fields of O$_3$ and CO observations from the Microwave Limb Sounder (MLS) instrument onboard Aura satellite and from the Measurements Of the Pollution In The Troposphere (MOPITT) instrument onboard Terra satellite, respectively. Secondly, to evaluate the added-value of stratospheric O$_3$ and tropospheric CO assimilated fields in regard to the composition of the UTLS region and to STE events in comparison to modelled O$_3$ and CO fields from MOCAGE.

Thus, an original objective of this study is to evaluate the capacity to improve the
description of STE events with the assimilation of the tropospheric CO field from MOPITT. To our knowledge, satellite CO data assimilation, in particular from the MOPITT instrument, has not yet been used in scientific studies related to stratospheric intrusion events. We will then demonstrate the capability of CO assimilated fields from MOPITT to describe a deep stratospheric intrusion in comparison to MLS O$_3$ assimilated fields. Both O$_3$ and CO observations are assimilated into the 3-D-CTM MOCAGE of Météo-France using a variational 3-D-FGAT (First Guess at Appropriate Time) method within the MOCAGE-PALM assimilation system. This paper is outlined as follows. Section 2 presents the satellite observations as well as the model and the assimilation system used in this study. In Sect. 3, we characterize the aforementioned event with the help of ozonesonde measurements and meteorological data. Section 4 presents a validation of the O$_3$ and CO assimilated products in comparison with other independent data. The characterization of the stratospheric intrusion event with O$_3$ and CO assimilated fields is described in Sect. 5. Main results are summarized in Sect. 6.

2 Data and analysis

2.1 Aura/MLS ozone observations

The Aura satellite was launched on 15 July 2004 and placed into a near-polar Earth orbit at ~705 km with an inclination of 98° and an ascending node at 13:45 h. It makes about 14 orbits per day. The MLS instrument onboard Aura uses the microwave limb sounding technique to measure chemical constituents and dynamical tracers between the upper troposphere and the lower mesosphere (Waters et al., 2006). It provides dense spatial coverage with 3500 profiles daily between 82° N and 82° S.

In this study we use the Version 2.2 of MLS O$_3$ dataset. It is a standard retrieval between 215 and 0.46 hPa with a vertical resolution of ~3 km in the upper troposphere and the stratosphere. The along-track resolution of O$_3$ is ~200 km between 215 and 10 hPa. The estimated single-profile precision in the extratropical UTLS region is of the
order of 0.04 ppmv from 215 to 100 hPa and between 0.05 and 0.2 ppmv from 46 to 10 hPa. For the assimilation experiment, MLS data are selected according to the precision and quality flags recommended in the MLS Version 2.2 Level data quality and description document (see http://mls.jpl.nasa.gov/data/v2-2.data_quality_document.pdf). The respective errors for each profile are taken into account in the assimilation process through the error covariance matrix of observations. Note that only measurements performed between 215 and 10 hPa are used during the assimilation experiment because of the limitation imposed by the upper boundary of the used version of the MOCAGE model, namely 5 hPa.

2.2 Terra/MOPITT carbon monoxide observations

The MOPITT instrument (Drummond and Mand, 1996) is onboard the Terra platform and has been monitoring global tropospheric CO from March 2000 to date. These data have been intensively validated (e.g. Emmons et al., 2004, 2009). The pixel size is 22 km × 22 km and the vertical profiles are retrieved on 7 pressure levels (surface, 850, 700, 500, 350, 250 and 150 hPa). The maximum likelihood method, used to retrieve the MOPITT CO, is a statistical combination of the measurements and a priori information (Rodgers, 2000). The retrieval profiles are characterized by their averaging kernels, which provide information on the vertical sensitivity of the measurements. In particular, the Degree of Freedom for Signal (DFS), which is the trace of the kernels matrix, indicates the number of independent pieces of information from the measurements. It depends, via the surface temperatures, on the latitudes and the alternating day/night periods. In this study, we consider MOPITT CO (Version 3) retrievals with less than 40% a priori contamination to insure a consistent and good quality dataset. MOPITT data are averaged in boxes of 2° × 2° to obtain super-observations directly assimilated into the used version of MOCAGE-PALM system. Moreover, in order to take into account of the vertical resolution of the MOPITT measurements, their averaging kernels as well as their a priori profiles are considered in the assimilation procedure. Note that the variance-covariance error matrices of MOPITT measurements are also taken
into account during the assimilation process through the error covariance matrix of the observations.

