Abstract

Between July and November 2008, simultaneous observations were conducted by several orbiting instruments that monitor carbon monoxide in the atmosphere, among them the Infrared Atmospheric Sounding Instrument (IASI) and Measurements Of Pollution In The Troposphere (MOPITT). In this paper, the concentration retrievals at about 700 hPa from these two instruments are successively used in a variational Bayesian system to infer the global distribution of CO emissions. Our posterior estimate of CO emissions using IASI retrievals gives a total of 793 Tg for the considered period, which is 40% higher than the global budget calculated with the MOPITT data (566 Tg). Over six continental regions (Eurasian Boreal, South Asia, South East Asia, North American Boreal, Northern Africa and South American Temperate) and thanks to a better observation density, the theoretical uncertainty reduction obtained with the IASI retrievals is better or similar than with MOPITT. For the other continental regions, IASI constrains the emissions less than MOPITT because of lesser sensitivity in the lower troposphere. These first results indicate that IASI may play a major role in the quantification of the emissions of CO.

1 Introduction

The launch of a weather satellite, like METOP, generates new information flows about the atmosphere and the Earth surface with applications beyond Numerical Weather Prediction. The exploitation of such data usually leads to feeding them to data assimilation systems, where they co-exist with other data of different origin (Hollingsworth et al., 2008). Ensuring the consistency of these systems in spite of the heterogeneous data flows is an important challenge for the satellite products since their definition varies for each instrument (Rodgers et al., 2003). Since the beginning of this century, several instruments have provided information about the atmospheric concentrations of carbon monoxide CO, a key molecule to inform about the impact of human activities on the
evolution of the composition of the atmosphere: MOPITT (Deeter et al., 2003), Atmospheric Chemistry Experiment-FTS (ACE-FTS) (Clerbaux et al., 2005), Tropospheric Emission Spectrometer (TES) (Luo et al., 2007), SCanning Imaging Absorption spectrometer for Atmospheric Chartography (SCIAMACHY) (Buchwitz et al., 2007) and IASI. Many subjective choices may induce inconsistencies (or biases) between these high-level products, like for the selection of the auxiliary datasets that help the concentration retrievals. This may explain why the estimation of the surface emissions of CO, which is a major application of these data, has actually been limited to MOPITT so far (Arellano et al., 2004; Pétron et al., 2004; Allen et al., 2004; Heald et al., 2004; Pfister et al., 2004; Turquety et al., 2007; Clerbaux et al., 2008; Chevallier et al., 2009).

In this paper, we compare the inversion of CO emissions from MOPITT concentration retrievals and from IASI retrievals at global scale for a five-month period (from 1 July 2008 until 30 November 2008) with the aim of evaluating the consistency of the two products in such an application. CO emissions are retrieved at resolution 2.5° in latitude and 3.75° in longitude from instantaneous satellite data. Our approach is based on the variational inversion system of Chevallier et al. (2005), then implemented by a simplified chemistry module (Chevallier et al., 2009). This multi-species system includes the simplified chemistry-transport model (CTM) LMDz-SACS and its adjoint Pison et al. (2008), optimizing the four main reactive species of the methane oxidation chain (CH$_4$, CO, formaldehyde HCHO and OH). Data and methods are described in the next section. The results are shown in Sect. 2.4 and discussed in the last section.

2 Method and data

2.1 Inversion system

The data assimilation system follows the work initiated by Chevallier et al. (2005) for CO$_2$. As described in Chevallier et al. (2009), it seeks an optimal solution for global CO sources that is statistically consistent, in a Bayesian sense, with both the observed
atmospheric concentrations and the available a priori information about the sources. The solution is found by the iterative minimization of a cost function $J$ defined as:

$$J(x) = (x - x_b)^T B^{-1} (x - x_b) + (H(x) - y)^T R^{-1} (H(x) - y)$$

(1)

$H$ is the CTM LMDz-SACS described in the next section coupled with the averaging kernels of the satellite retrievals. $x_b$ are the prior fluxes described in Sect. 2.3 with error statistics defined by the covariance matrix $B$. $y$ are the observations of Sect. 2.4, the error statistics of which are represented by the covariance matrix $R$. The state vector $x$ is made of the following variables:

- the global CO, CH$_4$, HCHO and methylchloroform MCF emissions at an 8-day and $3.75^\circ \times 2.75^\circ$ resolution,

- the 3-D-atmospheric source of HCHO from chemical oxydation of volatile organic compounds (VOC) and CH$_4$ at the same space-time resolution,

- the OH atmospheric concentrations at the same space-time resolution, except that only four degrees of freedom in latitude are actually kept by lack of MCF observations (Bousquet et al., 2005),

- the 3-D initial conditions of CO, CH$_4$, HCHO and MCF.

