Abstract.

It is well established that variable wintertime planetary wave forcing in the stratosphere controls the variability of Arctic stratospheric ozone through changes in the strength of the polar vortex and the residual circulation. While previous studies focused on the variations in upward wave flux entering the lower stratosphere, here the impact of downward planetary wave reflection on ozone is investigated for the first time. Utilizing the MERRA2 reanalysis and a fully coupled chemistry-climate simulation with NCAR’s Community Earth System Model (CESM1[WACCM]), we find two downward reflection effects on ozone: (1) the direct effect in which the residual circulation is weakened during winter, reducing the typical increase of ozone due to upward planetary wave events, and (2) the indirect effect in which the modification of polar temperature during winter affects the amount of ozone destruction in spring.

Winter seasons dominated by downward wave reflection events (i.e., reflective winters) are characterized by lower Arctic ozone concentration, while seasons dominated by increased upward wave events (i.e., absorptive winters) are characterized by relatively higher ozone concentration. This behavior is consistent with the cumulative effects of downward and upward planetary wave events on polar stratospheric ozone via the residual circulation and the polar temperature in winter. The results establish a new perspective on dynamical processes controlling stratospheric ozone variability in the Arctic.

1 Introduction

The dynamical linkage between the stratosphere and troposphere is dominated by planetary waves, which are generated in the troposphere by orographic and/or nonorographic forcing (e.g., Kuroda and Kodera 1999; Christiansen 2001; Plumb and Semeniu 2003; Polvani and Waugh 2004). These waves propagate upward into the stratosphere where they either dissipate (often manifested as a sudden stratospheric warming -SSW) and initiate downward zonal-mean coupling (e.g., Baldwin and Dunkerton 2001; Limpasuvan et al. 2004); or are reflected downward toward the troposphere, which results in downward wave coupling (DWC) (Perlwitz and Harnik 2003; Shaw et al. 2010; Lubis et al. 2016a). The DWC occurs when upward pulses of
wave activity decelerate the flow in the upper stratosphere, forming a downward-reflecting surface that redirects waves back to
the troposphere (see Harnik and Lindzen 2001, for theoretical considerations). The occurrence of DWC is tied to the so-called
bounded wave geometry of the stratospheric basic state, which is characterized by a well-defined high-latitude meridional
waveguide in the lower stratosphere and a vertical reflecting surface in the upper stratosphere (e.g., Shaw et al. 2010; Lubis
et al. 2016a).

The vertical coupling of planetary-scale waves between the stratosphere and troposphere can be directly examined via the
meridional eddy heat flux, since it is proportional to the vertical group velocity of the planetary waves (e.g., Shaw and Perlwitz
2013; Lubis et al. 2016a). Using extreme total (climatology plus anomaly) negative wave-1 heat flux values, the life cycle
of DWC and its subsequent impact on the circulation in the Northern Hemisphere (NH) have been studied extensively (e.g.,
Shaw and Perlwitz 2013, 2014; Dunn-Sigouin and Shaw 2015; Lubis et al. 2016a). Shaw and Perlwitz (2014) showed that the
occurrence of DWC events coincide with a transient reversal of the residual circulation in the stratosphere. This result is con-
sistent with Eliassen-Palm (EP) flux divergence in the stratosphere, induced by transient downward wave propagation during
the event (Dunn-Sigouin and Shaw, 2015; Lubis et al., 2016a). Since the variations in the stratospheric EP flux divergence
results in changes in the residual circulation (Plumb, 2002), it is therefore expected that DWC may influence the Arctic ozone
levels by changing the dynamical transport of ozone to the pole. This hypothesis will be tested in this study.

It is well established that planetary waves play an important role in shaping the ozone hole through their impact on the polar
vortex and on the residual circulation (e.g., Solomon 1999; Fusco and Salby 1999; Randel et al. 2002; Lubis et al. 2016b).
Randel et al. (2002) showed that variations in planetary wave forcing in the lower stratosphere during winter-spring exhibit a
strong correlation with column ozone, via the following mechanism. Increased (decreased) wave dissipation in the stratosphere
leads to strengthening (weakening) of residual circulation, which in turn increases (decreases) transport of ozone-rich air to
the polar lower stratosphere. On the other hand, strong (weak) winter planetary wave forcing causes a warmer (cooler) Arctic
lower stratosphere in early spring (Newman et al., 2001), resulting in smaller (larger) chemical ozone losses in spring. Manney
et al. (2011) reveal that the unprecedented large Arctic ozone loss in 2011 is highly correlated with extremely cold lower-
stratospheric temperatures in early spring. These extremely low temperatures are attributed to the unusually weak midwinter
planetary wave forcing in the stratosphere (Hurwitz et al., 2011), as expected from a close relationship between polar spring
temperatures and eddy heat flux in mid to late winter (Newman et al., 2001). Both of these dynamical ozone supply and
chemical ozone losses are equally important for the variability of column ozone in the Arctic winter stratosphere (Tegtmeier
et al., 2008).

Weaker planetary wave driving in the stratosphere, which affects ozone through both dynamical and chemical processes,
could arise from an enhanced number of extreme negative wave-1 heat flux events (i.e., DWC events), or from anomalously
low positive heat flux values. Many studies have shown that an increased number of major SSW events that are associated
with enhanced upward wave propagation into the stratosphere have led to significant increases of total column ozone and
polar temperature in the winter, and subsequently less springtime ozone destruction (e.g., Rose and Brasseur 1985; Randel
1993; Liu et al. 2011; Hocke et al. 2015). However, the impact of downward wave propagation associated with planetary
wave reflection on the ozone in the Arctic winter stratosphere has never been explored. Understanding the impact of DWC on
residual circulation and polar temperatures will help to improve our knowledge of the links between stratospheric dynamics and ozone variability.

The goal of this study is to investigate the impact of DWC on polar stratospheric ozone in the NH using both Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA2, Bosilovich et al. 2015) and the NCAR’s Community Earth System Model, Version 1.0.2 (CESM1 [WACCM]) model simulation. The new MERRA2 reanalysis improves on and augments the original MERRA reanalysis (Bosilovich et al., 2015). Therefore, it has a better representation of stratospheric ozone in high latitudes compared to the original MERRA reanalysis (see Appendix A1, Figs. A1 and A2). On the other hand, CESM1(WACCM) model is able to capture the main features of DWC in the NH winter (Lubis et al., 2016a), therefore it can be used to study the link between DWC and polar stratospheric ozone. Here, we focus on two kinds of DWC effects on ozone: (1) the direct effect, which is analyzed over the whole life cycle of the individual DWC event, and (2) indirect effect, which is analyzed through the seasonal impact of DWC on polar temperature.

The paper is structured as follows: Section 2 describes the data and methods. This includes the description of data, model simulation, and methods. In Section 3, the direct effects of DWC on the mean residual transport, temperature and ozone concentrations are analyzed, based on MERRA2 reanalysis product and a 100-yr transient simulation from the fully coupled chemistry-climate model CESM1(WACCM). Section 4 discusses the seasonal impacts of DWC events on the Arctic column ozone during seasons that are dominated by enhanced DWC events (reflective winters) and by enhanced upward wave events (absorptive winters). Finally, the results are summarized and discussed in section 5.