2.3 MOCAGE CTM and data assimilation system

The assimilation system used in this study is MOCAGE-PALM (Massart et al., 2005) developed jointly between Météo-France and CERFACS (Centre Européen de Recherche et de Formation Avancée en Calcul Scientifique) in the framework of the ASSET European project (Lahoz et al., 2007a). MOCAGE (MÔdèle de Chimie Atmosphérique à Grande Echelle) (Peuch et al., 1999) is a 3-D-CTM which covers the planetary boundary layer, the free troposphere, and the stratosphere. It provides a number of optional configurations with varying domain geometries and resolutions, as well as chemical and physical parametrization packages. It has the flexibility to use several chemical schemes for stratospheric and tropospheric studies. MOCAGE is used for several applications: operational chemical weather forecasting in Météo-France (Dufour et al., 2004) and data assimilation research (e.g. Cathala et al., 2003; Pradier et al., 2006; Clark et al., 2007; Semane et al., 2007; El Amraoui et al., 2008a,b; Semane et al., 2009). MOCAGE can be forced dynamically by external wind and temperature fields from either the European Centre for Medium-Range Weather Forecasts (ECMWF) analyses or the ARPEGE model analyses, the global operational weather prediction model of Météo-France (Courtier et al., 1991). The MOCAGE horizontal resolution used for this study is 2° both in latitude and longitude and the model uses a semi-Lagrangian transport scheme. It includes 47 hybrid (σ, P) levels from the surface up to 5 hPa, where \( \sigma = \frac{P}{P_s} \); \( P \) and \( P_s \) are the pressure and the surface pressure, respectively. MOCAGE has a vertical resolution of about 800 m in the vicinity of the tropopause and in the lower stratosphere. A detailed validation of the model using a large number of measurements during the Intercontinental Transport of Ozone and Precursors (ICARTT/ITOP) campaign was done by Bousserez et al. (2007). Its climate version has also been validated over several years by Teyssèdre et al. (2007). Moreover, MOCAGE has been combined with a Kalman Filter scheme to assimilate MOPITT
CO in order to calculate more realistic advection CO terms over Africa (Pradier et al., 2006). Recently, total columns of nitrous oxide (N\textsubscript{2}O) as measured by the Infrared Atmospheric Sounding Interferometer (IASI) instrument aboard the MetOp-A platform have been validated by MOCAGE in order to assess the transport processes in the tropics (Ricaud et al., 2009).

The assimilation module used in this study is PALM (Projet d’Assimilation par Logiciel Multiméthode): a modular and flexible software, which consists of elementary components that exchange data (Lagarde et al., 2001). It manages the dynamic launching of the coupled components (forecast model, algebra operators and input/output of observational data) and the parallel data exchanges. The technique implemented within PALM and used for the assimilation of O\textsubscript{3} and CO profiles from MLS and MOPITT, respectively, is the 3-D-FGAT method. This method is a compromise between the well-known 3-D-Var and 4-D-Var techniques (Fisher and Andersson, 2001). It compares the observation and background at the correct time and assumes that the increment to be added to the background state is constant over the entire assimilation window. The choice of this assimilation technique limits the size of the assimilation window, since it has to be short enough compared to chemistry and transport timescales. Using ozone profiles from the MIPAS instrument, this technique has already produced good-quality results compared to independent data and many other assimilation systems (e.g. Geer et al., 2006).

The assimilation system MOCAGE-PALM has been used to assess the quality of satellite ozone measurements (Massart et al., 2007). It has also been proven to be useful to overcome the possible deficiencies of the model. In this context, its assimilation product has been used in many atmospheric studies in relation to the ozone loss in the Arctic vortex (El Amraoui et al., 2008a), the tropics-midlatitudes exchanges (Bencherif et al., 2007), the stratosphere-troposphere exchanges (Semane et al., 2007), and the exchange between the polar vortex and the midlatitudes (El Amraoui et al., 2008b).
3 In-situ measurements and meteorological conditions during the stratospheric intrusion event

