Lanzhou, which is located in a steep Alpine valley in western China, is one of the most polluted cities in China during the wintertime. In this study, an Aerodyne high resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS), a seven-wavelength aethalometer, and a scanning mobility particle sizer (SMPS) were deployed during January 10 to February 4, 2014 to study the mass concentrations, chemical processes, and sources of sub-micrometer particulate matter (PM$_1$). The average PM$_1$ concentration during this study was 57.3 µg m$^{-3}$ (ranging from 2.1 to 229.7 µg m$^{-3}$ for hourly averages) with organic aerosol (OA) accounting for 51.2%, followed by nitrate (16.5%), sulphate (12.5%), ammonium (10.3%), black carbon (BC, 6.4%), and chloride (3.0%). The mass concentration of PM$_1$ during winter was more than twice the average value observed at the same site in summer 2012 (24.5 µg m$^{-3}$), but the mass fraction of OA was similar in the two seasons. Nitrate contributed a significantly higher fraction to the PM$_1$ mass in winter compared to summer, largely due to more favored partitioning to the particle phase at low air temperature. The mass fractions of both OA and nitrate increased by ~5% with the increase of the total PM$_1$ mass loading, while the average sulphate fraction decreased by 6%, indicating the importance of OA and nitrate for the heavy air pollution events in Lanzhou. The size distributions of OA, nitrate, sulphate, ammonium, and chloride all peaked at ~500 nm with OA being slightly broader, suggesting that aerosol particles were externally mixed during winter, likely due to stagnant air conditions (average wind speed: 0.82 m s$^{-1}$). All species showed evident diurnal variations reflecting the important local/regional sources.

The average mass spectrum of OA showed a medium oxidation degree (average O/C ratio of 0.28), which was lower than that during summer 2012. This is consistent with weaker photochemical processing during winter. Positive matrix factorization (PMF) with the multi-linear engine (ME-2) solver identified six OA sources, i.e., a hydrocarbon-like OA (HOA), a biomass burning OA (BBOA), a cooking-emitted OA (COA), a coal
3 combustion OA (CCOA), and two oxygenated OA (OOA) factors. One of the OOAs was semi-volatile (SV-OOA) and the other one of low-volatility (LV-OOA). SV-OOA was the most abundant OA component (24\% of OA mass), followed by COA (20\%), LV-OOA (19\%), CCOA (18\%), BBOA (11\%), and HOA (9\%). The mass fraction of primary OA (= HOA + BBOA + COA + CCOA) increased during high PM pollution periods, indicating that local primary emissions were a main reason for the formation of haze in Lanzhou during winter. The primary OA sources were more complex during winter than during summer. Radiocarbon ($^{14}$C) measurement was conducted on four PM$_{2.5}$ filter samples from this study, which allowed for a quantitative source apportionment of organic carbon (OC). The non-fossil sources on average accounted for 55 ± 3\% of OC which could be mainly from biomass burning and cooking activities, suggesting the importance of non-fossil sources for the PM pollution in Lanzhou. Combining with the PMF results, we also found that a large fraction (57\%) of the secondary OC was from non-fossil OC.

1 Introduction

Frequent haze pollution events in urban areas in China have been a widespread concern in recent years due to its high adverse health effects, visibility degradation and climate effects (Chan and Yao, 2008). The Chinese Central Government had put in extensive efforts to find urgent and suitable control strategies to reduce further deterioration of air quality. Strategies such as promoting energy conservation and emission reduction measures and new air quality standards (PM$_{2.5}$ currently vs. PM$_{10}$ in the past) have been implemented in the last three years. Many local governments have also launched measures such as shutting down some highly polluting factories and restricting the use of private vehicles to reduce air pollution in their cities. However, air pollution in China is still far from being controlled due to its complex sources and limited knowledge on the multiple pathways leading to secondary aerosol formation and dynamic variation of aerosol mass loading.
Lanzhou, the capital of Gansu province, is located at the northwest of China and has experienced air pollution issues since the 1960s due to emissions from the petrochemical industry and its valley terrain. Air pollution is still serious and has become more variable in recent years (since 2000) because of fast urbanization and increased energy consumption. The severity of air pollution often reaches maximum intensity during winter due to coal combustion for domestic heating and cooking, similar to the situations in most cities of northern China (Wang et al., 2014); In addition, the stagnant meteorological conditions during winter in Lanzhou such as calm wind and shallow planetary boundary layer (PBL) caused by its valley terrain, are also important factors influencing the transport and diffusion of air pollutants. Despite the serious air pollution during winter in Lanzhou, aerosol chemistry, sources, and formation and transformation processes were poorly documented in the literature, which limit the development and implementation of efficient control strategies.

The chemical and physical properties of atmospheric aerosol particles during winter, especially during haze episode, have been investigated in metropolitan cities in Eastern China (Sun et al., 2006; Zhao et al., 2013; Huang et al., 2014; Sun et al., 2014). For example, the mean aerosol optical depth at 500 nm were up to ~0.7 during the month-long heavy haze pollution episode during January 2013 in Beijing (Bi et al., 2014); The airborne microbes were found in particulate matter (PM) during hazy period which may potentially include respiratory microbial allergens and pathogens (Cao et al., 2014). Collection and analysis of filter samples have enabled quantification of the chemical composition of PM using a suite of off-line instruments (such as ion chromatography, organic and element carbon analyzer, inductively coupled plasma-mass spectrometry and so on) in the laboratory (He et al., 2001; Zheng et al., 2005; Sun et al., 2006; Sun et al., 2011a; Zhang et al., 2013; Zhao et al., 2013). Semi-continuous measurement with hourly time resolution on chemical composition of aerosol particle is better compared to filter collection for elucidating the chemical processes during haze episodes (Gao et al., 2011; Xue et al., 2014; Zheng et al., 2015).
Previous studies on source apportionment of aerosol particle identified dust, traffic, industry, cooking-related activities, and secondary formation as important contributors, although the contributions of individual sources may change drastically with location, season, and different apportionment algorithms (Zheng et al., 2005; Yu et al., 2013; Huang et al., 2014). For example, Zheng et al. (2005) used chemical mass balance (CMB) to quantitatively apportion the sources that contribute to fine PM concentration in Beijing and found coal combustion contributed 16% of fine PM mass in January. By contrast, principal component analysis of the same dataset estimated almost twice amount of aerosols from coal combustion (Song et al., 2006). Source apportionment techniques such as positive matrix factorization (PMF) allow for using thousands of individual species for source identification and the error of analysis to constrain the fitting, and would thus appear more suitable to identify and apportion PM to their sources. Compared with the number of aerosol source apportionment studies using PMF in Eastern China (e.g., Sun et al., 2013b; Zhang et al., 2013), there were fewer studies in inland cities of China (Elser et al., 2016), the results of which can be used for inter-comparison and understanding the difference of aerosol pollution in different parts of China. In addition, it has been known that a large mass fraction of ambient PM during haze episodes is from fine particles, of which secondary species (some carbonaceous components, sulphate, nitrate, and ammonium) are major components (Zhao et al., 2013). However, the formation and evolution mechanisms of those secondary species were relatively poorly understood (Sun et al., 2014). The possible fast chemical reactions occurring during haze pollution further complicate our understanding of the formation processes of secondary aerosol, where high time resolution instruments are likely the best tools to be used.