2 Data and Methods

2.1 MERRA2 Ozone

The new MERRA2 daily ozone product from 1980 to 2013 (Bosilovich et al., 2015) was used to investigate the impact of DWC on ozone. The data was stored on 42 pressure levels from the surface up to 0.1 hPa. MERRA2 assimilates ozone from the Solar Backscattered Ultra Violet (SBUV) radiometers from October 1978 to October 2004, and thereafter from the Ozone Monitoring Instrument (OMI) and AURA MLS (Microwave Limb Sounder) instrument (Bosilovich et al., 2015). These ozone datasets are assimilated with the Goddard Earth Observing System Model, Version 5 (GEOS-5) by using odd-oxygen mixing ratio \( q_{O_x} \) as its prognostic variable (Bosilovich et al., 2015). This includes an odd-oxygen family transport model providing the ozone concentration necessary for solar absorption. The vertically integrated ozone tendency is given as (Bosilovich et al., 2015):

\[
\frac{\partial q_{O_x}}{\partial t} = \left[-\nabla \cdot (\overline{v q_{O_x}})\right]_{DYN} + \left[\frac{\partial q_{O_x}}{\partial t}\right]_{PHY} + \left[\frac{\partial q_{O_x}}{\partial t}\right]_{ANA}
\] (1)

The dynamical contribution to the total ozone tendency is the convergence of odd-oxygen mixing ratio products (the first right-hand side term of Eq. 1). The total physics product (second term) includes the parameterized production and loss terms, and the analysis product (third term) is the corrected ozone tendency from data analysis. The analysis term (i.e., correcting tendency term) is part of the Incremental Analysis Update (IAU) (Bloom et al, 1966), which is used in the GEOS5 model and is an
In MERRA2, the total ozone tendency from physics is decomposed into contributions from the chemistry, turbulence, and moist physics. Given a parameterized ozone chemistry in MERRA2, the total ozone tendency from chemistry (CHM) is analyzed together with the correcting tendency term (i.e., CHM+ANA). The contributions of the turbulence and moist physics are negligible in the stratosphere (not shown) and therefore, are not considered in this analysis. We confirm that there are no major differences between the MERRA2 and AURA MLS ozone concentrations in the polar lower-to-mid stratosphere (see Appendix A1).

In addition, daily three-dimensional geopotential height, wind, and temperature fields from MERRA2 with the same period as the ozone (1980 to 2013) were also employed in this study. We note that the nature of downward wave pulses and the associated wave geometry in MERRA2 were found to be in good agreement with the results from the European Centre for Medium-Range Weather Forecasts (ECMWF) Re-Analysis (Lubis et al., 2016a) and the NCEP/NCAR Reanalysis datasets (not shown) and are therefore robust among the various reanalysis products.

2.2 CESM1(W ACCM) Simulation

The model simulation used in this study was performed with the NCAR’s Community Earth System Model (CESM) version 1.0.2. CESM is a state-of-the-art coupled model system which includes an ocean, land, sea ice and atmosphere components (Hurrell et al., 2013). The atmospheric component of the CESM used in this study is the Whole Atmosphere Community Climate Model (W ACCM), version 4 (Marsh et al., 2013), a fully interactive chemistry climate model consisting of a finite-volume dynamical core with 66 standard vertical levels (up to 140 km or ~ 5.1×10^{-6} hPa) and a horizontal resolution of 1.9° latitude × 2.5° longitude. Interactive chemistry is calculated within the 3-D chemical transport Model of Ozone and Related Chemical Tracers, Version 3 (MOZART-3; Kinnison et al. 2007).

In this study one 100-yr simulation (1955-2054) is free run with fixed surface emissions of greenhouse gases (GHGs) and ozone depleting substance (ODSs) at 1960s levels, allowing us to study the ozone variability unmasked from any anthropogenic influence. The simulation is run with interactive ocean and sea ice components. To represent a more realistic interaction between the tropics and extra-tropical dynamics, the QBO is nudged by relaxing tropical stratospheric zonal-mean winds towards observations following Matthes et al. (2010). The solar cycle is prescribed as spectrally resolved daily variations following Lean et al. (2005). Observed volcanic eruptions of the twentieth century are included by prescribing a monthly zonal-mean time series of volcanic aerosol surface area density (SAD), identical to that used in the CCMVal2 REF-B1 simulations (Eyring et al., 2010).

2.3 Dynamical Diagnostics

The influence of eddies on ozone transport is quantified from the transformed Eulerian mean (TEM) continuity equation for zonal mean tracer concentration (Andrews et al. 1987, Eq. 9.4.13). For linear, steady, conservative waves, the complete Eulerian mean tracer transport equation can be written in the form:

$$ \chi_t = -\bar{w}^* \chi_y - \bar{w}^* \chi_z + \epsilon z / H (\nabla \cdot \mathbf{M}) + \bar{S} $$

(2)
The Eq. 2 separates the local change in tracer concentration $\nabla T_i$ as a result of transport processes that occur due to advection by the residual circulation $(\overline{\nabla \chi}, \overline{\nabla \varphi})$, the eddy effects $(\rho_0^{-1} \nabla \cdot \mathbf{M})$, and the chemical production minus loss rate $(\mathbf{S})$ (Andrews et al., 1987). Here, $\mathbf{M}$ represents the diffusive effects of the eddies, plus advective effects that are not represented by the residual meridional circulation. We note that the sum of the first three right-hand side terms of Eq. 2 is equal to the total ozone tendency from dynamics in Eq. 1, while the last term of Eq. 2 is equal to the total ozone tendency due to chemistry and analysis in Eq. 1. The eddy effects are defined as the divergence of the eddy transport vector $(\mathbf{M})$, with components defined as in Eq. 9A.3 of Andrews et al. (1987):

$$
\mathbf{M} = 
\begin{pmatrix}
M^{(y)} \\
M^{(z)}
\end{pmatrix} = 
\begin{pmatrix}
-e^{-z/H} (\overline{v'} \chi - \overline{v'} \theta' \overline{\chi_z} / \overline{\vartheta_z}) \\
-e^{-z/H} (\overline{w'} \chi + \overline{v'} \theta' \overline{\chi_y} / \overline{\vartheta_z})
\end{pmatrix}
$$

(3)

The overbars indicate zonal means, primes are deviations from it and subscripts denote partial derivatives. The $\overline{\nabla \chi}$ and $\overline{\nabla \varphi}$ in Eq. 2 denote the TEM residual meridional and vertical winds defined as $\overline{\nabla \chi} = \overline{v} - \rho_0^{-1} (\rho_0 \overline{v' \theta'} / \overline{\vartheta_z})_z$ and $\overline{\nabla \varphi} = \overline{w} + (a \cos \phi)^{-1} (\cos \phi \overline{v' \theta' / \vartheta_z})_\phi$, respectively. The potential temperature and scale height are represented by $\theta$ and $H$, respectively. The Coriolis parameter and Earth’s radius are denoted by $f$ and $a$. In addition, the residual mean circulation calculated from the residual mass streamfunction $(\Psi_m)$ and the wave geometry diagnostic are also used in this study (see Appendix B, Eq. B1-3).

2.3.1 Identification of DWC Event

We use a similar definition of DWC event as in Lubis et al. (2016a) and Dunn-Sigouin and Shaw (2015), which is based on daily total (climatology plus anomaly) negative wave-1 meridional heat flux $(\overline{v'} T'_k)_{k=1}$ at 50 hPa averaged between 60° and 90°N, below the 5th percentile of the daily $\overline{v'} T'_k_{k=1}$ distribution. We focus our analysis on January, February and March (JFM), which is the period of maximum planetary wave coupling between the troposphere and stratosphere in the NH (Shaw et al. 2010; Lubis et al. 2016a). For time-lagged composites, the central date is the day on which $\overline{v'} T'_k_{k=1}$ has a minimum. Finally, the central dates of each event must be separated by at least 15 days. The time separation threshold is motivated by the time scale of planetary wave coupling between the stratosphere and troposphere (Perlwitz and Harnik, 2003). Events defined using the $\overline{v'} T'_k_{k=1}$ at 30 and 10 hPa exhibit similar qualitative behavior as those defined at 50 hPa.

Applying our identification algorithm leads a total number of 19 potential DWC events in MERRA2 reanalysis (see Table 1) and 58 in CESM1(W ACCM) (see Table S1 in supplemental material). The frequency of DWC events in MERRA and CESM1(W ACCM) is similar, about 6 events per decade. We also note that the number of events found here and the evolution of the downward and upward wave pulses are in a good agreement with the results of Dunn-Sigouin and Shaw (2015) (see later in Fig. 1). The minimum value of the total 5-day smoothed ozone tendency from 60° to 90°N during the date of DWC events is also shown in Table 1. It can be seen that DWC events are instantaneously linked to a transient reduction in ozone in the Arctic mid stratosphere (see Table 1 for MERRA2 and Table S1 in supplemental material for CESM1(W ACCM)). All the statistical significance for the composites is reported at the 95% level, based on a 1000-trial Monte Carlo test (see Appendix C). The
composites are done both for the total fields and the anomalies, which are defined as deviation from the daily climatological seasonal cycle.