3.1 Ozonesonde measurements of the ozone anomaly over Lerwick on 15 August 2007

In this section, with the help of ozonesonde measurements, we characterize a positive anomaly of ozone in the UTLS region which occurred over the British Isles on 15 August 2007. At 12:00 UTC, an ozonesonde was launched from Lerwick (60.14° N, 1.19° W) as a part of the VINTERSOL (Validation of INTERnational Satellites and study of Ozone Loss) European field campaign. Fig. 1a shows the volume mixing ratio profile of ozone over Lerwick (solid line) recorded on 15 August 2007. It also depicts a mean profile (dotted line), which corresponds to the average of all August ozone profiles measured between 2004 and 2007. The shaded area represents the standard deviation (±σ) with respect to the mean August profile. The measured ozone profile on 15 August 2007 over Lerwick shows a strong positive deviation in comparison to the mean profile from 100 to 300 hPa peaking at 250 hPa (~10 km). Moreover, simultaneous ozonesonde measurements show very low relative humidity values (RH<5%) from the stratosphere down to 250 hPa compared to the mean August profile as illustrated in Fig. 1b. Similarly, Figure 1c shows the temperature profile over the same location on 15 August 2007. The tropopause height on 15 August 2007, as indicated by reversal in temperature gradient, is low compared to the average of all August profiles (2004–2007). Its downward displacement is estimated to be about 2 km. Finally, Fig. 1 shows just below 400 hPa a layer, which is ozone-rich, 1 km thick, very dry, and associated with a break in the vertical temperature lapse rate at approximately 315 K isentropic level. All the characteristics of this layer suggest the existence of a tropopause fold below the anomalously low-altitude tropopause. This is a clear signature of a strong baroclinic development event which is very likely associated with an STE event. In the next sections, we will document this event using meteorological analyses from the ARPEGE model as well as assimilated fields of O₃ and CO from the MLS and MOPITT.
3.2 Meteorological conditions during the stratospheric intrusion event

The purpose of this section is to document the stratospheric intrusion which took place on 15 August 2007 over the northern British Isles with the help of the meteorological parameters. We give a dynamical context concerning the $\text{O}_3$ anomaly observed in the ozonesonde measurements and presented in Sect. 3.1. According to Hoskins et al. (1985), an upper-level cyclonic PV anomaly is associated with a decrease of the tropopause height. Therefore, the signature of stratospheric air descending to lower altitude levels can be seen in the potential vorticity field plotted on isentropic surfaces. Figure 2 top shows a PV isentropic map at 315 K on 15 August 2007 at 12:00 UTC from the ARPEGE analyses. It shows high values of PV over northern Great Britain which corresponds to an anomaly of the cyclonic PV at the tropopause. The PV contours are almost cut off from the stratospheric continuum and the PV maximum is located near the northern British Isles (61° N, 7° W). Also note on Fig. 2 top the strip of 1.5 potential vorticity units (pvu) stretching from western Spain to southern England which will be further below associated with the upper level dynamics of a tropopause fold. Figure 2 bottom shows a zonal vertical cross-section (longitude versus pressure) across the region of lowest altitude tropopause described by the Lerwick ozonesonde measurements. As expected, the tropopause decreases with height particularly between the longitude range 0–10° W due to the strong cyclonic PV anomaly occurring above. In this region of the lowest altitude tropopause along the upper level trough (as low as about 430 hPa), rapid mixing by turbulence and convection may lead to irreversible STE events (Gouget et al., 2000).

ARPEGE analyses are used in order to describe the synoptic conditions during the stratospheric intrusion event. Figure 3 shows analyses of geopotential height (Fig. 3a), and potential temperature (Fig. 3b) on the potential vorticity iso-surface 1.5 pvu. In addition, the horizontal wind (both velocity and direction) and the relative humidity at 250 hPa pressure level are presented in Fig. 3c and d, respectively. The meteorolog-
ical conditions show a typical baroclinic wave developing over western Europe with an intense trough extending from northeast of Iceland to northwest of Spain (Fig. 3a) and with jet-streaks on both sides of the upper-level trough (Fig. 3d). This trough isolates many tongues characterized by low values of geopotential height and potential temperature (see Fig. 3a and b). Above Lerwick, the region of the ozonesonde measurements (see Fig. 1), the dynamical tropopause (1.5 pvu iso-surface) descends to as low as 6.5 km altitude (Fig. 3a). This is the place where physical processes may lead to irreversible stratosphere-troposphere exchange. In addition, there is also a tropopause break from 10 km altitude down to 6.5 km altitude (Fig. 3a) stretching a line along the cyclonic-shear side of the eastern jet streak (Fig. 3b) from northwest of Spain to East of Denmark. The tropopause break and the parallel PV band stretching on 315 K (Fig. 2) are dynamical signatures of on-going upper-level frontogenesis and tropopause folding (Keyser and Shapiro, 1986). This kind of fold is generally a consequence of an ageostrophic circulation near a jet streak, where the air from the lower stratosphere is intruded into the troposphere. In our case, we notice horizontal winds in excess of 50 m/s, showing an upper-level jet streak with southwest winds from the north of Spain to the west of Denmark at the 250 hPa pressure level. As a consequence of this circulation, the stratospheric air enters the troposphere beneath the core of the jet and on its cyclonic (poleward) side. Characteristic signatures of the intruded air are high PV, low RH, high O$_3$ and low CO concentrations. Irreversible stratospheric intrusions may occur along the 315 K isentropic surface, as suggested by the ozone layer captured below the low tropopause on the ozonesonde measurements at Lerwick (see Fig. 1). In the following sections, we seek signatures of the upper level dynamics on the distribution of O$_3$ and CO by using modelled outputs, both in the free model run and with the assimilation of satellite observations.
4 Evaluation of O$_3$ and CO assimilated fields