Online instruments based on mass spectrometric techniques, such as Aerodyne aerosol mass spectrometer (AMS) (Jayne et al., 2000), appear to be the most advanced on probing the fast aerosol chemical processes because of the output of a large amount of chemical information and its fine time resolution (in minutes) and mass sensitivity (in ng
m$^{-3}$) (Canagaratna et al., 2007). Aerodyne high resolution time-of-flight mass spectrometer (HR-ToF-AMS) have been widely employed for the chemical characterization of submicron aerosol (PM$_1$) (DeCarlo et al., 2006). The instrument provides on-line quantitative mass spectra of the non-refractory (inorganic and organic) aerosol components with high time resolution. Frequently, the organic aerosol (OA) can be further analyzed using the PMF algorithm (Ulbrich et al., 2009; Zhang et al., 2011b), which can represent the organic mass spectral matrix as a set of source/process-related factor mass spectra and time series. In addition, carbon isotope technique has been recently applied to quantify the fossil/non-fossil origins of carbonaceous aerosols, and in combination with AMS-PMF analyses, the assessment of the origin of secondary organic aerosol (SOA) became possible (Minguillon et al., 2011; Huang et al., 2014; Zotter et al., 2014; Beekmann et al., 2015).

In a previous study, we used an HR-ToF-AMS, to investigate the chemical characteristics PM$_1$ in the urban area of Lanzhou during summer 2012 (Xu et al., 2014). During that study, organics in PM$_1$ was found to mainly originate from traffic, cooking activities, and chemical reactions which produced semi-volatile and less-volatility oxygenated OA. Compared to summer situation, energy consumption for heating is huge during winter and the dry and stable meteorological condition in the basin leads to longer aerosol lifetime during winter. Thus aerosols are influenced largely by very different chemical processes between the two seasons. Thus, more intensive measurements of PM chemical characteristics are needed to better understand aerosol sources, to quantify their lifetime in the atmosphere and to constrain the uncertainties of their climatic influences. During winter of 2013/2014, we conducted such a study at an urban site of Lanzhou. In this paper, we focus on the chemical speciation of PM$_1$ and source apportionment of OA.
2 Measurement and methods

2.1 Sampling site

Aerosol particle measurements were conducted from January 10 to February 4, 2014, at the top floor of a twenty-two story building (~70 m a.g.l) (36.05° N; 103.85° W, 1569 m a.s.l) in the campus of Lanzhou University (Fig. S1a). The campus is located in the Chenguan district of Lanzhou which is a cultural and educational area. The twenty-two story building sits at the western edge of the campus and faces a south-northern arterial road (Fig. S1a). At the campus side of this building, there is a three story dining hall of Lanzhou University, and over the arterial road side, there are many restaurants and residents. The room temperature was kept at ~20 °C by a central heating radiator. The weather in Lanzhou during the campaign was cold (avg. T = 0.5 °C) and dry (avg. RH = 28%), and was influenced by the Asian winter monsoon. Because Lanzhou is surrounded by mountains, atmospheric condition is normally stable with low wind speed (0.82 m s\(^{-1}\)) during this study. The sampling site represents a typical urban area dominated by residential and commercial area.

2.2 Instruments

The physiochemical properties of aerosol particles were monitored in real-time by a suite of instruments (Fig. S1b). The sampling inlet, constructed using 0.5 inch copper tube, stemmed out of the rooftop by about 1.5 m. A PM\(_{2.5}\) cyclone (model URG-2000-30EH, URG Corp., Chapel Hill, NC, USA) was used for removing coarse particles. The length of the sampling line was about 5 m. A diffusion dryer was placed upstream of this line to eliminate potential relative humidity (RH) effect on particles. The inlet was shared by an Aerodyne HR-ToF-AMS (Aerodyne, Inc., Billerica, MA, USA) for the size-resolved chemical speciation of non-refractory sub-micrometer PM (NR-PM\(_1\)), a single particle intra-cavity laser induced incandescence photometer (SP2, DMT, Inc., Boulder, CO, USA) for refractory black carbon (rBC) measurement, a customer-made scanning mobility particle sizer (SMPS) (Wiedensohler et al., 2012) for measuring particle size distribution between 10-800 nm, and a 7-λ aethalometer (model AE31, Magee Scientific,
Berkeley, CA, USA) to derive the mass concentration of light absorbing black carbon (BC) particles. The total air flow rate from the inlet was ~ 16 L min\(^{-1}\), with a vacuum pump drawing the air at a flow rate of 10 L min\(^{-1}\) and the other 6 L min\(^{-1}\) sampled by the instrument. The retention time of particles in the sampling line was less than 2.5 s. A parallel inlet with a 1:10 dilution stage was setup for real-time PM\(_{2.5}\) measurement using a tapered element oscillating microbalance (TEOM series 1400a, R&P, East Greenbush, NY, USA). The roof of the building also hosted instruments for monitoring meteorological parameters such as visibility, air temperature, wind direction, wind speed, and RH. The visibility was measured with a LED-based (880 nm) forward (42\(^\circ\)) scattering visibility sensor (model M6000, Belfort Ins., Maryland, USA).

2.2.1 HR-ToF-AMS operation

A detailed description of the principle and design of HR-ToF-AMS can be found elsewhere (Jayne et al., 2000; DeCarlo et al., 2006). Briefly, HR-ToF-AMS consists of three major sections: the inlet system, the particle sizing vacuum chamber, and the particle composition detection section. The combination of a 100 µm orifice and an aerodynamic lens in the inlet system are used to focus the airborne particles into a concentrated and narrow beam, and then accelerated into the vacuum chamber (~10\(^5\) Torr) modulated by a chopper for measuring aerodynamic size of the particle; Before being detected, the particles are flash vaporized under 600 °C and ionized by a 70 eV electron impact, and finally detected by the high resolution time-of-flight mass spectrometer. The chopper works at three positions alternately, i.e., an open position which transmits the particle beam continuously, a close position which blocks the particle beam completely, and a chopping position which modulates the beam transmission (2% duty cycle). The open and close positions yield the bulk and background signals for the airborne particle, respectively, while the chopping position modulates the particle beam by spinning chopper wheel (~150 Hz) to yield size-resolved spectral signals. The mass spectrometer in the detection section works in two modes based on the ionic path, i.e., V-mode and W-mode, with high sensitivity and high chemical resolution (~6000 m/∆m),
respectively. The highly sensitive V-mode signals are usually used for reporting mass concentration, while the high chemical resolution W-mode signals are used for the analyses of mass spectrum. The time resolution for both V and W modes was 5 min. Under V-mode, the instrument switched between the mass spectrum mode and the PToF mode every 15 s, spending 6 and 9 s on each, and cycled 20 times in one run; No PToF data were recorded in W-mode due to low signal-to-noise (S/N) ratios.

The instrument was calibrated for ionization efficiency (IE), inlet flow rate, and particle sizes using the standard procedure described by (Jayne et al., 2000). These three calibrations were performed at the beginning, in the middle and end of the field study. Particle-free ambient air was sampled at the end of the study to determine the detection limits (DLs) of individual species and also for adjusting the fragmentation table. Default relative ionization efficiency (RIE) values were assumed for organics (1.4), nitrate (1.1), sulphate (1.2), and chloride (1.3), while an RIE value of 3.9 was determined for ammonium following the analysis of pure NH$_4$NO$_3$. The close concentrations between measured ammonium and predicted ammonium based on the stoichiometric charge balance between nitrate, sulphate, and chloride (slope = 0.94, Fig. S4) suggest that these RIE values are suitable for this campaign.

2.2.2 Operations of other instruments

The SMPS consisted of a condensation particle counter (CPC) (TSI, model 3772) and a differential mobility analyser (DMA) was deployed at 5 min interval. Sample and sheath flow rates of the DMA were set to 1 L min$^{-1}$ and 5 L min$^{-1}$, respectively. The SMPS was calibrated using a polystyrene latex (PSL) standard prior to field measurements.