In this study, the June–November 2008 period is processed at once. However, the first month (June) will not be considered in the following because the inversion system hardly distinguishes errors in the fluxes for the first couple of weeks and errors in initial concentrations.

The M1QN3 limited-memory quasi-Newton software developed by Gilbert and Lemaréchal (1989) is our minimizer. Fifteen iterations are needed to reduce the norm of the gradient of $J$ by a 20-fold factor.

This inversion system follows statistical principles and a full probability distribution function (pdf) of the posterior CO emissions could in principle be inferred. With Gaussian prior and Gaussian observation uncertainties (fully described by $B$ and $R$), the posterior
pdf follows a multivariate Gaussian law. To limit the computational burden, the inversion system focuses on the solution with the largest probability. However, the width of the pdf is an important indicator of the reliability of the inferred emissions. Our approach to get the posterior uncertainty consists in performing an ensemble of inversions (Chevallier et al., 2007). The members of the ensemble differ by the prior emissions and by the observations: the ensemble of prior emissions follow the error statistics given by $B$ and the ensemble of observations follow the statistics given by $R$. Doing that, the ensemble of inverted emissions follow the theoretical posterior error statistics (see Sect. 3.1).

### 2.2 Chemistry-transport model

The global 3-D CTM used in this study is LMDZ-SACS (Chevallier et al., 2005; Pison et al., 2008). LMDZ is version 4 of the general circulation model developed at Laboratoire de Météorologie Dynamique (Hourdin et al., 2007). It is run here at global $3.75^\circ \times 2.75^\circ$ resolution, nudged towards the winds analysed by the European Centre for Medium-Range Weather Forecasts. SACS is the Simplified Atmospheric Chemistry System, which has been conceived as a simplication of the INCA scheme of Hauglustaine et al. (2004) and Folberth et al. (2006). As described by Pison et al. (2008), SACS aims to represent the oxydation chain of methane by solving the chemical interaction between a limited set of four species: CO, CH$_4$, HCHO and OH. The main assumption is to model only the production and the loss of CH$_4$, HCHO, CO and H$_2$ and to consider all other reactions as instantaneous. In order to save computing time in the iterative inversion system, LMDZ-SACS uses a number of fields pre-computed from LMDZ-INCA for the transport (e.g., atmospheric mass fluxes) and for the chemistry (e.g., reaction yields).

### 2.3 Prior emissions

The prior information provided to the inversion system mainly combines two datasets: version 3 of the Emission Database for Global Atmospheric Research (EDGAR3) inventory valid for 1995 for the fossil fuel emissions (Olivier and Berdowski, 2001) and...
version 2 of the Global Fire and Emission database (GFED-v2, Van der Werf et al., 2006) valid for 2006 for biomass burning. No effort is made here to adapt the 1995 EDGAR3 inventory or the 2006 GFED-v2 data to year 2008 in the prior (the adaptation is done by the inversion system based on the concentration observations). It should be reminded that since 1995 or even 2000, global economic growth, in particular in Asia, has modified the amplitude of the fossil fuel emissions (Ohara et al., 2007). Emissions of other species, like the biogenic ones, are those usually used in the LMDZ-INCA model and described in Folberth et al. (2006). The error standard deviations assigned to the prior emissions in the matrix $\mathbf{B}$ are set to 100% of the maximum value of the emission time series during the corresponding year for each grid point, as in Chevallier et al. (2009). This choice of a relatively large value has been made to relax the constrain on the prior emissions. This was found especially important for highly seasonal emissions such as fires. Additional tests are reported in the following using a value of 400%.