Throughout all this study, the model is forced by winds, temperatures, humidity and surface pressure from the ARPEGE analyses. The comprehensive chemical scheme RACMOBUS used for the assimilation of O$_3$ and CO measurements includes both the tropospheric RACM (Stockwell et al., 1997) and the stratospheric REPROBUS schemes (Lefèvre et al., 1994) since we are interested in the exchange between the troposphere and the stratosphere.

The assimilation experiments for O$_3$ and CO started on 20 July 2007. The initialization field for this date has been obtained by a free model run (MOCAGE with the detailed RACMOBUS chemistry scheme) started from the April climatological initial field. Thus, for each species (O$_3$ and CO), we have a free model run spin-up of more than 3 months in addition to 25 days of data assimilation concerning each species before the date of the stratospheric intrusion event. We estimate this spin-up period to be sufficient enough to have both O$_3$ and CO fields well balanced with respect to the atmospheric chemistry and dynamics.

In this section, we evaluate the quality of MLS O$_3$ and MOPITT CO assimilated fields into the MOCAGE-PALM assimilation system. This evaluation is required to test several assumptions introduced into data assimilation and to check the consistency of the analyses to the observations.

Several diagnostics, which consist of self-consistency tests, have been developed to check the quality of the assimilation runs (Talagrand et al., 2003). The chi-square ($\chi^2$) test enables assessment of the estimation of the observation and background error covariance matrices (e.g. Khattatov et al., 2000) as well as other parameters such as the model error growth (e.g. El Amraoui et al., 2004). A value of $\chi^2$ close to 1 indicates a good estimation of both error-covariance matrices, whereas a value of $\chi^2$ lower (greater) than 1 implies an overestimation (underestimation) of the observation and/or background error covariance matrices. Another consistent self-diagnostic is based on observation minus analysis (OMA) residuals and observation minus forecast (OMF) in-
novations. This diagnostic, defined in the observation space, checks the consistency of both forecast and analysis distributions with respect to the observations (Lahoz et al., 2007b).

4.1 Validation of O$_3$ assimilated fields

The assimilation period in this study is between 20 July and 19 August 2007 during which the value of $\chi^2$ for the O$_3$/MLS assimilation experiment varied between 0.81 and 1.22 with a mean value of 0.96. This result is satisfactory since it shows that both the observations and the background error covariance matrices were well estimated during the assimilation process.

Figure 4 shows the OMA and the OMF distributions for all MLS levels between 215 and 10 hPa corresponding to the assimilation period. The two distributions are nearly Gaussian which supports the fact that both observation and forecast are assumed to have Gaussian errors. We note that mean OMF values are close to zero (~0.08 ppmv), which suggests that the bias between the model and the observations is very small. Indeed, if the mean of the OMF statistics is significantly different from zero, this indicates a bias in the model or the observations. The OMA histogram is narrower than that for OMF and the bias is reduced. Besides, the standard deviation of OMA is smaller than that of OMF ($\sigma_{\text{OMA}}=0.44$ ppmv whereas $\sigma_{\text{OMF}}=0.93$ ppmv). This indicates that the analyses are closer to the observations than to the forecasts.

