Submitted to Atmospheric Chemistry and Physics (ACP)
Abstract:

Secondary organic aerosols (SOA) account for a large fraction of submicron particles in the atmosphere. SOA can occur in amorphous solid or semi-solid phase states depending on chemical composition, relative humidity (RH), and temperature. The phase transition between amorphous solid and semi-solid states occurs at the glass transition temperature \(T_g\). We have recently developed a method to estimate \(T_g\) of pure compounds containing carbon, hydrogen, and oxygen atoms (CHO compounds) with molar mass less than 450 g mol\(^{-1}\) based on their molar mass and atomic O:C ratio. In this study, we refine and extend this method for CH and CHO compounds with molar mass up to \(\sim 1100\) g mol\(^{-1}\) using the number of carbon, hydrogen, and oxygen atoms. We predict viscosity from the \(T_g\)-scaled Arrhenius plot of fragility (viscosity vs. \(T_g/T\)) as a function of the fragility parameter \(D\). We compiled \(D\) values of organic compounds from literature, and found that \(D\) approaches a lower limit of \(\sim 10\) (\(\pm 1.7\)) as the molar mass increases. We estimated viscosity of \(\alpha\)-pinene and isoprene SOA as a function of RH by accounting for hygroscopic growth of SOA and applying the Gordon-Taylor mixing rule, reproducing previously published experimental measurements very well. Sensitivity studies were conducted to evaluate impacts of \(T_g\), \(D\), hygroscopicity parameter (\(\kappa\)), and the Gordon-Taylor constant on viscosity predictions. Viscosity of toluene SOA was predicted using the elemental composition obtained by high-resolution mass spectrometry (HRMS), resulting in a good agreement with the measured viscosity. We also estimated viscosity of biomass burning particles using the chemical composition measured by HRMS with two different ionization techniques: electrospray ionization (ESI) and atmospheric pressure photoionization (APPI). Due to differences in detected organic compounds and signal intensity, predicted viscosities at low RH based on ESI and APPI measurements differ by 2-5 orders of magnitude. Complementary
measurements of viscosity and chemical composition are desired to further constrain RH-dependent viscosity in future studies.

1. Introduction

Secondary organic aerosols (SOA) account for a large fraction of submicron particles in the atmosphere and they play an important role in climate, air quality and public health (Goldstein and Galbally, 2007; Jimenez et al., 2009). Traditionally, SOA particles were assumed to be liquid with dynamic viscosity $\eta$ below $10^2$ Pa s, but a number of recent studies have shown that they can also adopt amorphous semi-solid ($10^2 \leq \eta \leq 10^{12}$ Pa s), or glassy solid ($\eta > 10^{12}$ Pa s) states, depending on chemical composition and temperature (Zobrist et al., 2008; Koop et al., 2011; Huang et al., 2018; Reid et al., 2018). The phase state is also strongly affected by relative humidity, as water can act as a plasticizer to lower viscosity (Mikhailov et al., 2009). Ambient and laboratory-generated SOA particles have been observed to bounce off the smooth hard surface of an inertial impactor at low RH, implying a non-liquid state (Virtanen et al., 2010; Saukko et al., 2012; Bateman et al., 2015; Jain and Petrucci, 2015), whereas predominantly biogenic SOA particles in the Amazon basin did not bounce off the impactor surface at high RH, implying they are primarily liquid (Bateman et al., 2016). Upon dilution or heating, SOA particles were observed to evaporate unexpectedly slowly (Cappa and Wilson, 2011; Vaden et al., 2011), and recent modeling studies have evaluated the contributions of low diffusivity and volatility to slow evaporation rates (Roldin et al., 2014; Yli-Juuti et al., 2017). Measurements of viscosity of SOA bulk material derived from oxidation of $\alpha$-pinene (Renbaum-Wolff et al., 2013; Zhang et al., 2015; Hosny et al., 2016), limonene (Hinks et al., 2016), isoprene (Song et al.,
2015), and toluene (Song et al., 2016a) have confirmed that SOA particles adopt a wide range of viscosities.

The particle phase state has been shown to affect gas uptake and chemical transformation of organic compounds due to kinetic limitations of bulk diffusion (Shiraiwa et al., 2011; Abbatt et al., 2012; Kuwata and Martin, 2012; Zhou et al., 2013; Slade and Knopf, 2014; Arangio et al., 2015; Davies and Wilson, 2015; Wang et al., 2015; Berkemeier et al., 2016; Marshall et al., 2016; Liu et al., 2018; Pratap et al., 2018; Zhang et al., 2018). Molecular motion can be hindered in a highly viscous matrix, slowing down photochemical reactions in particles (Lignell et al., 2014; Hinks et al., 2016). Water diffusion can be still fast even in an amorphous solid matrix under room temperature, but it can be hindered significantly under low temperatures (Mikhailov et al., 2009; Zobrist et al., 2011; Bones et al., 2012; Berkemeier et al., 2014; Price et al., 2014), affecting homogeneous vs. heterogeneous ice nucleation pathways (Murray et al., 2010; Wang et al., 2012a; Wang et al., 2012b; Baustian et al., 2013; Schill and Tolbert, 2013; Berkemeier et al., 2014; Schill et al., 2014; Lienhard et al., 2015; Ignatius et al., 2016; Knopf et al., 2018). Despite the substantial implications of the SOA particle phase state, its effects on gas-particle interactions have not yet been considered explicitly in current climate and air quality models (Shrivastava et al., 2017).