3 Direct Effect of the DWC on Polar Stratospheric Ozone

In the following sections we examine the effect of DWC events on polar stratospheric ozone in the observation and then in the model.

3.1 Observed Effect of DWC on Ozone

To examine the effects of DWC events on polar stratospheric ozone we first examine the connection between DWC, residual circulation, and Arctic temperatures during the composite life cycle in MERRA2 reanalysis. Figure 1a-d shows the composite life cycle of downward planetary wave events as a function of pressure and time from -20 to +20 days for (a) wave-1 heat flux anomaly, (b) wave-1 EP flux divergence anomaly, (c) residual circulation anomaly, and (d) total potential temperature tendency. There is a positive heat flux anomaly that migrates from the troposphere to the upper stratosphere from days -10 to -4 (Fig. 1a). This heat flux evolution coincides with large changes in anomalous wave-1 EP flux convergence in the high latitudes (Fig. 1b), suggesting that the upward propagating waves dissipate in the upper stratosphere prior to a DWC event. The associated EP flux convergence forces an anomalous positive (i.e., poleward) residual circulation and thus, leading to positive potential temperature tendency in the Arctic stratosphere (Figs. 1c-d). This positive potential temperature tendency is associated with air being advected downward over the pole, producing anomalous adiabatic warming. The changes in the residual circulation and the temperature tendency are consistent with anomalous EP flux convergence in the stratosphere due to upward propagation of planetary-scale waves prior to a DWC event.

From days -3 to +3, the stratospheric heat flux anomaly subsequently changes sign and reaches its minimum value (Fig. 1a). The high-latitude negative heat flux anomalies coincides with EP flux divergence anomalies in the stratosphere (Fig. 1b), suggesting that the upward propagating waves are reflected downward toward the troposphere resulting in EP flux divergence in the stratosphere. The high-latitude wave-1 EP flux divergence are dominated by the vertical component (not shown). In addition, the EP flux divergence anomalies resulting from transient evolution of the downward wave activity lead to anomalous negative (i.e., equatorward) residual circulation and the associated negative potential temperature tendency in the polar stratosphere (Figs. 1c-d). The negative residual circulation anomaly suggests a deceleration of poleward transport of air mass, resulting in negative potential temperature tendency over this region. The negative residual circulation and temperature tendency are consistent with anomalous EP flux divergence in the stratosphere induced by transient downward wave propagation from the stratosphere to the troposphere during the mature stage of DWC event.

Next, we analyze the implication of transient changes in residual circulation induced by DWC on polar stratospheric ozone in MERRA2. Figure 2 shows the corresponding transient evolution of the zonal-mean ozone tendencies averaged between 60 to 90°N. During downward wave events, the high-latitude total ozone tendency exhibits similar behavior as the heat flux pulse and the residual circulation. In particular, the event begins with a positive high-latitude stratospheric ozone tendency.
in the stratosphere from days -15 to -5 (Fig. 2a). This positive stratospheric ozone tendency subsequently changes sign and reaches its minimum value at 10 hPa, around day 0 (Fig. 2a). The evolution of the total ozone tendency is consistent with the evolution of high-latitude residual circulation anomalies (Fig. 1a). In particular, the positive (poleward) residual circulation anomaly in the stratosphere from days -15 to -5 leads to more ozone transport to the polar vortex, and the subsequent negative (equatorward) residual circulation anomalies between days -4 to +5 leads to more ozone transport out of the polar vortex.

To investigate the source of the transient changes in polar stratospheric ozone during DWC events, we decompose the total ozone tendency (Fig. 2a) into contributions of dynamics and chemistry-plus-analysis terms. It is shown that the evolution of total ozone tendency in the mid-lower and mid-upper stratosphere (between 100 and 1 hPa) is dominated by the dynamical term (Fig. 2b). The ozone tendency due to dynamics in the mid-lower stratosphere (100 and 10 hPa) is mainly attributed to the ozone transport via vertical (advection) residual circulation (Fig. 2d), while the tendency in the mid-upper stratosphere (above 5 hPa) is mainly attributed to effects of eddy transport (Fig 2f). Therefore, the dominance of the dynamical term on the total ozone tendency in the mid-lower stratosphere during the composite lifecycle is consistent with the transient changes in residual mean transport (Fig. 1c). On the other hand, the contribution of the chemistry to the total ozone tendency (Fig. 2c) is significant above 10 hPa prior to the mature stage of DWC event (from days -10 to -5, Fig. 2c) and peaks around day -7.

The negative ozone tendency due to chemistry in the upper stratosphere prior to DWC is likely associated with more chemical ozone loss due to increased temperature prior to a DWC event (Fig. 1d). This is consistent with the ozone sink reaction in the upper stratosphere, which is strongly dependent on temperature, where the increase (decrease) in temperature leads to more (less) ozone destruction (Brasseur and Solomon 2005). However, the magnitude is relatively weak compared to those caused by dynamics. These results suggest that transient changes in the polar mid-lower stratospheric ozone during the DWC life cycle are primarily due to changes in dynamical ozone transport.

The same conclusion can be drawn by assessing the instantaneous correlation between the two extreme stratospheric wave-1 heat flux events. Figure 3a shows a two dimensional histogram of total ozone tendency versus residual vertical wind anomaly (w*) averaged over 60-90°N at 50 hPa in MERRA2. The black contour lines indicate the distribution of all daily JFM samples from 1980 - 2013 (90 days yr⁻¹ x 34 yr = 3060 days). The red and blue dots indicate the days with positive and negative extremes in total wave-1 heat flux, respectively (the top and bottom 5%). Negative extremes are associated with DWC events. The overall shape of the distribution suggests a strong negative correlation between polar cap-averaged ozone tendency and w*. This is consistent with a direct calculation of time series correlation, which is statistically significant (R=-0.81). In addition, the days with positive and negative extremes (red and blue dots, respectively) are systematically skewed compared to the background distribution, suggesting that enhanced extreme negative heat flux (i.e., stronger DWC event) corresponds to a weaker residual circulation and a higher negative ozone tendency, and vice versa for positive extremes. In addition, Fig. 3b shows a similar diagnostic, but for the dynamical ozone tendency versus w*. Again, the overall two dimensional distribution suggests a strong negative correlation between dynamical ozone tendency and the vertical component of the residual circulation, with a temporal correlation coefficient of -0.82. This reflects the fact that the dynamical ozone tendency is strongly correlated with changes in residual circulation. In addition, we found a weak instantaneous relationship between chemical ozone tendency and temperature tendency in the upper stratosphere (R=-0.19, Fig. 3c), suggesting that transient changes of ozone due
to chemistry are less robust compared to the dynamical term. We note that although the analyses in Fig. 3 are based on the 5% negative extreme events, the described relationships do not depend on the fraction of extreme events considered (not shown), and thus these results are representative of the general behavior. The same conclusions are also obtained and are even more robust when we used total column ozone tendency (TCO) instead of an ozone-mixing ratio at 50 hPa (not shown). The results suggest that the instantaneous link between ozone and extreme wave-1 heat flux events is more dominated by the dynamical process, consistent with the results from Fig. 2 where the transient changes of ozone during the life cycle of DWC is mainly due to changes in ozone transport.