To further test the behaviour of the data assimilation system, assimilated fields of MLS O$_3$ observations have been compared to MOZAIC measurements. The MOZAIC programme was launched in January 1993. The measurements started in August 1994, with the installation of ozone and water vapour sensors aboard 5 commercial aircraft. In 2001, the instrumentation was upgraded by installing carbon monoxide sensors on all aircraft and a total odd nitrogen instrument (NO$_y$) aboard one aircraft. Ozone is measured by UV absorption (Thermo Instruments, Model 49–103). The instruments are calibrated before and after each period of deployment (~every 12 months) and in-flight quality control is achieved, both for bias and calibration factor, with a built-in
ozone generator. A comparison of the first 2 years of MOZAIC data with data of the ozonesonde network showed good agreement (Thouret et al., 1998). For the measurement of CO, the infra-red (IR) gas filter correlation technique is employed (Thermo Environmental Instruments, Model 48CTL). This IR instrument provides excellent stability, which is important for continuous operation without frequent maintenance. The sensitivity of the instrument was improved by several modifications (Nédélec et al., 2003), achieving a precision of ±5 ppbv or ±5% for a 30 s response time. A complete description of the MOZAIC programme may be found at http://mozaic.aero.obs-mip.fr/web/ and in the IGAC Newsletters (Cammas and Volz-Thomas, 2007).

The comparison between MLS O₃ assimilated field and MOZAIC observations is made in terms of time-series over the assimilation period (20 July–19 August). Assimilated O₃ output are then collocated to MOZAIC data in terms of time and space. Note that only observations above the altitude pressure of 280 hPa are considered since we are interested in the tropopause layer (The cruise flight altitude pressure of MOZAIC aircraft is around 200 hPa). Figure 5 shows the time-series of O₃ assimilated field with its standard deviation (shaded colour) compared to MOZAIC data for a one month period. The behaviour of both datasets is consistent throughout the period of comparison. Nevertheless, assimilated fields underestimate the O₃ distribution compared to MOZAIC measurements. The bias between aircraft and assimilated O₃ is about 11.5 ppbv with a RMS of ~33.5 ppbv and a correlation coefficient of 0.81. These results suggest that MOZAIC in-situ measurements and O₃ assimilated field are in good agreement in the UTLS region.

As an additional validation, the deduced total column from O₃/MLS assimilated field is compared to the total column measured by the OMI (Ozone Monitoring Instrument) sensor onboard Aura satellite (Levelt et al., 2006). OMI is a nadir-scanning instrument that detects backscattered solar radiance at visible (350–500 nm) and UV wavelength channels (270–314 nm and 306–380 nm) to measure O₃ column with near global coverage over the Earth with a spatial resolution of 13 km×24 km at nadir (except for polar night latitudes).
Figure 6 shows a comparison between $O_3$ total columns deduced from the MOCAGE free run, OMI and MLS assimilated field corresponding to 15 August 2007. MOCAGE obviously underestimates the amount of $O_3$ total column, whereas total columns from OMI and MLS assimilated field are nearly the same, especially in the area of interest. The average bias between OMI and free model run (assimilated field) is positive (negative) with a value of 17.64 DobsonUnit (DU) ($-13.21$ DU) and a corresponding RMS of 12.82 DU ($12.10$ DU). The correlation coefficient is 0.66 and 0.82 between OMI and free model run and between OMI and assimilated MLS, respectively.

The validation exercise with MOZAIC and OMI datasets confirms that the assimilation of $O_3$ from the MLS instrument improves the $O_3$ distribution, particularly in the UTLS region. This $O_3$ product will be used later in order to characterize the depth of the stratospheric intrusion in comparison to the PV field.

4.2 Validation of CO assimilated fields

Concerning the assimilation of MOPITT CO, the value of $\chi^2$ varied between 0.4 and 0.6. This shows that the observation and/or background error covariance matrices are somewhat overestimated in our assimilation experiment. To try to converge towards a value as close as possible to 1, we conducted several tests with different values of the background error which show that the variation of this parameter has little effect on the value of $\chi^2$. Thus, the low value of $\chi^2$ is most likely due to the overestimation of the error covariance matrices of MOPITT observations. Despite this fact, we prefer working with the actual error covariance matrices of the retrieved MOPITT CO since (i) they are a consistent characteristic of MOPITT that takes into account many considerations: instrument characteristics, retrieval algorithm and validation, and (ii) the MOPITT assimilated field gives satisfactory results in comparison to independent data (see Figs. 8 and 9 and their associated comments).

Figure 7 presents the OMA and the OMF distributions for all MOPITT levels corresponding to the period between 20 July and 19 August 2007. Similar conclusions as for MLS $O_3$ assimilated fields can be deduced. The two distributions are nearly Gaussian.
and the mean OMF values are close to zero (\(\sim -1.44 \text{ ppbv}\)) suggesting that the bias between the model and the observations is very small. The OMA histogram is narrower than that for OMF (\(\text{mean}_{\text{OMA}} = 1.09\)) and the standard deviation of OMA is smaller than that of OMF (\(\sigma_{\text{OMA}} = 9.17 \text{ ppbv}\) whereas \(\sigma_{\text{OMF}} = 19.03 \text{ ppbv}\)).