Partitioning of semi-volatile compounds into viscous particles may result in kinetically-limited growth in contrast to quasi-equilibrium growth (Perraud et al., 2012; Shiraiwa and Seinfeld, 2012; Booth et al., 2014; Zaveri et al., 2014; Mai et al., 2015; Liu et al., 2016), which also affects the evolution of particle size distribution upon SOA growth (Shiraiwa et al., 2013; Zaveri et al., 2018). Chamber experiments probing mixing timescales of SOA particles derived by oxidation of various precursors such as isoprene, terpene, and toluene have observed strong
kinetic limitations at low RH, but not at moderate and high RH (Loza et al., 2013; Ye et al., 2016; Ye et al., 2018). Gorkowski et al. (2017) did not observe significant diffusion limitations for glycerol and squalene in α-pinene SOA. Quasi-equilibrium versus kinetically-limited or non-equilibrium SOA growth remains an open issue and warrants further investigations.

Group contribution methods have been used to predict the viscosities of pure compounds when the functionality and molecular structure are known (Sastri and Rao, 1992; Rothfuss and Petters, 2017). Song et al. (2016) showed that estimations from group contribution approaches combined with either nonideal or ideal mixing reproduced the RH-dependent trends particularly well for the alcohol, di-, and tricarboxylic acid systems with viscosity of up to 10^4 Pa s. By contrast, model calculations overestimated the viscosity of more viscous compounds including mono-, di-, and trisaccharides by many orders of magnitude (Song et al., 2016b). A recent study compiled viscosity of organic compounds with atmospherically relevant functional groups, investigating the influence of the number and location of functional groups on viscosity (Rothfuss and Petters, 2017). These studies provide important insights in estimating the viscosity of individual organic compounds.

Particle phase state can be characterized by a glass transition temperature \( T_g \), which is a characteristic temperature representing a non-equilibrium phase transition from a glassy solid state to a semi-solid state as the temperature increases (Koop et al., 2011). Recently, we have developed a method to estimate \( T_g \) of pure organic compounds comprised of carbon, hydrogen, and oxygen (CHO compounds) with molar mass less than 450 g mol\(^{-1}\) based on their molar mass and atomic O:C ratio (Shiraiwa et al., 2017). It has been applied successfully in a global chemistry climate model to predict \( T_g \) and the phase state of atmospheric SOA, which indicated that SOA particles are mostly liquid or semi-solid in the planetary boundary layer, while they
should be glassy in the middle and upper troposphere (Shiraiwa et al., 2017). A recent study provided a consistent result, suggesting that mixing timescales of organic molecules within SOA are often < 1 h in a global planetary boundary layer (Maclean et al., 2017).

It has been shown that SOA particles contain oligomeric compounds with molar masses higher than 450 g mol⁻¹ (Gao et al., 2004; Tolocka et al., 2004; Nizkorodov et al., 2011; Nozière et al., 2015), which makes the previously developed parameterization incomplete. In this study, we extend the parameterization of $T_g$ to higher molar mass compounds, and apply it to high-resolution mass spectrometry data for toluene SOA and biomass burning particles. The Arrhenius approach and the Gordon-Taylor mixing rules were applied to estimate viscosity of SOA bulk materials to compare with the literature reported viscosity measurements. This method will be useful for estimations of viscosity of organic particles, for which high-resolution mass spectra are available. It can also be applied in global or regional models to evaluate impacts of the particle phase state on the role of SOA in climate and air quality.

2. Parameterization development

2.1 Glass transition temperature

Figure 1a shows the dependence of $T_g$ on the molar mass ($M$) of organic compounds. Solid markers represent measured $T_g$ of 258 CHO compounds (Koop et al., 2011; Dette et al., 2014; Rothfuss and Petters, 2017), while open markers represent 654 CHO compounds in SOA (Shiraiwa et al., 2014). Markers are color-coded by atomic O:C ratio. Their melting points ($T_m$) were estimated by the Estimation Programs Interface (EPI) Suite software version 4.1 (US-EPA, 2012) and their $T_g$ were estimated using the Boyer-Kauzmann rule: $T_g = g \cdot T_m$ with $g = 0.7$ (Koop et al., 2011; Shiraiwa et al., 2017). This rule can provide good estimates of $T_g$, as has been
validated in previous work (Koop et al., 2011) and also shown in Fig. A2(a). A subset of data shown in Figure 1 was originally published in Shiraiwa et al. (2017) for compounds with $M < 450$ g mol$^{-1}$. This version of the figure has been updated to include a number of experimentally measured $T_g$ values of larger compounds with $M$ up to 1153 g mol$^{-1}$, including aliphatic compounds containing OH and/or COOH groups. Specifically, data for 76 aliphatic alcohols, 39 carbohydrates and their derivatives, 4 carboxylic acids, and 4 hydroxy acids, as compiled by Rothfuss and Petters (2017), have been added to Figure 1. Eight of these compounds are carbohydrates with $M > 450$ g mol$^{-1}$. These updates are critical for reliable parameterization of $T_g$ based on $M$. When $M$ increases above $\sim 500$ g mol$^{-1}$, the slope of $T_g$ decreases, making it challenging to extrapolate the low-$M$ data from the original Shiraiwa et al. (2017) study to higher $M$ values. When $M$ increases to $\sim 1000$ g mol$^{-1}$, the corresponding $T_g$ appears to level at around 420 K.