Our results so far indicate that the life cycle of DWC involves a transient reversal of poleward to equatorward residual circulation anomaly, and subsequent changes in potential temperature tendency and ozone from being positive to negative values. Therefore, it is worth checking whether the effects on residual circulation, temperature tendency, and ozone could integrate to zero over the life cycle of the wave, indicating the impacts would be reversible. To this end, we first calculated the time integration of residual circulation anomaly and temperature tendency averaged over the levels where their effects are significant (i.e., between 100 and 1 hPa) (Figs. 4a-b). The results show that both time-integrated residual circulation and temperature tendency over the composite of DWC life cycle is nearly zero, indicating that the impacts is reversible. The reversibility implies that the effect of DWC on the residual circulation and temperature is canceled out over the life cycle of the wave, as indicated by the time tendencies that change from being positive to negative (Figs. 4a-b). In addition, the results from the DWC lifecycle are compared with the results from the upward wave events. The upward wave event is defined in a similar manner as DWC event, but for the meridional heat flux values above the 95th percentile of the JFM distribution. It is shown that the time-integration of both quantities over the life cycle of upward wave events is irreversible over the life cycle (i.e., positive value), with the time tendencies not reversing during the life cycle (Figs. 1c-d and see also Fig. S1). This means that increased upward wave events result in stronger residual circulation and warmer polar vortex in winter. Thus the overall effect of having more DWC events in winter is to have weaker residual circulation and colder polar vortex (i.e., DWC weakens the typical increase of residual circulation and temperature induced by upward wave events in winter).

Likewise, we also calculated the time-integrated evolution of ozone tendency at 50 hPa and total column ozone (TCO) tendency averaged between 60 to 90°N for both DWC events (blue lines) and upward wave events (red lines) (Fig. 4c). The results showed that the time integration of the ozone and TCO tendencies over the life cycles of DWC is nearly zero, indicating a reversible impact on ozone (Fig. 4c, horizontal blue lines). On the other hand, the time integration of the ozone and TCO tendencies during upward wave events is positive, indicating a net-increased ozone during the life cycle of upward wave event (Fig. 4c, horizontal red lines and see also Fig. S2). Thus, the overall direct effect of having more DWC events in winter is to have lower ozone levels in the polar stratosphere due to weakening of typical increase of ozone induced by upward wave events.

A complementary analysis of wave-2 heat flux events is shown in the supplementary material (Figs. S4 and S5). Overall, the evolution of the wave-2 events involve weaker heat flux values and weaker EP flux divergence (Fig. S4a and Fig. S4b, consistent with Dunn-Sigouin and Shaw (2015)) and thus, result in a weaker connection with the ozone time-tendency (Fig. S5).
The stratospheric impacts associated with downward wave-2 events on ozone are not as robust as the corresponding downward wave-1 events (Fig. S5).

3.2 Simulations of the Effect of DWC on Ozone

Determining the connection between DWC, stratospheric residual circulation, and polar temperature is one of the keys to improving our understanding of the link between stratospheric dynamics and ozone variability, both in the real atmosphere and in the stratosphere-resolving chemistry-climate models. In this section, we attempt to test if the linkages between DWC and transient changes in polar stratospheric ozone can be reproduced in a current chemistry-climate model, CESM1(WACCM).

In addition, a larger sample of events in the model allows us to underpin the findings from the reanalysis dynamics by robust, statistically significant results.

Figure 5 shows the composite life cycle of downward planetary wave events as a function of pressure and time from -20 to +20 days for (a) wave-1 heat flux anomaly, (b) wave-1 EP flux divergence anomaly, (c) residual circulation anomaly, and (d) total potential temperature tendency in CESM1(WACCM). Consistent with MERRA2, the model simulation showed that the life cycle of DWC events involve a transient reversal of wave-1 heat flux anomaly, wave-1 EP flux divergence anomaly, residual circulation anomaly and potential temperature tendencies (Fig. 5a). In particular, there is a positive heat flux anomaly prior to DWC events from days -18 to -4, coinciding with EP flux convergence anomalies in the stratosphere (Fig. 5b). The high-latitude heat flux anomaly evolution coincides with poleward residual circulation anomaly, and the corresponding positive potential temperature tendency in the Arctic stratosphere (Figs. 5c-d). We should note that the positive wave-1 heat flux signal in the model persist longer compared to MERRA2, which is mainly associated with a common model bias in the background circulation which feeds back on the wave dynamics and wave-mean flow interaction (Lubis et al., 2016a).

This explains why the evolution of the residual circulation anomaly and the associated temperature tendency in the model last longer prior to the mature stage of DWC:

From days -3 to +3, the vertical heat flux anomaly subsequently changes sign (Fig. 5a), producing negative wave-1 heat flux anomalies in the stratosphere. This negative flux anomaly coincides with a positive residual circulation anomaly and negative temperature tendency in the stratosphere (Figs. 5c-d). The equatorward anomaly of the residual circulation and the associated adiabatic cooling in the stratosphere is again consistent with wave-1 EP flux divergence in the stratosphere due to transient downward wave propagation from the stratosphere to the troposphere (Fig. 5b).

Although there is a difference in the time-scale of the upward wave pulses prior to DWC events between the model and MERRA2, the model is relatively good in reproducing the evolution of DWC:

Next we examine the effect on ozone tendencies, as was done in Fig. 2. Figure 6 shows the time evolution of total ozone tendencies during the composite life cycle. Consistent with MERRA2, the negative ozone tendency in the model occurs during the time of strongest DWC events (days -3 to +3), between 100 and 5 hPa (Fig. 6a). This negative ozone tendency is preceded by a positive ozone tendency (days -20 to -5). This positive ozone tendency values persist longer in the model compared to MERRA2, which is consistent with a more persistent upward wave flux and the associated poleward residual circulation anomalies prior to DWC events in the model. The transition of positive to negative ozone tendency in the lower-to-mid stratosphere
is consistent with poleward to equatorward residual circulation anomalies (Fig. 5a). Interestingly, there is a strong positive ozone tendency in the upper stratosphere (above 5 hPa) during the time of maximum DWC events, which is not captured by MERRA2. This discrepancy will be discussed in the following paragraph.

By decomposing the total ozone tendency into dynamical and chemical terms, it is shown that transient changes in ozone dynamics dominate the total ozone tendency during the composite life cycle (Fig. 6b-c). In the mid-lower stratosphere, the ozone tendency due to dynamics is mainly attributed to the vertical advection process (Fig. 6d), while in the upper stratosphere the eddy transport effect becomes dominant (Fig. 6f). In addition, the strong positive total ozone tendency in the upper stratosphere during the time of maximum DWC events is attributed to the dynamical ozone tendency due to eddy transport effect and vertical advection through the residual circulation (Fig. 6f). The magnitude of these two quantities in the upper stratosphere is relatively higher in the model compared to MERRA2, and therefore, which leads to the differences in ozone tendency in the upper stratosphere (Fig. 2d,f vs. Fig. 6d,f). The detailed analysis of why these model terms are biased is beyond the scope of the current study. On the other hand, the ozone tendency due to chemistry in the upper stratosphere is somewhat weaker and in the opposite sign of the ozone tendency due to dynamics (Fig. 6c). The overall results support our observational-based analysis that the transient changes in polar stratospheric ozone during a DWC event are mainly attributed to changes in the dynamical ozone transport.

As with MERRA2, this general relationship between DWC and polar stratospheric ozone in the model simulation can be also assessed through the instantaneous correlation between the two extreme stratospheric wave-1 heat flux events. Figure 7 shows a similar diagnostic as in Fig. 3, comparing the two-dimensional distribution of the polar cap-averaged ozone tendencies and residual circulation during extreme wave-1 heat flux events. Consistent with MERRA2, the days with positive and negative extremes (red and blue dots, respectively) are systematically skewed compared to the background distribution, so that stronger DWC events correspond to stronger negative ozone tendency and weaker residual circulation (Figs. 7a, \( r = -0.82 \)). A similar instantaneous correlation is found between dynamical ozone tendency and \( w^* \) (\( r = -0.85 \)), but not for the ozone tendency due to chemistry (\( r = -0.11 \)). This is again consistent with the observational-based analysis, that the polar mid-lower stratospheric ozone during the DWC life cycle is instantaneously linked to changes in dynamical ozone transport.