All these results concerning the OMF and the OMA statistics for both \(\text{O}_3/\text{MLS}\) and \(\text{CO/MOPITT}\) obviously illustrate the capability of data assimilation to reduce the bias between the observations and the model, and therefore adds value.

To validate the CO assimilated fields, we compare them to in-situ MOZAIC measurements in terms of time-series and vertical profiles. For time-series comparison, the same methodology is applied as for \(\text{O}_3\) comparison (see Sect. 4.1). Figure 8 shows the time-series of MOPITT CO assimilated field with its standard deviation (shaded colour) compared to MOZAIC data over the same period as for \(\text{O}_3\). Again, only observations above the altitude pressure of 280 hPa are considered. We note from Fig. 8 that the behaviour of both datasets is the same over the full period of comparison and MOZAIC measurements remain generally inside the error bars of CO assimilated field. The maxima and the minima of CO are well localized in both datasets. Note that assimilated fields underestimate the CO concentrations in comparison to MOZAIC measurements. The bias between aircraft and assimilated CO is about 7.4 ppbv with a RMS of \(\sim 16.4 \text{ ppbv}\) and a correlation coefficient of 0.77. This suggests that MOZAIC in-situ measurements and assimilated CO are in good agreement in the UTLS region.

Another comparison was conducted with collocated vertical profiles of both datasets over the two MOZAIC airports visited over the whole assimilation period, Frankfurt, Germany (52.35° N, 14.55° E) and London, UK (51.3° N, 0.10° W). Note that collocated observations are selected in 2° radius area over both airports. The comparison between MOZAIC and CO assimilated profiles over the two airports are shown in Fig. 9. Both comparisons show a very good agreement between MOZAIC and CO assimilated profiles. The difference between MOZAIC and assimilated profiles, for both locations, are very small at all altitudes and the vertical variability is similar for both datasets.

After validating the assimilated CO product using MOZAIC in-situ data, we compared
the total column deduced from assimilated CO to that retrieved from the Aqua/AIRS (Atmospheric Infrared Sounder) instrument. AIRS instrument onboard Aqua was launched in 2002 with its primary goal of determining the vertical profiles of temperature and water vapour in the Earth’s atmosphere (Aumann et al., 2003). CO retrievals are obtained from the 2160–2200 cm\(^{-1}\) portion of the spectrum on the edge of the 1–0 vibration-rotation band of CO, and the AIRS retrieval method was described by Susskind et al. (2003) and McMillan et al. (2005). AIRS CO measurements are provided at approximately 45 km × 45 km horizontal resolution and 1600 km swath, and therefore, combined with its cloud clearing capability, AIRS can obtain near daily global coverage. AIRS tropospheric CO profiles as well as the mixing ratios at 500 hPa have been compared with those of MOPITT (Warner et al., 2007). An average CO bias of 10–15 ppbv between AIRS and MOPITT observations is identified and the biases are mainly due to the prior information used in the retrieval algorithms.

Figure 10 presents the comparison between the results of MOCAGE free model run, the assimilation of MOPITT CO in MOCAGE-PALM and AIRS CO total column independent data. Note that, for this comparison, the averaging kernels of AIRS have not been applied to neither MOCAGE nor to assimilated total columns, since we are not interested in a quantitative evaluation of the different products. This Figure clearly shows the positive impact of MOPITT CO assimilation with an obvious improvement in terms of CO distribution (see the differences, AIRS-MOCAGE and AIRS-Assimilated MOPITT: Fig. 10d and e, respectively). Total columns from AIRS and assimilated field almost show the same behaviour: a maximum of CO on the west side of the British Isles, and a minimum of CO over the British Isles and northward. These features are not present in the MOCAGE free model run. The close agreement between the assimilated CO MOPITT field and the AIRS data provides confidence in the MOCAGE-PALM results.

These validation tasks confirm that the MOPITT CO assimilated fields within MOCAGE-PALM is well suited for the study in relation with the stratospheric intrusion event.
5 Characterization of the stratospheric intrusion event with O$_3$ and CO assimilated fields

In this section, we focus on the comparison of the STE event representation as diagnosed in Sect. 3, with MOCAGE runs with and without assimilation of satellite data.