The SP2 uses an intra-cavity Nd:YAG laser at 1064 nm to determine the optical size of a single particle by light scattering and, if material within the particle absorbs at this laser wavelength, the refractory mass of the particle quantified by detection of the main light-
The absorbing component is rBC. The SP2 incandescence signal was used to obtain single particle rBC mass after calibration with Aquadag standard BC particles. The measured rBC mass is converted to a mass equivalent diameter, which is termed as the BC core diameter ($D_c$) - the diameter of a sphere containing the same mass of rBC as measured in the particle. Any measured particle with a detectable incandescence signal is referred to as an rBC particle, whereas a particle which only exhibits a scattering signal is termed as a non-BC particle. The total rBC mass loading is reported as the sum of all detected single particle rBC masses.

The aethalometer measures the optical attenuation (absorbance) of light from LED lamps emitting at seven wavelengths (370, 470, 520, 590, 660, 880, and 950 nm) with a typical half-width of 20 nm. The difference in light transmission through the particle-laden sample spot and a particle free reference spot of the filter is attributed to the absorption caused by aerosol. The attenuation of light is converted to the BC mass concentration using wavelength-dependent calibration factors as recommended by the manufacturer. BC was measured using data at 880 nm using a specific attenuation cross section of 16.6 m$^2$ g$^{-1}$ and an empirical correction factor (2.14) for the shadowing effect during the campaign. The flow rate was maintained at 4.8 L min$^{-1}$ calibrated using a flow meter. Detection limit of the aethalometer BC was determined to be 0.16–0.28 µg m$^{-3}$ with a flow rate of 4.8 LPM and 5 min time interval, calculated as three times the standard deviation ($3\sigma$) of the dynamic blanks. The TEOM was operated at a temperature of 40 °C in order to minimize mass loss due to volatilization of semi-volatile aerosol compounds. The time resolution of PM$_{2.5}$ mass concentration was 5 min.

2.3 Data processing
2.3.1 General AMS data processing

The HR-ToF-AMS data were processed using the standard software of SQUIRREL (v1.56) and PIKA (v1.15c) (http://cires.colorado.edu/jimenez-group/ToFAMSResources/ToFSoftware/index.html) to determine the mass
concentrations and the size distributions of the NR-PM$_1$ species and the ion-speciated mass spectra of organics, written in IGOR (Wavemetrics, Inc., Lake Oswego, OR, USA). An empirical particle collection efficiency (CE) of 0.5 was used, which has been widely used in field studies employing AMS with a dryer installed in front of the equipment's particle inlet. This CE value was further validated by the consistency between HR-ToF-AMS and SMPS data ($R^2 = 0.9$, Slope = 1.48, Fig. 3). The elemental ratios of OA (O:C, H:C, and OM:OC) for this study was determined using the "Aiken ambient" method (Aiken et al., 2008) other than the "improved-ambient" method (Canagaratna et al., 2015) which increased O:C on average by 27%, H:C on average by 10%, and OM:OC on average by 7% (Fig. S2). These "Aiken ambient" results of elemental ratios are more suitable here to allow for comparison with those during summer 2012.

2.3.2 Positive Matrix Factorization (PMF) analyses

The source decomposition of organics was analysed by PMF with the multilinear engine (ME-2) algorithm which serves to reduce rotational ambiguity within the PMF2 algorithm. The ME-2 algorithm allows the user to add a priori information into the model (e.g., source profiles) to constrain the matrix rotation and separate the mixed solution or the weak solution. The PMF analysis of organic matrix using ME-2 algorithm is implemented within the toolkit SoFi (Source Finder) and perform by the so-called a-value approach (Canonaco et al., 2013). First, organic matrix was analysed using the PMF2.exe algorithm in robust mode (Paatero and Tapper, 1994) and explored using the PMF Evaluation Toolkit (PET) (Ulbrich et al., 2009). The PMF solution was evaluated following the procedures outlined in Table 1 of Zhang et al. (2011a) including modification of the error matrix and downweight of low S/N ions. Moreover, based on the AMS fragmentation table, some organic ions were not directly measured but scaled to the organic signal at $m/z$ 44, which were downweighted by increasing their errors by a factor of 3. Some highly polluted periods were deleted during PMF analysis such as January 22-23, 2014. The results of four, five, and six factor solutions with $f_{Peak}$ at 0 are shown in supplementary material (Fig. S5-S7). It is easy to find that a hydrocarbon-like
OA (HOA) factor, a cooking-emitted OA (COA) factor, a semi-volatile and low-volatility oxygenated OA (SV-OOA and LV-OOA) factors could be clearly separated in the four-factor solution; for the HOA factor, there were significant contributions from \(m/z\) 60, 73, 92, and 115 in the mass spectrum, suggesting a mixing of multiple sources. In the five-factor solution, a coal combustion-emitted OA (CCOA) factor was separated; however, \(m/z\) 60 and 73 which are related to biomass burning OA (BBOA) could not be separated.

We then performed OA source apportionment using the ME-2 algorithm by constraining the profiles of HOA and BBOA with the fixed a-value of 0.1 for HOA and 0.4 for BBOA. The a-value test was performed following the technical guidelines presented in Crippa et al. (2014). The reference profile of HOA was adopted from the HOA of the summer study and the reference profile of BBOA was adopted from the nine-factor PMF solution of this study.

The size distributions of individual OA factors were determined via a multivariate linear regression technique (Ge et al., 2012). This algorithm assumes that each OA mass spectrum is the linear superposition of the mass spectra of individual OA factors, whose mass profiles are constant across the whole size range. Further details about the algorithm can be found in Xu et al. (2014).

2.3.3 Radiocarbon (\(^{14}\)C) data analysis

In order to identify the origins of SOA, we conducted \(^{14}\)C analysis on four filter samples. These filter samples were collected at the CAEERI site which is about 500 m away from the LZU site (Fig. S1a). Filter samples were collected using a low volume \(PM_{2.5}\) sampler (16.7 L min\(^{-1}\)) during January 2014 with a 24 h sampling time in every week for each filter (January 3rd, 8th, 15th, and 23rd, respectively) on pre-baked quartz filters. One field blank filter was collected and analysed to correct the filter sample measurements. Organic carbon (OC) was separated from the filters by combustion at 375 °C during 200 s in pure oxygen in a thermo-optical OC/EC analyser (Model 4L, Sunset Laboratory Inc, USA) (Zhang et al., 2012). The carbon isotopic analysis was conducted by online
coupling of the OC/EC analyser with the accelerator mass spectrometry system MICADAS at the University of Bern, Switzerland (Zotter et al., 2014; Agrioso et al., 2015). Fossil $^{14}\text{C}$ measurement results were transferred into the non-fossil fraction ($f_{\text{NF}}$) of OC using a conversion factor of 1.03.

For the apportionment of AMS-PMF OA factors using $^{14}\text{C}$ data (Zotter et al., 2014), we assume that all OC sources are represented by the six PMF factors and the $f_{\text{NF}}$ in NR-PM$_1$ was the same as that in PM$_{2.5}$. The OA mass of each PMF factor and total OA were first converted to OC mass using the OM:OC ratios derived from its MS (OM:OC$_{\text{HOA}}$ = 1.29, OM:OC$_{\text{BBOA}}$ = 1.5, OM:OC$_{\text{COA}}$ = 1.27, OM:OC$_{\text{CCOA}}$ = 1.37, OM:OC$_{\text{SV-OOA}}$ = 1.55, OM:OC$_{\text{LV-OOA}}$ = 2.01, OM:OC$_{\text{total}}$ = 1.51). For the OC mass concentration of the AMS factors, the following notations, hydrocarbon-like organic carbon (HOC), biomass burning organic carbon (BBOC), cooking organic carbon (COC), coal combustion organic carbon (CCOC), oxygenated organic carbon (OOC), total organic carbon from AMS (TOC$_{\text{AMS}}$), were adopted in the following sections. An $f_{\text{NF}}$ value was assumed a priori for the primary PMF factors HOC, BBOC, COC, and CCOC. The average $f_{\text{NF}}$ of OOC is then derived by the equation below:

$$f_{\text{NF,OOC}} = \frac{\text{TOC}_{\text{AMS}} - f_{\text{NF,HOC}} \times \text{HOC} - f_{\text{NF,BBOC}} \times \text{BBOC} - f_{\text{NF,COC}} \times \text{COC} - f_{\text{NF,CCOC}} \times \text{CCOC}}{(\text{SV-OOC} + \text{LV-OOC})}$$

Here HOC is assumed to originate from gasoline and diesel exhaust and contains exclusively of fossil carbon, i.e., $f_{\text{NF,HOC}} = 0$; BBOC is estimated partly from fossil carbon such as soft coal due to the popular usage in local residents, i.e., $f_{\text{NF,BBOC}} = 1$; COC is assumed to originate from non-fossil carbon such as cooking oil and dressing, i.e., $f_{\text{NF,COC}} = 1$; CCOC is estimated to originate from coal combustion, i.e., $f_{\text{NF,CCOC}} = 0$. 