As a last step, the direct cumulative effects of DWC on residual circulation, temperature tendency, and ozone was analyzed (Fig. 8). We first analyzed the time integration of the residual circulation anomaly and polar temperature tendency during the composite lifecycle of the wave (Figs. 8a-b). It is shown that the impacts on both residual circulation and potential temperature tendency over the life cycle of DWC events are reversible, consistent with MERRA2. We note, however, that there are differences in the values of potential temperature tendency between the model and MERRA2. The large values in the model are likely related to the modeled temperature bias that is a common problem in CCMs (Austin and Butchart, 2003; Eyring et al., 2010). In particular, WACCM still exhibits a bias in the stratospheric westerly jets and polar temperatures in the NH winter, where the largest biases in the stratosphere are in the location of the maximum of the NH westerly jet (Marsh et al., 2013). Nevertheless, the model results in general support the observational-based analysis with MERRA2, that the DWC event acts to dampen the typical strengthening of residual circulation and the associated adiabatic warming induced by upward planetary waves.
Furthermore, the direct cumulative effects of DWC events on ozone in the model were examined in the same way as in Figs. 8a-b. The time evolution of total column ozone (TCO) tendency and ozone tendency at 50 hPa averaged between 60 to 90°N for the composite of DWC event (blue lines) and upward wave event (red lines) is shown in Fig. 8c. Confirming the results from MERRA2, the time integration of significant TCO and ozone tendencies is zero, indicating a reversible impact on the ozone (Fig. 8c, blue lines). However, the positive ozone tendency values prior to DWC events persist longer in the model compared to MERRA2, which is consistent with the persistent poleward residual circulation anomalies. Further study is therefore still required to understand the bias in the ozone magnitude in the model prior to a DWC event. On the other hand, the time integration of the significant TCO and ozone tendencies during upward wave event are positive, indicating a net increase in ozone (Fig. 8c, red lines). This is consistent with our previous findings suggesting that the direct effect of the full wave reflection life cycle is to weaken the typical increase of ozone due to upward planetary wave events.

4 Seasonal Impact of DWC on Ozone

The former analysis shows that an individual DWC event has a statistically significant impact on the polar stratospheric ozone. While the impact of an individual event occurs on a short time scale, several events in an individual JFM season may produce an impact on a longer time scale. In this section, we briefly examine the cumulative impacts of DWC on ozone during seasons that are dominated by DWC events.

4.1 Reflective versus Absorptive Winters

In order to analyze the seasonal impact of DWC on polar stratospheric ozone, we classify winters as reflective and absorptive based on the basic state of the stratosphere during winter, whereas previous study used the wave 1 heat flux definition (Shaw and Perlwitz, 2013). The classifications are based on the vertical wavenumber \( m \) (averaged between 1-5 hPa and 65-75°N) and zonal mean wind at 30 hPa \( U30 \) (averaged between 60-85°N) in winter months (JFM), similar to Perlwitz and Harnik (2003) and Harnik (2009). The vertical wave numbers \( m \) are calculated using the wave geometry diagnostic of Harnik and Lindzen (2001), which separates the more commonly used index of refraction (c.f. Charney and Drazin 1961) into vertical and meridional wavenumber contributions. The wavenumbers are diagnosed from the solution to the wave equation associated with the conservation of potential vorticity in spherical coordinates (see Appendix B4).

Reflective winters (with dominant DWC events) are defined when \( m < 0 \) and \( U30 > 2.5 \) standard deviation \( \sigma \) of all JFM months, while absorptive winters (with dominant upward wave events) are defined when \( m > 0 \) and \( U30 < 2.5\sigma \). We note that \( m < 0 \) often occurs during or after sudden warming events. Thus in defining a reflection index based on \( m \), we only look at negative \( m \) events for which winds in the lower stratosphere remain strong (Harnik 2009). Therefore, we exclude the years with SSW events from the potential reflective winters in contrast to the wave-1 heat flux definition of Shaw and Perlwitz (2013) where SSWs are included. We note, however, that the two definitions of reflective (absorptive) winters give similar results. In both cases reflective (absorptive) winters are dominated by a large amount of extreme negative (positive) heat flux events (see Fig. S7). However, the resulting polar stratospheric temperature response is weaker for the wave-1 heat flux definition due to
The inclusion of SSWs (not shown). The time series of selected reflective and absorptive winters are shown in Fig. 9. Using this definition, we found the most reflective (absorptive) winters, 8 (11) in MERRA and 30 (29) in CESM1(WACCM) (see Table 2).

Figure 10 shows composites of the zonal-mean wind, wave-1 geopotential height, and temperature difference in JFM for the composite of reflective and absorptive winters in MERRA2 and in CESM1(WACCM). During reflective winters, the maximum zonal-mean zonal wind resides in the mid-stratosphere, and consequently the region of vertical reflecting surface extends down to 3 hPa (Figs. 10a,b). There is also a clear meridional waveguide below 10 hPa between 50 and 80°N, which channels the reflected wave activity to the high-latitude troposphere (essentially preventing dispersion of the waves in the meridional direction before they reach the midtroposphere). This vortex configuration is favorable for DWC events, which is indicated by an eastward phase tilt with heights of the wave-1 structure from the mid-troposphere to the lower stratosphere (Figs. 10c,d). In addition, the Arctic mid-lower stratosphere is significantly colder; the polar cap temperature at 50 hPa is 6 K lower than the climatological mean in MERRA 2 (Fig. 10e) and is approximately 7 K colder in the model. This cooling is consistent with a strong (undisturbed) polar vortex, which is associated with less wave absorption in the stratosphere due to mainly enhanced DWC events or to a lack of upward wave propagation from the troposphere.

In contrast, during absorptive winters, waves can propagate all the way up through the stratosphere because the reflecting surface vanishes so that the vortex tends to be weaker due to more wave deceleration (Figs. 10g,h). The meridional waveguide occurs below 30 hPa between 50 and 80°N, allowing more upward planetary wave propagation from the troposphere to penetrate in the stratosphere. This configuration is favorable for upward wave events, indicated by the westward phase tilt with height of the wave-1 structure from the lower troposphere to the upper stratosphere (Figs. 10i,j). The Arctic mid-lower stratosphere is significantly warmer, by approximately 4 K higher than the climatological mean at 50 hPa in MERRA2 (Fig. 10k) and by about 6 K warmer in the model (Fig. 10l). The warmer and more disturbed polar vortex during absorptive winters is consistent with enhanced upward propagating waves from the troposphere into the stratosphere, resulting in stronger wave-mean flow interaction.

4.2 Seasonal Impact on Ozone in Winter and Spring

In order to estimate the seasonal impacts of DWC events on ozone, we analyzed ozone differences between reflective and absorptive seasons for mid winter (Jan-Feb) and late winter/early spring (Mar-Apr) in the MERRA2 and in the CESM1(WACCM) (Fig. 11). Here, we recall the reflective seasons (i.e., winters dominated by DWC events) as REF, and the absorptive seasons (i.e., winters dominated by upward wave events) as ABS.

The results show that the seasonal effects of DWC leads to a reduction of ozone concentration in the stratosphere during mid winter (Figs. 11a,b) and early spring (Figs. 11g,h). These results are in agreement with our analysis over the life cycle of DWC showing that: (1) a reversible reduction of poleward residual circulation induced by DWC event weakens the typical increase of ozone induced by upward wave event during mid winter (the direct effect of DWC) and (2) the cold polar vortex in midwinter due to DWC events results in more ozone loss during early spring (the indirect effect of DWC). To distinguish between the two effects quantitatively, we examine the contribution of dynamics and chemistry terms to the mean differences
between the two types of winters (i.e., REF minus ABS). We note that responses of ozone and ozone tendency in REF and ABS winters are symmetric with respect to the climatological mean, meaning that ABS and REF anomalies (relative to climatology) are similar but opposite to each other (see Fig. S8 and Fig. S9). The results showed that a reduction of ozone concentration during mid winter in REF compared to ABS is caused by negative ozone tendency due to dynamics, in both MERRA2 (Fig. 11a) and model simulation (Fig. 11b). This is consistent with the direct impact of DWC on ozone in mid winter, where the reversible impact of DWC on ozone over the life cycle leads to less ozone increase in the Arctic. On the other hand, there is a positive chemically driven ozone anomaly in the upper stratosphere during mid winter (Fig. 11e). This positive anomaly is likely associated with less chemical ozone loss in the upper stratosphere, due to decreased temperature (cold) in REF in mid winter. This is consistent with the ozone sink reaction in the upper stratosphere, which is more strongly dependent on temperature, where the increase (decrease) in temperature leads to more (less) ozone loss (Brasseur and Solomon 2005). However, we found that this positive anomaly in the model is not as robust as in MERRA2 (Fig. 11f), so that further studies are needed to check the contribution of ozone chemistry in REF during mid winter. In summary, the results showed that the accumulative impact of DWC in mid winter reduces the seasonally averaged dynamical ozone transport to the polar region (see also Fig. S9c and Fig. S10c).