5.1 Signature of the stratospheric intrusion in O$_3$ assimilated fields

To look for the ozone signature indicating stratospheric intrusions, we analyse modelled and assimilated O$_3$ fields on isentropic maps and in vertical cross-sections (Fig. 11). The isentropic distribution of modelled O$_3$ over the domain of interest (Fig. 11a) is quite homogeneous. However, the upper level dynamics is associated with very weak maxima over the two regions of interest. Firstly, over northern UK where the positive anomaly of ozone in the lowermost stratosphere and the tropopause fold were observed (see Fig. 1), and secondly over northwestern Spain where a PV strip on the 315 K surface suggested the existence of a tropopause fold. The vertical cross-section north of UK (Fig. 11b) confirms a strong underestimation of modelled O$_3$ well above the dynamical tropopause (1.5 pvu isoline). This is due to the fact that there is no evidence of an ozone maximum in the 300–200 hPa layer between 10° W and 0° W, where the ozonesonde measurements (Fig. 1) indicated a positive ozone anomaly. Further, at 400 hPa, where a tropopause fold is suggested on the ozone sounding (Fig. 1), there is less signature of a stratospheric intrusion in the modelled O$_3$ field. A large improvement is made by the O$_3$ assimilated field for which values are 50% to 100% greater than modelled O$_3$ ones in regions of interest (Fig. 11c). The O$_3$ assimilated field displays in the 300–200 hPa layer, a maximum with ozone values in excess of 500 ppbv (Fig. 11d), which better fits with the positive ozone anomaly observation, although there is still a quite strong underestimation. On the 315 K isentropic surface where the stratospheric intrusion dives below 400 hPa between 10° W and 0° W, O$_3$ assimilated field is marginally increased (Fig. 11c, d). This improvement is insufficient to quantitatively reproduce the stratospheric intrusion event. This can be explained by the fact that O$_3$
retrievals from the MLS sensor are only available above the 215 hPa pressure level and that the information acquired by assimilation has not propagated through atmospheric transport further below the 200–300 hPa layer in such a very deep stratospheric intrusion. In the next section, we will further describe the STE event representation with the assimilation of CO from MOPITT.

5.2 Signature of the stratospheric intrusion in CO assimilated fields

The 315 K CO distribution from the free run of MOCAGE (Fig. 12a) does not show the expected minima of CO tracing stratospheric intrusions. In the vertical cross-section (Fig. 12b), the lowermost stratosphere between 10°W and 0°W is associated with free run modelled CO values of about 80 ppbv, which are too big to suggest a stratospheric origin. MOPITT CO observations, which are generally sparse and have a low vertical resolution (~3–4 km) in the UTLS region, lack in principle the spatial and temporal resolutions required to capture stratospheric intrusion events, for which the synoptic variability is quite important. However, the assimilation of MOPITT observations and the transport greatly improve the distribution of CO in the UTLS region as demonstrated by the ability of the run with assimilation to capture signatures of stratospheric intrusions. The CO assimilated field distribution at 315 K (Fig. 12c) obviously exhibits an intense minimum of CO (<60 ppbv) north of UK where the ozonesonde measurements (see Fig. 1) indicate a very low tropopause overhanging a tropopause fold, in agreement with the potential vorticity maximum on the 315 K surface (Fig. 2 top). In the vertical cross section (Fig. 12d), the distribution of the assimilated CO field has been improved in the tropopause region, which is bounded by the dynamical tropopause (1.5 pvu isoline) and the thermal tropopause deduced from lapse rates of ARPEGE temperature profiles. A minimum of assimilated CO nicely fits within the stratospheric intrusion down to 400 hPa between 10°W and 0°W. At longitudes of upper level ridges with a higher tropopause (35°W, 10°E, and 35°E), the CO assimilated field displays high values compared to the free model run field (Fig. 12b, d) up to the thermal tropopause. The thermal tropopause has almost the same behaviour as the
dynamical tropopause, nevertheless it is higher. This is in accordance with the finding of Kim et al. (2001). The thermal tropopause is strongly influenced by uplift vertical motion, whereas the dynamical tropopause is more influenced by downward motion. This explains the large CO concentration observed above the dynamical tropopause. This could be the consequence of the uplift vertical air motion which modify the height of the thermal tropopause, whereas the dynamical tropopause changes through diabatic heating such as radiative heating as reported by Kim et al. (2001). Indeed, the stratospheric intrusion event located between 10°W and 0°W is better represented by the dynamical tropopause. Discussions about the difference between the thermal and the dynamical tropopauses are beyond the scope of this paper. For more explanations, the reader is referred to e.g., Kim et al. (2001); Wirth (2001) and references therein.