2.4 Observation data

2.4.1 IASI CO retrievals

As part of the payload of the METOP-A platform, the IASI interferometer has been flying on a low sun-synchronous polar orbit since October 2006, with equator crossing time about 09:30 and 21:30 LST. Its high spectral resolution allows simultaneous sounding of key meteorological and climate variables in the atmosphere, like temperature and carbon monoxide, while its large swath of about 2200 km provides near global coverage of the Earth twice a day. Each observation consists of 4 footprints of 12 km diameter (at nadir), every 50 km (Clerbaux et al., 2009). The CO products are retrieved from the IASI radiance spectra on a near real time mode (observation+3 h) at LAT-MOS. The present study makes use of the CO partial columns products as generated by the latest version of the FORLI-CO (Turquety et al., 2009), a retrieval code based on optimal estimation. The retrieved profiles are defined on a vertical grid of 19 stan-
standard levels (from 0.5 km to 18.5 km) and are provided with individual averaging kernels. CO total column products obtained by this processing algorithm have been validated against other spaceborne thermal infrared measurements (George et al., 2009), including MOPITT. In the continuity of our previous developments for MOPITT (Chevallier et al., 2009), only the layer closest to 700 hPa is used here (see next paragraph). Most cloudy situations are filtered out before the concentration retrieval. Less reliable retrievals have been identified for latitudes within 25° from the poles, at nighttime, and at locations with surface emissivity greater than 0.98 (icy surface) or lower than 0.93 (over desert). Those data are excluded from the inversion.

2.4.2 MOPITT CO retrievals

The MOPITT instrument has been flown onboard the NASA EOS-Terra satellite, on another low sun-synchronous orbit that crosses the equator at 10:30 and 22:30 LST. The spatial resolution of its observations is about 22 km at nadir. Its 640-km swath is smaller than for IASI and three days worth of measurements are needed to achieve global coverage. MOPITT has been operated nearly continuously since March 2000. Its products (here L2V5) have been made available at NASA Langley Atmospheric Science Data Center. They include CO mixing ratio at 7 standard pressure levels between the surface and 150 hPa for cloud free spots. We use the 700 hPa-level CO retrievals as a compromise between closeness to the surface and noise level (Deeter et al., 2003), together with their associated averaging kernels. Following the MOPITT data quality statement (http://web.eos.ucar.edu/mopitt/data/), only retrievals between 65° S and 65° N are used, as the weight of the a priori CO profile in the MOPITT retrievals increases towards the pole. Similarly, only the retrievals that are well constrained by the MOPITT radiances (i.e. for which the prior contribution is less than 50%, Deeter et al., 2004) are exploited. Nightime MOPITT observations may be biased (Crawford et al., 2004; Emmons et al., 2004) and have been left out.
2.4.3 Data processing

Both IASI and MOPITT retrievals are averaged at the CTM resolution (2.5° × 3.75°) at the orbit level in order to reduce the effect of correlated errors between neighbouring observations in the inversion system. About 840 000 IASI “super-observations” remain in the 6-month inversion against 515 000 “super-observations” for MOPITT, that has a lower spatial coverage. The number of observations are presented in Fig. 2 according to the 13 continental regions of Fig. 1. By comparison, an observing system that would provide one “super-observation” per day on each CTM grid box between 65° N and 65° S during the same period would have about 913 500 “super-observations”, which is not much larger than the IASI database used here.

As described by Emmons et al. (2004), by Turquety et al. (2009) and by George et al. (2009), and in order to properly compare MOPITT and IASI retrievals with the CTM outputs \( \mathbf{y}_{CTM} \), the corresponding \( \mathbf{A} \) is used to create a profile \( \tilde{\mathbf{y}} \):

\[
\tilde{\mathbf{y}} = \mathbf{A} \mathbf{y}_{CTM} + (\mathbf{I} - \mathbf{A}) \mathbf{y}_b
\]

with \( \mathbf{I} \) the identity matrix and \( \mathbf{y}_b \) the prior concentrations used in the MOPITT and IASI retrievals at NASA and LATMOS, respectively.

The averaging kernels inform about the sensitivity of the retrievals to the true CO profile, with the remainder of the information coming from the a priori profile \( \mathbf{y}_b \). They are valuable indicators of the vertical resolution of the products (Deeter et al., 2003). In both IASI and MOPITT products, a single prior concentration profile is used for all soundings, while an averaging kernel is provided with each profile.