During early spring, the lower ozone concentration in REF compared to ABS in the upper stratosphere (between 3 and 1 hPa) and in the lower-to-mid stratosphere (between 100 hPa and 50 hPa) (Figs. 11g,h) is maintained by negative ozone tendency due to chemistry terms (Figs. 11k,l). This is consistent with the indirect impact of DWC on ozone that leaves the polar vortex cold in mid winter (i.e., dampening the typical warming induced by upward wave event in winter, Fig. 1f and Fig. 5f), and thus resulting in more ozone destruction in spring due to more accumulation of ODS on polar stratospheric clouds. This is also consistent with a strong polar vortex associated with increased DWC events (Figs. 10a,b). Comparing the ozone tendency due to chemistry in REF to the climatological mean values, we found that the indirect accumulative impact of DWC in spring results in increase of seasonally averaged chemical ozone loss (see Figs. S8k,l and Figs. S9k,l). The aforementioned indirect effect of DWC should only affect ozone concentration in spring when the polar stratosphere becomes sunlit. Moreover, we also note that there is a positive dynamical ozone tendency anomaly in late winter (Figs. 11i,j) resulting from the opposite responses of dynamical ozone tendency in REF and ABS during late winter (Figs. S8i,j and Figs. S9i,j). The increased ozone tendency due to dynamics in REF is likely associated with the occurrence of early final warming events (Fig. S10), allowing more waves to break in the stratosphere in late winter and thus, enhancing the dynamical ozone transport to the pole during this period. However, since the contribution from chemistry is dominant during REF, the total net effect of DWC on ozone is still negative (i.e., less ozone concentration), which is expected during reflective winters. In contrast, during ABS, the final warming is delayed until late spring resulting in less dynamical ozone transport to the pole during late winter (Fig. S10). This behavior is consistent with the previous observational studies (e.g., Hu et al. 2014), showing that early spring final warming events, which, on average, occur in early March tend to be preceded by non-SSW winters (i.e., typical of REF winter), while late spring final warming that on average take place up until early May are mostly preceded by SSW events in midwinter (typical of ABS winter).
5 Conclusions and Discussion

The goal of this study was to investigate the impact of DWC on polar stratospheric ozone in order to fully understand the mechanisms controlling the variability of Arctic stratospheric ozone. The key results of this study are as follows:

1. The impact of DWC on the residual circulation and on potential temperature tendency is reversible over the lifecycle, indicated by the time tendencies that change from being positive to negative. Thus the overall effect of having more DWC events in winter is to have a weaker residual circulation and colder polar vortex (i.e., DWC weakens the typical increase of residual circulation and temperature induced by upward wave events in winter).

2. A direct effect of DWC events on ozone, via advection to the pole by the induced residual circulation, is reversible, suggesting that DWC weakens the typical increase of ozone due to upward planetary wave events in winter. This is consistent with a stronger transport of ozone to the pole during upward planetary wave events in the absence of DWC events.

3. An indirect effect of DWC events, via a cooling of the winter polar vortex as a result of the reversible impact of DWC on the polar temperature tendency over the lifecycle, leads to increased springtime ozone loss through heterogeneous chemical processes.

4. Winter seasons dominated by DWC events (i.e., reflective winters) are characterized by a lower stratospheric ozone concentration in winter and spring. This behavior is consistent with the cumulative effects of downward planetary wave events on polar stratospheric ozone via the residual circulation and the polar temperature in winter.

Our results establish a new perspective on dynamical processes controlling Arctic ozone variability. Previous studies have shown that variations in upward planetary waves entering the lower stratosphere in midwinter determine the magnitude of ozone loss in the Arctic polar vortex (e.g., Randel et al. 2002; Newman et al. 2001; Weber et al. 2003; Tegtmeier et al. 2008). In particular, these studies showed that weaker midwinter planetary wave forcing in the stratosphere due to weaker upward wave propagation leads to lower spring Arctic temperatures, and thus to more ozone destruction in spring. Our results suggest that weaker planetary wave forcing in the stratosphere can also be attributed to enhanced DWC events in the presence of the vertical reflecting surface. This leads to positive EP flux divergence in the stratosphere, leading to less ozone transport in early winter and more ozone destruction in spring. A schematic presentation of the DWC influence on polar stratospheric ozone over the life cycle of the wave is shown in Fig. 12. During an upward absorption stage of the wave life cycle, the transport of ozone to the pole increases due to strong wave deceleration induced by upward wave propagation (Figs. 12a,c). The stronger residual circulation causes anomalous adiabatic warming over the pole due to air being advected downward. Furthermore, during a downward reflection stage, increased DWC events in the presence of a vertical reflecting surface leads to a positive divergence of the EP flux in the stratosphere, resulting in a weaker residual circulation in winter, and thus, less ozone transport to the pole (Figs. 12b,c). Thus, the overall direct effect of DWC on ozone is canceled out (reversible) over the life cycle, suggesting that DWC events weaken the typical increase of ozone due to upward wave event (Fig. 12c). In addition, since the polar vortex is
cold and strong during reflective winter, more ozone destruction will occur in spring due to heterogeneous chemical processes. Our results suggest that low polar stratospheric ozone levels in mid winter and spring can occur if the DWC events dominate the upward wave events in the Arctic winter stratosphere.

Recent studies have shown that large chemical ozone loss in the spring of 2011 is one of the major reasons for the unprecedented low Arctic column ozone (e.g., Manney et al. 2011; Isaksen et al. 2012; Hommel et al. 2014). This is attributed to extremely low mid-winter temperatures in the lower stratosphere resulting from weaker midwinter planetary wave forcing (Hurwitz et al., 2011). Shaw et al. (2014) hypothesized that the extreme negative eddy heat flux events observed during March 2011 could contribute to ozone loss via a weakening of the residual circulation, which leads to weakened transport, a lowering of Arctic temperatures and thus large springtime ozone loss. Our results confirmed this by showing that a lower ozone concentration in mid winter and early spring during reflective years are associated with both a weakening of ozone transport and an increase of springtime ozone loss induced by DWC events. Since winter of 2011 is classified as a reflective winter – characterized by a vertical reflecting surface and strong downward wave reflection—, the lower Arctic column ozone in 2011 can thus be attributed also to enhanced DWC events.

Our results also reveal that the amount of wave absorption directly influences polar Arctic temperatures, and therefore the amount of ozone destruction in spring. Since wave absorption is minimal during reflective winters, the winters tend to be cold with more ozone destruction. The process of wave reflection and absorption is highly variable, and the amount and location depends on the tropospheric source of the waves, on the structure of the vortex, on which the waves propagate, and on non-conservative effects (McIntyre and Palmer, 1983; Harnik and Lindzen, 2001; Harnik and Heifetz, 2007). Therefore, a better understanding of the tropospheric and stratospheric conditions that lead to such events is needed to improve our understanding of the link between stratospheric dynamics and ozone variability.

A recent multi-model inter-comparison of chemistry climate models (CCMs) concludes that the models do not produce a consistent prediction of the evolution of Arctic temperatures and ozone loss in the twenty-first century, mainly because of discrepancies in the model’s dynamics (SPARC CCMVal 2010, Chapter 4). Understanding the impact of DWC events on polar stratospheric ozone and temperatures could provide a useful diagnostic to validate the influence of stratospheric dynamics on springtime column ozone in coupled CCMs.