13
3 Results and discussions

3.1 Overview of field study

3.1.1 Meteorological conditions

Fig. 1 shows the time series of meteorological parameters and PM$_1$ components during January 10–February 4, 2014. During the campaign, the measurement site mainly received air masses from northern and northwestern associated with low wind speeds (on average: 0.8 ± 0.4 m s$^{-1}$). The wind directions were associated with the typical anticyclone mesoscale weather forced by Tibetan Plateau in Lanzhou during winter. The mountains to the north and south of the city significantly reduced the wind speed. Air temperature was typical in winter of Lanzhou ranging from −10 to 14 °C (average = 0.5 ± 5.0 °C), but was a little warmer after the Chinese New Year (January 31, 2014) (Fig. 1a). No precipitation event occurred during the campaign, and RH was pretty low ranging from 8.8 to 50.7% (avg. = 27.7 ± 9.1%). The visibility ranged from 3.7 to 50 km (avg. = 16.0 ± 8.7 km).

3.1.2 Inter-comparisons

The inter-comparisons between AMS vs. SMPS and TEOM are shown in Fig. S3. Comparison between the mass concentration of PM$_1$ and the volume of particle measured by SMPS is tightly correlated ($R^2 = 0.9$) with a slope of 1.48, which represents the average density of bulk particles, assuming that the AMS and the SMPS measure a similar particle population. This value is indeed very close to the estimated PM$_1$ density (1.46) based on the measured particle composition for this study (using density of 1.2 g m$^{-3}$ for organics, 1.72 g m$^{-3}$ for NH$_4$NO$_3$, 1.77 g m$^{-3}$ for (NH$_4$)$_2$SO$_4$, 1.52 g m$^{-3}$ for NH$_4$Cl and 1.8 g m$^{-3}$ for BC) (Zhang et al., 2005; Bond and Bergstrom, 2006). The mass concentration of PM$_1$ is also closely correlated ($R^2 = 0.71$) with TEOM PM$_{2.5}$ concentrations with a slope of 0.73. Similar contribution of PM$_1$ to PM$_{2.5}$ were also observed in other cities in China during winter (Elser et al., 2016), such as Beijing (0.74 during 2011) (Sun et al., 2013b). Note that the actual mass ratio between PM$_1$ and PM$_{2.5}$
should be higher than these values since refractory materials such as crustal components were not measured.

3.1.3 PM\textsubscript{1} composition, variation, and acidity

The average mass concentration of PM\textsubscript{1} (NR-PM\textsubscript{1} + BC) was 57.3 µg m\textsuperscript{-3} (ranging from 2.1 to 229.7 µg m\textsuperscript{-3} for hourly average) during this study, with 51.2% of organics, 16.5% of nitrate, 12.5% of sulphate, 10.3% of ammonium, 6.4% of BC, and 3.0% of chloride (Fig. 2a). The average mass concentration was more than twice the average value observed during summer 2012 (24.5 µg m\textsuperscript{-3}). All species showed similar day-to-day variation with nitrate being the most significant one (Fig. 1d), suggesting an important local source for nitrate. The mass contributions of PM\textsubscript{1} species from low to high PM\textsubscript{1} concentrations showed an increased contribution for organics (49% to 53%) and nitrate (13% to 18%), but a decreased contribution for sulphate (17% to 11%) and BC (7.3% to 5.3%) suggesting somewhat different chemical processes/sources for each species during the haze pollution (Fig. 2b). Specifically, the increased organics was mainly due to the contribution of primary OA (POA) based on PMF analysis (more discussion are given in section 3.5). During the late part of Chinese New Year holiday (February 3 to end of the study), PM\textsubscript{1} concentration decreased in association with increased wind speed. NR-PM\textsubscript{1} appeared to be neutralized throughout this study, as indicated by an overall stoichiometric charge balance between the anions (i.e., nitrate, sulphate, and chloride) and the cation ammonium (slope = 0.94, Fig. S4). This result indicates that the inorganic particulate species were mainly present in the forms of NH\textsubscript{4}NO\textsubscript{3}, (NH\textsubscript{4})\textsubscript{2}SO\textsubscript{4}, and NH\textsubscript{4}Cl in PM\textsubscript{1}.

3.1.4 Size distribution

The average chemically-resolved size distributions of NR-PM\textsubscript{1} species are shown in Fig. 3a. While all components peaked between 400–500 nm, organic aerosol presented a wider distribution than the inorganics and extended to ~250 nm, suggesting the influence of fresh organics (primary OA, more discussion are given in section 3.4). These features were similar to those found in most urban sites by the AMS. The similar mode size of
inorganics and SOA (Fig. 3c) suggested the well external mixed air mass during the sampling period. The mass contributions of chemicals at the major peak (400–500 nm) were organics (~50%), nitrate (~20%), ammonium (~15%), sulphate (~10%), and chloride (~5%); while the contribution of organics increased with the decreasing of size mode (Fig. 3c). Comparing with the results observed during 2012 summer, the size distributions of aerosol particle during winter were narrower, although the mode sizes of major peaks were similar, indicating highly mixed and aged aerosol particles during winter.

3.2 Diurnal variations of aerosol species

All species show significant diurnal variations during the study suggesting the important local and regional sources of aerosol (Fig. 4). The observed diurnal trends of BC presented two dominant peaks with one at late morning (10:00–12:00) and another at early evening (20:00–22:00). The morning peak did not overlap with the rush hours (7:00–9:00), different than that of summer 2012; the BC mass loading started to increase from 6:00 continuously during morning, and reached maximum between 10:00–12:00 and then dropped down after the noon time. Another combustion tracer, carbon monoxide (CO), also showed the similar morning peak (Fig. 5). This morning peak was likely resulted from the formation of inversion layer during winter at Lanzhou which promoted accumulation of air pollutants from enhanced human activities in the morning. This inversion layer frequently formed from night time and diffused after the noon time due to the valley terrain. The temperature profile observed at the suburban Lanzhou (Yuzhong, ~30 km from the sampling site) showed a strong inversion in the low boundary layer during the morning time (Fig. S8). The evening peak of BC could result from increased human activities such as traffic, cooking, and heating coupled with low boundary layer after sunset. Organics had two sharp peaks at the noon time (12:00–13:00) and early evening (19:00–20:00) which correspond to lunch time and dinner time, respectively, indicating the importance of cooking-related emissions of OA. PMF analysis show that
cooking-emitted aerosol could contribute up to 30 – 60% of organics during meal times (section 3.4.3).