The errors are assigned in the inversion system as a combination of the retrieval error reported in the MOPITT and IASI datasets, and of the CTM errors arbitrarily set to 50% of the retrieval values, without correlation.
3 Results

3.1 Uncertainty reduction

The map of the expected uncertainty reduction on the emissions from IASI is shown in Fig. 3. The uncertainty reduction is defined as \(1 - \frac{\sigma_a}{\sigma_b}\) \times 100, with \(\sigma_b\) the prior error standard deviation and \(\sigma_a\) the theoretical posterior error standard deviation (see Sect. 2.1). The reduction is larger in the Northern Hemisphere than in the Southern one. It reaches 65% per pixel in South Asia.

The uncertainty reductions on the emissions aggregated in the 13 continental regions of Fig. 1 are shown in Fig. 4. In the inversion with IASI retrievals, the uncertainty reduction is maximal in the South American Temperate region (70%), in South Asia (68%) and in Northern Africa (69%). Significant reductions are also seen for other regions (e.g., 48% in Europe).

The uncertainty reduction with IASI is higher than with MOPITT for three regions (Eurasian Boreal, South East Asia and South Asia) and similar to MOPITT in the regions North American Boreal, South American Temperate and Northern Africa. For the eight other regions, the uncertainty reduction obtained using MOPITT retrievals is significantly larger than in the experience with the IASI data: around 25% larger for Europe, USA and South American Tropical and around 45% larger for Middle East and Australia. As a sensitivity test, the error standard deviation assigned to the prior fluxes has been set to 400% against 100% (see Sect. 2.3). The impact on uncertainty is found to be small, with differences in the reduction of a few percents only (not shown). The reasons for the differences between the uncertainty reductions of IASI and MOPITT are twofold. First, the averaging kernels exhibit significant variability depending on location and time, through variability of the atmospheric temperature profile, surface pressure and temperature, etc. (Deeter et al., 2003). In general, the maximum sensitivities for IASI are observed between 6 and 10 km (Turquety et al., 2004) whereas MOPITT averaging kernels peak between 4 and 7 km. Second, the number of IASI “super observations” is larger than for MOPITT, as seen in Fig. 2, except over North-
ern Africa (97 000 vs. 91 000). When IASI and MOPITT provide a similar number of retrievals (e.g., in the Middle East or in Australia), the difference in uncertainty reduction is driven by the difference in averaging kernels, giving an advantage to the lower-sounding MOPITT.

3.2 IASI and MOPITT CO concentrations

As can be seen in Fig. 5a and Fig. 6a, MOPITT and IASI agree in the concentration patterns reasonably well, with high CO concentrations over Central Africa and East Asia, respectively associated with biomass burning and urban pollution.

The observed IASI (a), prior simulation (b) and IASI posterior simulation (c) CO concentrations are displayed in Fig. 5 for July 2008. The first-guess concentrations fit the IASI data rather well in the Southern Hemisphere. In the Northern Hemisphere, an underestimation by about 60% is seen, and even more over Alaska and East Asia (120%). These discrepancies are significantly reduced after the inversion. For MOPITT, as displayed in Fig. 6, and as for IASI, first-guess concentrations seem to be underestimated in the Northern Hemisphere. Over Central Africa and Indonesia, two regions that are affected by biomass burning, the CO simulated concentrations are higher than the observations (+40%). After optimization, some overestimation persists over this region (+30%). Indeed, the model does not exactly fit the observations since the analysis is pulled both towards the observations and towards the prior.

The MOPITT inversion is verified against the IASI concentrations and vice versa. Comparing both Fig. 5c, d and Fig. 6c, d, we can see that the IASI posterior concentrations present higher intensities than MOPITT posterior concentrations in the Northern Hemisphere, especially over the regions East Asia, Central Africa, and North American Boreal. To understand these discrepancies, a summary of differences between both satellite products is shown in Fig. 7 for the Northern Hemisphere, the Southern Hemisphere, the Tropics and for the whole globe. IASI and MOPITT retrievals are consistent to a large extent with a global correlation coefficient of 0.94. Among the latitudes bands, the highest correlation (at 0.83) is found in the Tropics (between 30° S and 30° N). This
coefﬁcient then decreases in the mid-latitudes of the Northern Hemisphere (0.76) and of the Southern Hemisphere (0.75). However, IASI shows many more high values than MOPITT: the slope ranges from 1.44 in the Tropics to 1.69 in the Northern Hemisphere.