Appendix A: Ozone Profiles in MERRA2

The Aura Microwave Limb Sounder (MLS) ozone product (Waters et al., 2006) from 2005 to 2013 was used to validate the quality of ozone data from MERRA2. Figures A1a and A1b show the vertical profiles of zonal mean ozone mixing ratios in MERRA2 and MLS averaged between 60-90°N for (left) annual and (right) winter JFM means, from 2005 and 2013. It can be seen that the vertical profile of ozone mixing ratios, both mean (contour) and ranges (shading) in MERRA2, shows a reasonable agreement with MLS data from the lower to midstratosphere. Above 3 hPa – where photochemical processes become more dominant –, both the mean and the spread in MERRA2 slightly deviate from the MLS, which is likely associated with model ozone biases in MERRA2 due to a simplified (parameterized) ozone chemistry used in GEOS-5 model (Bosilovich...
et al., 2015). Furthermore, we also confirm that there are no major differences between the MERRA2 and MLS total column ozone climatologies (Fig. A1c). As shown by the solid red line and spreads in Fig. A1c, the MERRA2 total column ozone differs very little from MLS.

Figure A2 shows the differences between the daily total ozone and the ozone anomaly time series in MERRA1 and MERRA2 relative to MLS from 2005 to 2013. It is shown that a positive bias of total ozone mixing ratio in MERRA1 in the lower-to-mid stratosphere (between 100 and 5 hPa) is no longer exists in MERRA2 (Figs. A2d,e). There is also good improvement in total ozone mixing ratio in the upper stratosphere, as indicated by a significant reduction of negative ozone bias in MERRA2 in comparison to MERRA1. Likewise, ozone anomaly in MERRA2 is in a good agreement with MLS dataset compared to MERRA1 (Figs. A2i,j). In summary, we find that the ozone dataset from MERRA2 is significantly improved compared to MERRA1 (Rienecker et al., 2011) (see Figs. A2) and thus, the analysis based on this dataset is meaningful and more reliable.

### Appendix B: Residual-Mean Circulation and Wave Geometry Diagnostics

Understanding how circulation is controlled by planetary waves is the key to connecting the wave driving to polar temperatures and transport of trace gases such as ozone. The transformed Eulerian mean formulation (Andrews et al., 1987) can be used to directly examine wave effects on the circulation and ozone transport to the polar vortex (Fusco and Salby 1999; Plumb 2002; Lubis et al. 2016b). The residual mean circulation is calculated from the streamfunction ($\Psi$) of the residual TEM meridional $\vec{v}^*$ and vertical $\vec{w}^*$ winds, as follow:

$$\langle \vec{v}^*, \vec{w}^* \rangle = \frac{1}{\rho_0 \cos \phi} \left( -\Psi_z, -\frac{1}{a} \Psi_\phi \right), \quad (B1)$$

and hence,

$$\Psi^* = \rho_0 \cos \phi \int_z^{\infty} \vec{v}^* e^{-z/H} \partial_z, \quad (B2)$$

The residual mass streamfunction $\Psi^*_m \text{(units in kg/s)}$ we obtain by:

$$\Psi^*_m = (2\pi a) \rho_0 \cos \phi \int_z^{\infty} \vec{v}^* e^{-z/H} \partial_z. \quad (B3)$$

where $\Psi^*_m \rightarrow 0$ as $z \rightarrow \infty$.

Furthermore, in order to diagnose vertical reflecting surfaces and meridional wave guides for stratospheric planetary wave propagation, the index of refraction ($n^2$) is separated into contribution from meridional and vertical wavenumbers using a quasi-geostrophic (QG) potential vorticity (PV) equation on a $\beta$ plane, with a specified zonal wavenumber ($k$) and phase speed ($c$), as follow (see Harnik and Lindzen 2001; Lubis et al. 2016a, for details):

$$n^2 = \frac{N^2}{f^2} \left\{ \frac{\bar{q}_y}{\bar{v} - c} - k^2 + f^2 \frac{e^{z/2H}}{N} \left( \frac{e^{-z/H}}{N} \right) \left( \frac{e^{z/2H}}{N} \right) \right\} \equiv m^2 + \frac{N^2}{f^2} l^2. \quad (B4)$$
where $\eta_y$ is the meridional gradient of zonal mean potential vorticity, $N^2$ is the buoyancy frequency, and $\beta$ is the variation of the Coriolis parameter with latitude. Since the basic state is non-separable in latitude and height, this equation is solved by using a QG model (Harnik and Lindzen, 2001), in which the wave numbers are diagnosed from the wave solution $\psi$, as $m^2 = -Re(\psi_{zz}/\psi)$ and $l^2 = -Re(\psi_{yy}/\psi)$. A reflecting surface for vertical propagation is the $m^2 = 0$ surface. Here, the coefficients of the wave Eq. (B4) are calculated using monthly-mean zonal-mean zonal wind and temperature data.

Appendix C: Statistical Significance of Anomalous Values

The statistical significance of the composite anomalies was evaluated using a Monte Carlo test similar to Lubis et al. (2016a) and Schreck et al. (2012). In this test, Null cases were identified using dates with the same months and days as the original composite, but from the other years. For example, if a DWC event in MERRA2 occurred on 17 February 1981, then its corresponding Null cases would be every 17 February from 1980 and from 1982 to 2013. Null composites were calculated by randomly selecting the same number of dates from the Null cases as had been in the original composite. The Null hypothesis is that the difference between the composite anomaly and the broader population is zero. There are two ways to reject the Null hypothesis: (1) if the composite anomaly is greater than 975 of the 1000 random samples, and (2) if the composite anomaly is less than 975 of the 1000 random samples. That means by random chance, there is a 50 out of 1000 chance of rejecting the Null hypothesis, hence the 95% level. This significance test is advantageous since it accounts for the sample size and the possibility that variance may change with the time of year.