Sulphate presented two peaks with one occurring at the noon time (11:00–14:00) in accordance with the photochemical processes; this peak is narrower than that during summer, likely due to relatively weak photochemical activities. Another minor peak occurred between 20:00–22:00 which was likely due to the lowered boundary layer depth. The significantly higher concentration of sulphate during winter than summer suggests a higher precursor SO$_2$ emission and stagnant atmospheric conditions in winter. The diurnal pattern of sulphate during winter was similar to that of summer 2012 at Lanzhou and summer 2011 at Beijing, but was different from that of Beijing during winter 2011/2012 where aqueous processing was found to could play an important role (Sun et al., 2013b). Chloride had similar diurnal pattern with sulphate, although the evening peak was more obvious. The major source of hydrochloric acid is biomass burning, coal combustion and waste combustion (Ianniello et al., 2011). The significant evening peak could be related with these sources coupled with the shallow boundary layer. The high background concentrations of chloride during day and night suggest a persistent emission of hydrochloric acid which could be from the heating factory and power plants. The diurnal pattern of chloride during winter was different from that during summer 2012 which peaked during the night time due to temperature-dependent gas-particle partitioning. Nitrate peaked between 12:00–16:00, right after the peak of sulphate. The formation of nitrate during afternoon suggests that nitrate was dominated by the homogeneous photochemical production. Fig. 5 shows the variations of NO$_x$ and O$_3$ calculated from data downloaded from one station monitored by the Ministry of Environmental Protection of China, ~3 km southwest of sampling site (Fig. S1a); NO had a morning peak (7:00–10:00) and an evening peak (19:00–21:00) corresponding to rush hours; NO$_2$ increased from 10:00 which formed from NO consumed by OH radical and decreased from 14:00 corresponding to the formation of nitrate and O$_3$ during afternoon. The diurnal change of NO$_x$ ($\Delta$NO$_x$) mixing ratio was ~50 ppbv (from 150 to 100 ppbv), while the diurnal change of the sum of $\Delta$O$_3$ and $\Delta$NO$_3^-$ was ~30 ppbv. Considering the
higher mixing layer height during afternoon, it seems that nitrate was mainly formed from the photochemical processing of NOx. The diurnal pattern of nitrate during winter was vastly different from that during 2012 summer which was mainly controlled by the dynamic of mixing layer and gas-particle partitioning. It seems that atmospheric ammonia was first neutralized by sulphuric acid and hydrochloric acid to form ammonium sulphate and ammonium chloride, and the remaining ammonia may then combine with nitric acid to form ammonium nitrate.

3.3 Bulk characteristics and elemental ratios of OA

Table 1 shows the average elemental mass composition and mass contributions of six ion categories to the total organics. Carbon contributed 66% to the organics following by oxygen (25%), hydrogen (8%), and nitrogen (1%); correspondingly, C₅H₇⁺ dominated the organics by 59%, following by C₅H₇O⁺ (26%), C₅H₇O₂⁺ (10%), H₂O₃⁺ (2%), and C₅H₇N₂⁺ (2%). Compared with the results of 2012 summer, the organics in winter had higher carbon (66% vs. 59%) and C₅H₇⁺ content (59% vs. 56%), and lower oxygen content (25% vs. 26%) (Fig. 6c); this suggests that the organics during winter had a higher fraction of primary compounds than those during summer which is likely due to weaker photochemical activities, lower boundary layer height and more emissions from primary sources. The average O/C of organics, an indicator for oxidation state, was 0.28 during this study which was somewhat lower than that of summer 2012 (0.33) (Fig. 6a and b). Photochemical processing of organics during winter appeared to be significantly weaker and shorter than those during summer as shown by the diurnal pattern of O/C (Fig. 6d). The diurnal profile of H/C was inversely correlated with that of O/C, and the peaking of organic aerosol concentration usually corresponded to the high H/C ratio and low O/C ratio, indicating the dominant role of primary OA.

3.4 Source apportionment of OA

Source apportionment via PMF with ME2 engine on OA mass spectra resolved six components, i.e., HOA, COA, CCOA, BBOA, SV-OOA, and LV-OOA. Each component
has a unique mass spectral pattern, diurnal pattern, and temporary variation which correlated with corresponding tracers such as inorganic species. Two OOA components can be regarded as surrogates of secondary OA (SOA), with LV-OOA for more aged SOA and SV-OOA for fresher SOA; The HOA, BBOA, COA and CCOA components are regarded as primary OA (POA) based on their low O/C ratios and good correlations with primary aerosol tracers (Fig. 7). Comparison with the source apportionment results of summer 2012, the organic sources and chemical processes during winter 2013/2014 were more complex due to the multiple primary sources. Detailed discussion of each factor is given in the following subsections.

3.4.1 HOA

HOA factors had been frequently separated from the OA in urban area due to the emission from traffic and/or other fossil combustion activities (e.g., Sun et al., 2011b; Ge et al., 2012). The diurnal pattern of HOA in winter 2013/2014 of Lanzhou shows two predominant peaks in the morning (10:00–12:00) and evening (20:00–21:00), respectively (Fig. 5). The morning peak started from 6:00 was mainly associated with the morning traffic rush hours, and it maximized at late morning associating with the inversion layer as discussed in Section 3.2. The evening peak was relevant with the evening rush hours and low PBL depth after sunset. The relatively low concentration during afternoon was probably due to the high PBL depth as shown by the mass concentration variations of BC. The correlation between HOA and BC was high ($r = 0.84$, Fig. 7f and Table 2), as a big fraction of BC has been thought to emit from traffic activities and commonly used as a tracer of traffic emission. The minimum of HOA concentration, which typically occurred during afternoon or middle night, was still up to ~2 μg m$^{-3}$ suggesting a high background of HOA which is likely due to the stagnant air condition unfavourable for the diffusion of aerosol. The size distribution of HOA showed a mode size of ~200 nm (Fig. 3b) corresponding to the primary emitted aerosol behaviours and HOA could account for ~25% mass of aerosols between 100-300nm (Fig. 3c). The average concentration of HOA during 2013/2014 winter was 2.6 μg m$^{-3}$
accounting for 9% of organics (Fig. 8a). This concentration was higher than that of 2012 summer in Lanzhou (2.6 vs. 1.8 μg m$^{-3}$) likely due to the lower PBL during winter and stagnant air conditions. The mass contribution from HOA is similar to the result of 2013 winter at Beijing (9%) which was also the lowest contributor to the total OA (Sun et al., 2013b; Zhang et al., 2014), probably due to more modern vehicles were used in the past years.

3.4.2 BBOA

BBOA component had been widely observed in USA and European countries during winter due to the traditional wood burning for residential heating (Alfarra et al., 2007). The BBOA component is thought to be less important in China because coal is the major fuel during winter. BBOA could be an important component in China during some special periods. For example, Zhang et al. (2015a) identified a BBOA factor in urban Nanjing, southeast of China, during harvest seasons of summer and autumn because of the burning of straw. The BBOA component has also been identified in some regions in China where the coal resource is scarce. For example, Du et al. (2015) separated a BBOA factor at a rural site of the northern Tibetan Plateau due to the widely usage of cow dung cake for heating in this region. The BBOA component has also been identified during winter in cities in southern China because of rich wood resource in these regions (He et al., 2011; Huang et al., 2011; Huang et al., 2013). To our knowledge, only two recently papers have reported the identification of a BBOA factor during winter using online measurement in an urban area of northern China (Elser et al., 2016). Although the high contribution of non-fossil carbonaceous aerosol was found (Zhang et al., 2015) and the mass spectra of organic in other cities (such as Beijing) during winter have also significant contributions from m/z 60 and 73 (Sun et al., 2013b; Zhang et al., 2014), it is difficult to separate the BBOA using general PMF because of its similar temporal variation with CCOA, such as diurnal pattern (Fig. 4). BBOA contributions presented a clear periodic change (Fig. 1), and on average were high during night time and low during daytime (Fig. 5). This trend is consistent with conventional usage of biomass for
heating. The time series of BBOA was also closely correlated with BC and chloride (Table 2) due to significant emission of these species from biomass burning. The average mass concentration of BBOA was 3.2 μg m$^{-3}$, on average contributing 11% of the total OA mass for the entire study (Fig. 8a), but could reach up to 20% during night and down to less than 5% during afternoon (Fig. 8b). This average concentration was close to the results observed at southern Chinese cities such as Jiaxing (~3.9 μg m$^{-3}$) (Huang et al., 2013), Kaiping (~1.36 μg m$^{-3}$) (Huang et al., 2011) and Shenzhen (~5.2 μg m$^{-3}$) (He et al., 2011).