3.3 Emissions

The total posterior CO emissions from July to November 2008 are shown in Table 1. Overall, both inversions lead to an increase of the CO emissions compared to the corresponding prior, with respectively +18% with MOPITT and +65% with IASI for the whole Earth. Both inversions provide analysis increments (posterior minus prior) of the same sign in most parts of the world (except for South Asia and Europe), even though the amplitude differs. An important increase is observed in Southern Africa, a region which is affected by biomass burning (+29% with MOPITT and +94% with IASI) and for South East Asia (+37% with MOPITT and +100% with IASI) as already noted in other studies (Carmichael et al., 2003; Palmer et al., 2003; Pétron et al., 2004; Arellano et al., 2004; Allen et al., 2004; Heald et al., 2004; Wang et al., 2004). These two regions are the largest emitters of CO among the 13 regions deﬁned, in the MOPITT and IASI analyses, with respectively 84 and 126 Tg for Southern Africa, and 78 and 114 Tg for South East Asia.

Posterior emissions are lower than the prior estimates in Indonesia, likely because the prior biomass burning inventory corresponds to an ENSO year 2006, and in the USA (−23% with MOPITT and −5% with IASI). For Europe and South Asia, the MOPITT-based posterior emissions are lower than the corresponding prior (−9%), which contrasts with the IASI-based posterior budgets (+21% and +6%, respectively). Both posterior emissions give the same budget of 20 Tg in the South American Tropical region but the difference ranges from 3% for Indonesia to 46% for South East Asia. The analysed total emissions with IASI are 40% higher than with MOPITT (793 against 566 Tg).
4 Conclusions

This paper shows the first comparison between inversions of CO emissions using IASI and MOPITT retrievals of CO concentrations at about 700 hPa. IASI and MOPITT global concentration patterns are similar, but IASI retrievals show larger concentrations, especially in the Northern Hemisphere. Consequently, the global CO emissions from July to November 2008 found with IASI (793 Tg) is 65% higher compared to the corresponding prior (479 Tg) and 40% higher than with MOPITT (566 Tg). The theoretical computations shown here indicate that, in principle, the IASI inverted emissions should be as reliable, or even more, than with MOPITT for six continental regions (Eurasian Boreal, South Asia, South East Asia, North American Boreal, Northern Africa and South American Temperate), thanks to its large data density. For the seven other regions, MOPITT better constrains the emissions because of better sensitivity in the lower troposphere than IASI.

To date, relatively limited experience has been gathered with IASI CO retrievals, in particular in comparison with the well-documented MOPITT 9-year database. Only a few months worth of IASI data were available for this study. Moreover, the fact that they correspond to recent dates prevented us from benefitting from surface measurements to rate the inversions. In spite of these limitations, the preliminary results gathered here show good promises for IASI to help pinning down the CO emissions.

A multi-instrument inversion strategy may filter the product-specific biases of the retrievals, with the inversion providing concentration values somewhere in-between the retrieval products. However, some biases may be shared by the two instruments, like the possible underestimation of very large concentrations (e.g., in fire plumes) caused by the use of a single prior profile in both concentrations products. Some improvements of the inversion results are also expected from the inclusion of formaldehyde retrievals, like those from the Ozone Monitoring Instrument (OMI) (Levelt et al., 2006). Indeed, observations of HCHO should indirectly constrain the emissions in the inversion system by informing about the secondary production of CO.
Acknowledgements. IASI has been developed and built under the responsibility of the Centre National d’Etudes Spatiales (CNES, France). It is flown onboard the Metop satellites as part of the EUMETSAT Polar System. The IASI L1 data are received through the EUMETCast near real time data distribution service. We acknowledge the NCAR Science team for MOPITT data. The authors acknowledge the Ether French atmospheric database (http://ether.ipsl.jussieu.fr) and LATMOS for providing the IASI data. Authors wish to thank F. Marabelle (LSCE) for computer support. The first author is funded by CNES.

The publication of this article is financed by CNRS-INSU.