Figure 1. Evolution of the downward planetary wave events as a function of time from days -20 to +20 and pressure from MERRA2: (a) wave-1 meridional heat flux anomaly (black contours), (b) wave-1 EP flux divergence anomaly, (c) residual mass-streamfunction anomaly, and (d) potential temperature tendency averaged from 60 to 90°N. The contour intervals are \(\pm [1, 2, 4, 8, 16, 32, ...] \text{Km}^{-1}\) for Fig. 1a, \(\pm [0.5, 1, 2, 4, 8, 16, ...] \text{ms}^{-1}\text{day}^{-1}\) for Fig. 1b, \(\pm 1 \times 10^9 [0.5, 1, 2, 4, 8, 16, 32, 64,...] \text{kg} \text{s}^{-1}\) for Fig. 1c, and \(\pm 0.5 \text{K day}^{-1}\) for Fig. 1d. The gray shading indicates statistical significance at the 95% level using a 1000-trial Monte Carlo test. The periods of the maximum DWC event (days -3 to +3) are bounded by two vertical blue lines.
Figure 2. Evolution of the ozone tendencies for the composite of DWC event as a function of time and pressure, averaged from 60 to 90°N from MERRA2: (a) total ozone tendency, (b) ozone tendency anomaly due to dynamics and (c) due to parameterized chemistry. Tendency from the dynamics is decomposed into (d) vertical advection, (e) meridional advection, and (f) eddy transport effects based on Eq. 1. The periods of the maximum DWC event (days -3 to +3) are bounded by two vertical blue lines. Stippling indicates statistical significance at the 95% level using a 1000-trial Monte Carlo test.
Figure 3. Two-dimensional joint probability density distribution of (a) residual vertical wind velocity versus total ozone tendency, (b) residual vertical wind velocity versus ozone tendency due to dynamics and (c) potential temperature tendency versus ozone tendency due to parameterized chemistry, averaged over 60 to 90°N at 50 hPa (for a,b) and at 5 hPa (for c), in JFM from MERRA2. The axes are normalized to standard deviations in each quantity. Black contours show the probability distribution of all JFM days during 1980-2013 (contour shown are 1, 2, 3, 4, 5,.. % of total). Red and blue dots show days with 5% extreme maximum and minimum total wave-1 meridional heat flux. Larger circles indicate the mean of the distribution of all data (grey), high extremes (red), and low extremes (blue).
Figure 4. The time evolution of residual mass-streamfunction anomaly, temperature tendency, and ozone for the composite of DWC event (blue lines) and upward wave event (red lines). (a) Residual mass-streamfunction anomaly and (b) temperature tendency averaged from 100 to 1 hPa and 60 to 90°N. (c) Total column ozone tendency (solid lines) and mixing ratio ozone tendency (dashed lines) at 50 hPa, averaged between 60-90°N. The horizontal lines indicate the time-integrated significant values of each quantity over the life cycle. The time-integrated values for the upward wave event are divided by 10 for display purposes. Statistical significance at the 95% level is denoted with thick solid lines based on a 1000-trial Monte Carlo test.
Figure 5. Same as Fig. 1, but from a 100-yr CESM1(WACCM) simulation.
Figure 6. Same as Fig. 2, but from a 100-yr CESM1(WACCM) simulation.
Figure 7. Same as Fig. 3, but from a 100-yr CESM1(WACC) simulation.
Figure 8. Same as Fig. 4, but from a 100-yr CESM1(WACCM) simulation.
Figure 9. Time series of seasonal (JFM) mean of $m$ (line) and $U30$ (shading). The blue (red) asterisk indicates the reflective (absorptive) winters defined based on vertical wavenumbers and mid-stratosphere zonal mean wind (further discussed in the text).
Figure 10. Composites of the zonal-mean zonal wind, wave-1 geopotential height, and temperature mean differences for reflective (REF) and absorptive (ABS) winters in JFM from MERRA2 and CESM1(WACCM). (a,b,g,h) The zonal-mean zonal wind (black contour lines) superimposed with vertical and meridional wavenumbers (red and green contour lines). The grey shading indicates regions of wave evanescence and the red (green) contour line indicates the vertical reflecting surface \( m^2 = 0 \) (meridional wave guide \( l^2 = 0 \)). Contour interval for the zonal mean wind is 5 m/s. (c,d,i,j) The wave-1 geopotential heights averaged between 60 to 70°N; contour interval is logarithmic powers of 2: ± [0.5, 1, 2, 4, 8, 16, 32, 64, 128, 256,...] m. (e,f,k,l) The zonal mean temperature differences (REF or ABS minus the 1980-2013 climatological mean). Blue (red) contours indicate cooler (warmer) regions compared to the climatology. The contour interval is 1 K. The stipplings indicate differences significant at the 95% confidence level.
Figure 11. Composite-mean difference (REF minus ABS) of the (a,b,g,h) zonal mean ozone, (c,d,i,j) ozone tendency due to dynamics, and (e,f,k,l) ozone tendency due to chemistry averaged between January-February and March-April, from MERRA2 and CESM1(WACCM). The climatological mean values are denoted by green contour. The contour lines for this plot have increments of 50 units for total ozone and 2 units for ozone tendency. The solid (dashed) lines indicate positive (negative) values. The zero contour lines are plotted in thick darkgreen. Stipplings denote differences significant at the 95% confidence level.
Figure 12. Schematic presentation of the DWC influence on polar stratospheric ozone over the life cycle of the wave: (a) upward absorption stage of the wave life cycle, (b) downward reflection stage of the wave life cycle, with reversed tendencies. The red (blue) shading indicates negative (positive) anomaly in EP flux divergence. (c) The associated time evolution of ozone tendency over the life cycle of DWC, where the absorptive and reflective stages are denoted by the red and blue solid lines, respectively. In contrast, the evolution of ozone tendency associated with the life cycle of upward wave events, which consist only of a longer absorption stage, is denoted by the red dashed line.
Figure A1. (a-b) Vertical profile of zonal mean ozone (ppmv) from MERRA2 and AURA MLS averaged between 60-90°N for (left) annual and (right) winter JFM means. (c) Daily climatology of total column Arctic ozone (vertically integrated from 100-1 hPa) in Dobson Units (DU). The solid black (red) curve denotes the climatological mean of MERRA2 (AURA MLS) ozone, and the gray (purple) shading indicates the range from MERRA2 (AURA-MLS) for the 2005-2013 time period.
Figure A2. Time series of total ozone (left column) and ozone anomaly (right column) averaged between 60-90°N as a function of height and time for (a,f) MERRA-1, (b,g) MERRA2, and (c,h) AURA MLS datasets from 2005 to 2013. Also plotted, the total ozone and ozone anomaly differences between MERRA-1 and AURA MLS (Fig. A2d and Fig. A2i, respectively), and the differences between MERRA2 and AURA MLS (Fig. A2e and Fig. A2i, respectively).

Figure S1. Evolution of the upward wave events as a function of time from days -20 to +20 and pressure: (a) wave-1 meridional heat flux anomaly (black contours) and zero contour of the total wave-1 meridional heat flux (blue contour), (b) wave-1 EP flux divergence anomaly, (c) residual mass-streamfunction anomaly, and (d) potential temperature tendency averaged from 60 to 90°N. The black contour intervals are: \( \pm 1 \times 10^9 [0.5, 1, 2, 4, 8, 16, 32, 64, \ldots] \) kg s\(^{-1}\) for Fig. S1c and \( \pm 0.5 \) K day\(^{-1}\) for Fig. S1d. The gray shading indicates statistical significance at the 95% level using a 1000-trial Monte Carlo test. The periods of the maximum DWC event (days -3 to +3) are bounded by two vertical red lines.
Figure S2. Evolution of the ozone tendencies for the composite upward wave event as a function of time and pressure, averaged from 60 to 90°N: (a) total ozone tendency, (b) ozone tendency anomaly due to dynamics and (c) due to parameterized chemistry. Tendency from the dynamics is decomposed into (d) vertical advection, (e) meridional advection, and (f) eddy transport effects based on Eq.1. The periods of the maximum DWC event (days -3 to +3) are bounded by two vertical red lines. Stippling indicates statistical significance at the 95% level using a 1000-trial Monte Carlo test.
Figure S3. As in Fig. S1, but from a 100-yr CESM1(WACCM) simulation. The gray shading indicates statistical significance at the 95% level using a 1000-trial Monte Carlo test. The periods of the maximum DWC event (days -3 to +3) are bounded by two vertical red lines.
Figure S4. As in Fig. S2, but from a 100-yr CESM1(WACCM) simulation. The periods of the maximum DWC event (days -3 to +3) are bounded by two vertical red lines. Stippling indicates statistical significance at the 95% level using a 1000-trial Monte Carlo test.
Figure S5. Evolution of the downward wave (k=2) events as a function of time from days -20 to +20 and pressure: (a) wave-2 meridional heat flux anomaly (black contours) and (b) wave-2 EP flux divergence anomaly. The black contour intervals are: $\pm 1 \times 10^9 [0.5, 1, 2, 4, 8, 16, 32, 64, ...] \text{kg s}^{-1}$ for Fig. S5a and $\pm 0.5 \text{K day}^{-1}$ for Fig. S5b. The gray shading indicates statistical significance at the 95% level using a 1000-trial Monte Carlo test.
Figure S6. As in Fig. 3, but for wave 2.
Figure S7. (a). Probability distribution functions of reflective (blue) and absorptive (red) winters. The vertical black lines represent the 5th (-17.5 Kms$^{-1}$) and 95th (63.6 Kms$^{-1}$) percentile values of the daily distribution from all years. (b) Percentage (frequency) of extreme negative high-latitude averaged wave-1 heat flux events at 50-hPa level vs extreme positive events at the same levels during JFM for all years (black circle), reflective years (blue triangle) and absorptive years (red asterisk).
Figure S8. Composite-mean difference (REF or ABS minus climatological mean (CLM)) of the (a,b,g,h) zonal mean ozone, (c,d,i,j) ozone tendency due to dynamics, and (e,f,k,l) ozone tendency due to chemistry from MERRA, averaged between January-February and March-April. Stipplings denote differences significant at the 95% confidence level.
Figure S9. As in Fig. S8, but from 100-yr CESM1(WACCM) simulation. Stipplings denote differences significant at the 95% confidence level.
Figure S10. (top) Time series of the polar vortex evolution during the time of final vortex breakup in the NH from MERRA2. The final breakup day is defined as the first day when the is negative, and never recovers. (bottom) Composites of the vortex for REF (blue) and ABS (red) winters. Dark green contour lines denote the time series of zonal mean wind from all years.
Table S1. As in Table 1, but for the CESM1(WACCM) simulation.