The size distribution of BBOA peaked at ~400nm which is close to accumulation mode (Fig. 3b). This feature suggests that the BBOA factor observed during this study was likely aged. This behaviour has been observed in some studies and two BBOA factors were identified as a result: one fresh BBOA and one aged BBOA (Zhang et al., 2015a). The relative high O/C and the dominance of an accumulation mode in the size distribution of BBOA were also observed during winter in Fresno, a major city in the Central Valley of California, USA (Ge et al., 2012; Young et al., 2015). These observations are consistent with recent observations that levoglucosan, a major product of biomass burning, can be quickly (within a few hours) oxidized once in the atmosphere (Bougiatioti et al., 2014). Due to the mean RH during the whole study was lower than 30%, it seems that biomass emissions were oxidized mostly in the gas phase and the oxidize products subsequently partitioned into the particle phase (Qin and Prather, 2006).

3.4.3 COA

The COA component has been widely identified in urban AMS studies and observational results by other instruments recently, and it is regarded as important source of OA in urban areas (Abdullahi et al., 2013 and references therein). The MS of COA in this study had a major contribution from C$_x$H$_y$+ ions (79.7%) with also an important contribution from C$_x$H$_y$O$_r$+ ions (15.5%), similar as those in HOA (80.6% and 13.7%) (Fig. S9). In comparison with the HOA spectrum, COA had a higher m/z 55 to 57 ratio (2.1 vs. 0.7)
Fig. 7) which had been postulated as a significant indicator for COA (Sun et al., 2011b; Mohr et al., 2012). In the V-shape plot defined by Mohr et al. (2012), which uses \( f_{55} \) vs. \( f_{57} \) after subtracting the contributions from factors of OOA, CCOA, and BBOA (denoted as OOA\_CCOA\_BOA_sub, i.e., \( f_{55}^{\text{OOA\_CCOA\_BOA_sub}} \) and \( f_{57}^{\text{OOA\_CCOA\_BOA_sub}} \)), the data can be clearly represented with ones during morning close to HOA line and ones during meal times close to COA line (Fig. S10). The MS of COA is highly similar to that of summer 2012 observation (\( R^2 = 0.95, \) slope = 0.97, Fig. S11) which was found to resemble closely the COA MS from other locations (Xu et al., 2014). In fact, the COA components were found to be associated with heating of cooking oils rather than burning of meat/food itself, and indeed the COA mass spectra from cooking of different dishes were highly similar (He et al., 2010). The O/C and H/C ratios of COA were 0.09 and 1.71, respectively, suggesting its feature as POA. This O/C ratio was slightly lower (0.09 vs. 0.11) and the H/C was slightly higher than that of 2012 summer (1.71 vs. 1.69). The size distribution of COA was also peaking between 100–200 nm similar to that of HOA (Fig. 3b). The diurnal variation of COA displayed two predominant peaks standing out at lunch time (12:00–13:00) and dinner time (19:00–20:00), respectively (Fig. 5), and a small breakfast peak (~8:00). This pattern was consistent with that of summer 2012 (Fig. 4) which resulted from the consistent routine life during winter and summer. The enhanced COA concentration at dinner time might be mainly due to the low PBL height and the activity of a formal meal with more attendants and longer time than that of lunch. The temporal variation correlated tightly with \( C_6H_{10}O^+ \) (\( R^2 = 0.95, \) Fig. 8d) which has been reported as the high resolution mass spectral markers for ambient COA (Sun et al., 2011b; Ge et al., 2012).

The average contribution of COA to organics was 20% (~10–50%) (Fig. 8a) with an average mass concentration of 5.86 μg m\(^{-3}\) which was much higher than those of HOA and BBOA. This contribution is similar to those in Beijing during winter (average 19% of OA with a range of 16–30%) (Sun et al., 2013b), Fresno (~19% of OA) (Ge et al., 2012), Barcelona (17% of OA) (Mohr et al., 2012), and Paris (11–17%) (Crippa et al., 2013).
This high fraction indicates that COA is an important local source of OA in Lanzhou regardless of clear or hazy periods (section 3.5).

3.4.4 CCOA

A CCOA component had been identified in this study with its MS similar to the OA from coal burning in lab study (Dall’Osto et al., 2013). The MS of CCOA had high signals at \( m/z \) 41, 43, 44, 55, 57, 69, 91 and 115 (dominated by \( C_nH_y^+ \) ions) (Fig. 7i) (Elser et al., 2016). \( C_nH_y^+ \) ions in total account for 75.3% of CCOA MS, following by \( C_nH_yO_1^+ \) (14.7%) and \( C_nH_yO_2^+ \) (9.4%). The fractions of \( C_nH_y^+ \) and \( C_nH_yO_1^+ \) were similar with those in HOA MS (Fig. S9), but the CCOA MS had high signal intensity at \( m/z \) 44 (mainly \( CO_2^+ \)) which is different from that of HOA (Fig. 7). This high \( CO_2^+ \) fraction was also observed in CCOA MS in Changdao island in China during winter (Hu et al., 2013). Wang et al. (2015) suggested this high \( CO_2^+ \) signal is from the oxidative transformation of the pyrolysis products during coal burning. Zhang et al. (2008) reported that 48–68% of particulate organic matter from coal combustion aerosol is found in the form of organic acids. The O/C ratio is thus higher than that of HOA (0.17 vs. 0.10) with a lower H/C ratio (1.67 vs. 1.73). The CCOA also locates in a relatively high and left position in the triangle plot defined by Ng et al. (2010) (Fig. 13a). These features indicate CCOA is a POA factor but is more oxygenated than HOA. The time-dependent concentrations of CCOA correlated with BC \( (r = 0.74) \) and chloride \( (r = 0.62) \) which also correlated well with HOA and BBOA (Table 2). The CCOA mass loading remained high from 20:00 to 10:00, slowly decreased to a minimum at 16:00, and then increased from 16:00 to 20:00 (Fig. 5). This diurnal pattern was similar to that of BBOA which were all mainly emitted from heating. The slower decreasing rate during morning and increasing rate during late afternoon for CCOA than those of BBOA could related with wide usage of coal, such as cooking and power plants. In our summer 2012 observation, we also observed OA signals from coal combustion which have been persistent emitted during the whole year in Lanzhou. The size distribution of CCOA peaked ~450 nm (Fig. 3b), similar with that of BBOA.
The average CCOA mass concentration was 5.3 μg m$^{-3}$, accounting for 18% of total OA mass (Fig. 8a). The mass fraction of CCOA could reach to 25% of OA during night and decreased to 3% during afternoon (Fig. 8b). This indicates that CCOA was an important OA component similar as that in Beijing OA (15–55%) (Zhang et al., 2014; Elser et al., 2016), but its mass fraction of PM$_{2.5}$ (~9%) was at the low end of the values observed at Beijing and Xi’an (9–21%) (Huang et al., 2014).