A possible perspective of this study is a further investigation of processes contributing to the observation of a mixing layer at the tropopause.

Finally, a relative minimum of CO assimilated field stretching out from over western Spain to Brittany (northwest of France) (Fig. 12c) also fits well with the potential vorticity strip (Fig. 2 top). This has been described in Sect. 3 as the dynamical signature of a tropopause fold developing beneath the jet streak over western Europe (Fig. 3c). Signatures of this tropopause fold in the run with assimilation are further described. As suggested by the 1.5 pvu contour in a vertical cross-section at 45°N (Fig. 13b), the tropopause fold develops down to 500 hPa. The CO assimilated field, which is consistent with the upper-level dynamics, with values less than 70 ppbv, has been transported down to below 300 hPa, whereas the CO values from the free model run exceed 80 ppbv at the same location (not shown). The O₃ assimilated field (Fig. 13a) shows ozone values greater than 200 ppbv inside the tropopause fold down to 400 hPa, whereas modelled free run of O₃ values larger than 200 ppbv stay above 150 hPa in the run without assimilation (not shown). These results demonstrate that the assimilation of O₃ from MLS and CO from MOPITT is a very efficient tool for STE studies.
6 Conclusions

In this study, by using the global chemical transport model of Météo-France MOCAGE, we demonstrate the capability of assimilated fields of MLS O$_3$ and MOPITT CO observations to better describe the UTLS region and a stratosphere-troposphere exchange (STE) event in comparison with modelled free run of O$_3$ and CO fields. The novel result of this study demonstrates the usefulness of assimilated fields of CO retrieved from a tropospheric measurement sensor, such as MOPITT, in a STE event.

The assimilated products for both O$_3$ and CO revealed an improvement compared to the free model run results. They have been validated using independent MOZAIC aircraft measurements in terms of vertical profiles as well as total columns in comparison with OMI and AIRS instruments for O$_3$ and CO, respectively. The bias between aircraft and assimilated O$_3$ is about 11.5 ppbv with a RMS of $\sim$33.5 ppbv and a correlation coefficient of 0.81. The bias between aircraft and assimilated CO is about 7.4 ppbv with a RMS of $\sim$16.4 ppbv and a correlation coefficient of 0.77. In terms of total columns, the comparison between CO assimilated field and AIRS data revealed very good qualitative agreement. For O$_3$, the average bias between total columns from OMI and assimilated field is negative with a value of $-13.21$ DU and a corresponding RMS of 12.10 DU, and a correlation coefficient of 0.82. These validation exercises have revealed a generally good agreement between assimilated fields and different independent data either in terms of vertical profiles or total columns.

The studied stratospheric intrusion event occurred on 15 August 2007 over the British Isles and was accompanied by an intense tropopause folding. It was documented using meteorological analyses from the ARPEGE model, the global operational weather prediction model of Météo-France. The signature of this event has been verified using the vertical distribution of ozonesonde measurements over Lerwick, UK. Both MLS O$_3$ and MOPITT CO measurements lack the spatial and the temporal resolutions required to characterize the synoptic variations of the event. Moreover, O$_3$ MLS observations are only valid from 215 hPa up to the upper stratosphere, which is a strong limitation.
to reproduce deep stratospheric intrusions into the troposphere. Owing to its good dynamical forcing, the free model run provides rather realistic $O_3$ and CO vertical distributions. However, modelled $O_3$ and CO do not reproduce the features of the deep intrusion observed in this study. Assimilated data from MLS improve the representation of $O_3$ in the UTLS region, nevertheless this improvement is not sufficient enough to reproduce the intensity and the depth of the stratospheric intrusion event well. Conversely, assimilated CO data from MOPITT succeed in capturing the deep structure of the event both horizontally and vertically. The behaviour of CO assimilated fields is consistent with the synoptic evolution of the meteorological parameters in the UTLS region. This is in accordance with the fact that CO is a good tracer in this region, where complex dynamical and chemical processes occur.

Finally, it should be noted that the results of this work open new perspectives for using assimilated MOPITT CO data in STE studies. At this step, we are able to combine measurements from different sensors including their own uncertainties and vertical resolutions. Data assimilation of chemical observations from different sensors will be needed for a quantitative representation of chemical species in the UTLS region. Therefore, it will be a very efficient tool for STE studies.