3.4.5 SV-OOA and LV-OOA

Two or more OOA components are commonly separated by PMF in urban areas which correspond to fresh SOA and aged SOA (Jemenez et al., 2009), and the MS of SOA factors all have predominant contributions at $m/z$ 43 and 44. The MS of fresher SOA such as SV-OOA has higher contribution at $m/z$ 43 (mainly C$_2$H$_3$O$^+$, accounting for 73% of $m/z$ 43 in this study), while aged SOA such as LV-OOA has higher signal at $m/z$ 44 (mainly CO$_2^+$, accounting for 98% of $m/z$ 44 in this study). The contribution of C$_x$H$_y$O$_z$ in SV-OOA was 35.6% followed by C$_x$H$_y^+$ (50.1%), C$_x$H$_2$O$_2^+$ (9.4%), H$_2$O$_1^+$ (1.4%), C$_x$H$_2$N$_p^+$ (3.0%), and C$_x$H$_2$O$_2$N$_p^+$ (0.4%) (Fig. S9). The O/C ratio of SV-OOA was 0.31 and H/C was 1.47 consistent with fresh SOA. The MS of LV-OOA was comprised of 22.1% of C$_x$H$_2$O$_2^+$, 35.6% of C$_x$H$_2$O$_1^+$, 34.5% of C$_x$H$_y^+$, 5.5% of H$_2$O$_1^+$, 2.0% of C$_x$H$_y$N$_p^+$, and 0.4% of C$_x$H$_2$O$_2$N$_p^+$ (Fig. S9). The O/C and H/C ratios of LV-OOA were 0.67 and 1.29, respectively. Compared with those of summer 2012, both O/C and H/C ratios of SV-OOA during winter 2013/2014 were higher (0.31 vs. 0.28 for O/C, 1.47 vs. 1.34 for H/C), while they were both slightly lower for LV-OOA (0.67 vs. 0.68 for O/C and 1.29 vs. 1.34 for H/C). These results indicate that the atmospheric oxidation capacity during winter was still very strong. The positions of SV-OOA and LV-OOA in triangle plot of $f$CO$_2^+$ vs. $f$C$_2$H$_2$O$^+$ are situated in the upper left corner (Fig. 13a), respectively, suggesting the oxidation evolution of OOA. The MS of SV-OOA and LV-OOA were similar with those of summer 2012 ($R^2 = 0.98$ for LV-OOA and $R^2 = 0.77$ for SV-OOA, Fig. S11). Note that the C$_x$H$_y^+$ ions in SV-OOA were mainly from by $m/z$ 39, 41, 91 and 115 (Fig. S9).
which were also found to be enriched in coal combustion organic aerosols. This feature is similar to that of summer 2012, potentially suggesting that part of SV-OOA was from further oxidation of CCOA.

The temporal variations of SV-OOA and LV-OOA were highly correlated with secondary inorganic species: SV-OOA vs. sulphate ($R^2 = 0.79$) and LV-OOA vs. nitrate ($R^2 = 0.71$) (Fig. 7a and b, Table 2). These patterns are somewhat contradictory to previous AMS findings that SV-OOA typically correlates better with nitrate due to their similar semi-volatile characteristics while LV-OOA tends to correlate better with sulphate as they are both low-volatility species. These correlations were indeed observed during the summer study of 2012 (Xu et al., 2014). The behaviours of the two OOA factors during this study were likely due to the low air temperature and low RH conditions which favoured secondary aerosol formation primarily through gas reactions.

Ammonium sulphate was quickly formed in the atmosphere than nitrate, and when SO$_2$ was completely consumed, ammonium nitrate would be formed. The concentration of NO$_x$ was higher than SO$_2$ (120 vs. 35 ppbv) which the consumption of oxidants by sulphate was relatively less. This phenomenon was also observed in winter time of Beijing which showed strong photochemical formation of nitrate during afternoon (Sun et al., 2013b).

The diurnal variation profiles of SV-OOA and LV-OOA all showed one bump with the SV-OOA peaking between 11:00–14:00 and LV-OOA peaking between 12:00–18:00, suggesting the importance of photochemical processes for both OOA factors. The size distribution of the OOA (SV-OOA + LV-OOA) had a mode size of ~550 nm (Fig. 3b) reflecting the feature as SOA. This size mode is slightly bigger than those of OOA in other studies such as Fresno (460 nm) and Lanzhou summer 2012 (~450 nm) likely due to the high concentration of gas precursors and longer lifecycle of aerosol during winter.
The mass concentrations of SV-OOA and LV-OOA were 7.0 and 5.6 µg m$^{-3}$ with the mass contributions of 24% and 19% to OA, respectively (Fig. 8a). These contributions were lower than those during summer 2012 in Lanzhou (27% for SV-OOA and 32% for LV-OOA) especially for LV-OOA, likely due to the relative weak solar radiation during winter and more primary sources in winter. The diurnal total contribution of OOA (SV-OOA + LV-OOA) varied between 40%–70% (Fig. 8b), suggesting the importance of SOA in the air pollution throughout the day at Lanzhou.

3.5 Primary and secondary OA

As shown in Fig. 2b, the mass fraction of organics increased with the increase of PM$_1$ concentration, so it is important to know the relative contributions of primary and secondary OA components during the pollution periods. Fig. 9a shows the scatter plot of SOA (= SV-OOA + LV-OOA) and POA (= HOA + BBOA + COA + CCOA) during this study. It is clear that POA and OOA show correlation during the periods of POA less than ~15 µg m$^{-3}$ associated with low mass fractions of OA. When POA and OA fraction increased significantly, POA and OOA show almost no correlation, indicating the importance of POA in the severe aerosol pollutions in Lanzhou during winter. This is different than the observation from summer 2012, during which SOA had a stable contribution to PM$_1$ (Fig. 9b), due to more complex POA sources and larger contributions from these sources to PM$_1$ mass loading during winter compared to summer. This is even more evident when comparing each POA factor with OA (Fig. 10). The COA had the biggest contribution to the increased organics can explained 56% of the increase of organics, followed by HOA (28%). The components of CCOA and BBOA also had positive contributions to the increase of PM$_1$ mass. However, both OOA components had negative slopes with organics with SV-OOA being the major one, likely suggesting that the formation of SV-OOA might be limited during heavy haze period in Lanzhou since the reduction of solar radiation may to some extent weaken the photochemical oxidation activities. The phenomenon of POA dominating during haze periods is different from the results in other cities in China (Huang et al., 2014). For example, Elser et al. (2016)...
found significant increased contribution from SOA and secondary inorganic aerosol during haze periods in 2013/2014 winter in Xi'an and Beijing. This is likely due to the higher RH values in the eastern China which is more favourable for the aqueous-phase production of SOA. Indeed, Sun et al. (2013a) observed significant increase of secondary inorganic aerosol during high RH periods in Beijing.

The average contribution of POA to organics decreased from 60.0% to 39.3% during Chinese New Year festival of 2014 (Fig. 1) due to the reduced primary aerosol sources such as HOA (9.8% to 3.3%), COA (21.1% to 11.6%), CCOA (18.2% to 15.4%), and BBOA (10.8% to 9.0%). This is an indication that control of cooking activities and traffic emissions in this residential area may be effective strategies for air quality improvement during winter.

3.6 Fossil and non-fossil OC

OC measured by OC/EC analyser on two filters (OC\textsubscript{filter}) and corresponding AMS (OC\textsubscript{AMS}) online measured results are shown in Fig. 11a. The average ratio of OC\textsubscript{AMS}/OC\textsubscript{filter} was ~1.5 for these two filters likely due to the analytical uncertainties of different instruments (30% for AMS and 20% for OC\textsubscript{filter}), which was also observed in other studies (Zotter et al., 2014). The data from the \textsuperscript{14}C measurement for the filter samples are listed in Table S1. The total average of \textit{f}_{NF} in these four filters was 55 ± 3%, with 54% and 57% for filters during Jan. 15 and Jan. 23, respectively. Comparison with other studies, the average \textit{f}_{NF} value in this study was lower than those in Xi'an (63%) and Guangzhou (65%), and higher than those in Beijing (42%), while similar with those in Shanghai (51%) during 2012/2013 winter (Zhang et al., 2015). Combining with the \textit{f}_{NF} value (the total average of \textit{f}_{NF} for the total average AMS results) and the contributions of fossil (F) POC (HOC and CCOC) and non-fossil (NF) POC (BBOC and COC), the \textit{f}_F and \textit{f}_{NF} for SOC could be obtained (Fig. 11b). The average \textit{f}_F and \textit{f}_{NF} for POC and SOC are summarized into Fig. 12. The \textit{f}_F and \textit{f}_{NF} for POC during Jan. 15 were 47% and 53%, while for SOC were 44% and 56%. For all AMS data, the \textit{f}_F and \textit{f}_{NF} in POC were 47%
and 53%, while for SOC were 43% and 57%. The F-POC during Jan. 15 was comprised by 21% HOC and 26% CCOC, and NF-POC by 16% BBOC and 37% COC. For all AMS data, the F-POC was comprised by 16% HOC and 31% CCOC, and NF-POC by 17%

BBOC and 36% COC.

3.7 Evolution of OA and relationship between odd oxygen and SOA

The evolution of OA chemical composition upon aging has been an important subject which is used to understand the formation of SOA. The methods to characterize this evolution include the application of several specific diagrams, such as the AMS triangle plot ($f_{44}$ vs. $f_{43}$ or $f_{CO_2^+}$ vs. $f_{C_2H_5O^+}$) (Ng et al., 2010). $f_{44}$ is a tracer for aged OA (mostly $CO_2^+$), while $f_{43}$ (mostly $C_2H_3O^+$, with some contribution from $C_3H_7^+$) is mainly associated with freshly formed SOA and POA. POA factors are usually located towards the lower and lower-left corner in triangle plot, and with the aging, move up toward the region of SV-OOA indicating by the increased $f_{43}$ and $f_{44}$; and with further aging, OA move toward the region of LV-OOA indicating by the increased $f_{44}$ and decreased $f_{43}$. In the plot of $f_{44}$ vs. $f_{43}$ of this study (Fig. 13a), the data distributed in a narrow space and move up vertically in the triangle space suggesting significant increasing in $f_{44}$. The data from the low (night time) to the high (afternoon time) $f_{44}$ value corresponded to the evolution of the photo radiation intensity suggesting the photochemical processes. The LV-OOA lay at the top of the data consistent with its highly oxidized feature, while BBOA, COA, and HOA all lay at the bottom of triangle space. CCOA is above those of other primary factors consistent with the results of high acid contents in coal burning OA.

In the plot of $f_{CO_2^+}$ vs. $f_{C_2H_5O^+}$ (Fig. 13b), most of data moved out of triangle space because of the high contribution of $C_3H_7^+$ at $m/z$ 43, especially for data during night time. $f_{CO_2^+}$ and $f_{C_2H_5O^+}$ both increased before the noon time, after that $f_{C_2H_5O^+}$ stopped at ~0.05 and $f_{CO_2^+}$ kept increase likely suggesting the evolution of SV-OOA to LV-OOA.

In comparison to the results in summer 2012, the data in winter were more concentrated in the triangle space suggesting air masses with similar source contribution during winter.
In order to understand the possible sources of oxygenated OA, we also compared the diurnal variations between LV-OOA and \( O_x \) (Fig. 13c). Both \( O_x \) and OOA are products of photochemical reactions and the comparison between \( O_x \) and OOA can offer insight into the evolution of OA due to the dependence of the ratio on the VOC species (Herndon et al., 2008), assuming aqueous processing and night time oxidation for OOA were less important, such as during this study due to the low RH. High SOA vs. \( O_x \) slopes were observed (larger than 0.12 \( \mu g \ m^{-3} \ \text{ppb}^{-1} \)) where aromatic VOC dominated the photochemical processing, while a low slopes (\(-0.03 \mu g \ m^{-3} \ \text{ppb}^{-1}\)) were observed where alkene VOCs dominated the photochemical processing (Wood et al., 2010; Hayes et al., 2013). Fig. 13c shows the scatter plot between \( O_x \) and LV-OOA and sized by the mass concentration of BBOA. \( O_x \) and LV-OOA showed tight correlation (\( R^2 = 0.9 \)) with a slope of 0.18 \( \mu g \ m^{-3} \ \text{ppb}^{-1} \) which suggested the aromatic VOCs may be a large contributor to SOA formation. This result was consistent with the distribution of VOC components in China where aromatic VOC is dominant among VOCs in northern China (Zhang et al., 2015b). Liu et al. (2012) suggested that aromatics emissions in Chinese cities had been underestimated in models by a factor 4-10 which could lead to ~50% increase of SOA production. Apart from the sources of coal combustion, biomass burning, and traffic for aromatic VOC emission (Liu et al., 2008), cooking activities had recently been concerned for accounting for aromatic VOC loading. He et al. (2015) show that Chinese cooking can emit amount of alkanes (41.75%), alkenes (27.23%), and aromatics (28.35%). Combining with \(^{14}\text{C}\) results, it suggested that sources that emit modern carbon (e.g., cooking and biomass burning) seem to be higher emission of aromatic VOC than traffic and coal combustion together.

4 Conclusions

In order to understand the sources and chemical processes of the air pollution during winter in Lanzhou, a field study was conducted at an urban site of Lanzhou during January 10 – February 4, 2014 using a suit of on-line instruments. The results show that the average mass concentration of PM\(_1\) (NR-PM\(_1\) + BC) was 57.3 \( \mu g \ m^{-3} \) (ranging from
2.1 to 229.7 µg m⁻³ for hourly averages), with 51.2% of organics, 16.5% of nitrate, 12.5% of sulphate, 10.3% of ammonium, 6.4% of BC, and 3.0% of chloride. These mass loading levels and chemical compositions were similar to those observed in Beijing during winter. The mass concentration of nitrate and organics increased with the increase of PM₁ loading, while sulphate decreased, indicating the importance of OA and nitrate during severe air pollution. The size distributions of all the species displayed a moderate size at 400–500 nm, suggesting that aerosol particles were largely externally mixed during winter. All species presented significant diurnal variations. BC had two peaks at 10:00–12:00 and 20:00–22:00, respectively. Further analysis indicated that the first peak was resulted from the inversion layer during morning which accumulated the air pollutants from early morning and until the break-up at around noon time. The evening peak of BC was related to human activities such as traffic and coal combustion coupled with the shallow PBL. OA presented two peaks corresponding to lunch and dinner time suggesting cooking to be an important source. Sulphate peaked during the noon time (11:00–14:00) indicating the importance of photochemical processes. Nitrate presented an afternoon peak (12:00–16:00) which indicate the photochemical processing of NOx. PMF analysis of organic mass spectrum with the ME-2 engine identified six organic aerosol sources: i.e., HOA, BBOA, COA, CCOA, SV-OOA, and LV-OOA. POA, which includes HOA, BBOA, COA, and CCOA, accounted for 57% of OA mass and showed an increased in concentration with the increase of PM₁ loading. This is an indication that POA emission was one of the main reasons for the occurrence of heavy air pollution episodes. The temporal profile of LV-OOA tightly correlated with that of nitrate, while those of SV-OOA with sulphate correlated. This observation was different than those observed during other studies and during summer at Lanzhou, indicating the importance of photochemistry for nitrate during winter in Lanzhou due to cold air temperature and low RH conditions.¹⁴C analysis of OOC indicated that 57% of the SOC was formed from non-fossil VOC source including biomass burning and cooking.