Such dependence on $M$ has been described for polymers with the Fox-Flory equation:

$$T_g(M) = T_{g,\infty} - \frac{K_m}{M}$$

(Fox Jr and Flory, 1950), where $K_m$ is a constant and $T_{g,\infty}$ is the asymptotic value of $T_g$ specific to the polymer. We conducted a literature search and found that most of the reported $T_{g,\infty}$ values fell below $\sim 500$ K (Fox Jr and Flory, 1950; Onder et al., 1972; Montserrat and Colomer, 1984; Polymer handbook, 1999; Papadopoulos et al., 2004; Matsushima et al., 2017). The Fox-Flory equation works very well for high molar mass compounds and is also generally applicable to smaller compounds (Koop et al., 2011), as supported by an approximately linear dependence of $T_g$ on the inverse molar mass in Fig. A1(a). Figure 1b plots the values of $T_g$ as a function of the atomic O:C ratio of organic molecules. Figures 1a and 1b clearly demonstrate that $T_g$ depends primarily on the molar mass with a weak dependence on the atomic O:C ratio.
A parameterization for $T_g$ calculation based on the molar mass and atomic O:C ratio was developed in our recent work, which is applicable to CH and CHO compounds with $M < 450$ g mol$^{-1}$ (Shiraiwa et al., 2017):

$$T_g = A + BM + C^2M^2 + D (O:C) + E M (O:C)$$  \hspace{1cm} (1)$$

where $A = -21.57 \pm 13.47$ [K], $B = 1.51 \pm 0.14$ [K mol g$^{-1}$], $C = -1.7 \times 10^{-3} \pm 3.0 \times 10^{-4}$ [K mol$^2$ g$^{-2}$], $D = 131.4 \pm 16.01$ [K] and $E = -0.25 \pm 0.085$ [K mol g$^{-1}$], respectively. These values were obtained by fitting the measured $T_g$ of 179 CH and CHO compounds with $M < 450$ g mol$^{-1}$ with multi-linear least squares analysis. Note that application of Eq. (1) may provide unreasonable $T_g$ values for compounds with $M > 500$ g mol$^{-1}$ because it does not account for the strong curvature in the $T_g$ vs. $M$ dependence shown in Figure 1a.

In this study we have developed an improved parameterization to predict $T_g$ of CH and CHO compounds using the number of carbon ($n_C$), hydrogen ($n_H$), and oxygen ($n_O$) that can also be applied to higher molar mass compounds. Motivated by a good correlation between $T_g$ and volatility (Fig. 1a in Shiraiwa et al., 2017), we use an equation with a similar formulation to the equation used to predict the saturation mass concentration or volatility (Donahue et al., 2011; Li et al., 2016):

$$T_g = (n_C^0 + \ln(n_C)) b_C + \ln(n_H) b_H + \ln(n_C) \ln(n_H) b_{CH} + \ln(n_O) b_O + \ln(n_C) \ln(n_O) b_{CO}$$  \hspace{1cm} (2)$$

where $n_C^0$ is the reference carbon number, $b_C$, $b_H$ and $b_O$ denote the contribution of each atom to $T_g$, and $b_{CH}$ and $b_{CO}$ are coefficients that reflect contributions from carbon-hydrogen and carbon-oxygen bonds, respectively. These values were obtained by fitting the measured $T_g$ of 42 CH compounds and 258 CHO compounds with multi-linear least squares analysis with 68% prediction and confidence intervals. The best-fit parameters are summarized in Table 1.
Note that the evaluation dataset used to derive Eq. (2) contains CH compounds with \( M < 260 \text{ g mol}^{-1} \) (see Fig. A2b for comparison of measured and predicted \( T_g \)). Thus, the application of Eq. (2) to higher molar mass compounds may require further investigations when measured \( T_g \) for higher molar mass compounds becomes available. We plan to continue to refine our method as additional glass transition data on high molar mass compounds become available. Figure 1c shows that the \( T_g \) values predicted using Eq. (2) are in good agreement with the \( T_g \) values measured in experiments (see also Fig. A1(b)) or estimated by the Boyer-Kauzmann rule as indicated by the high correlation coefficient of 0.95. \( T_g \) of individual compounds can be predicted within \( \pm 21 \) K as indicated by the prediction band (dotted lines in Fig. 1c); however, this uncertainty may be much smaller for multicomponent SOA mixtures under ideal mixing conditions as indicated in the confidence band (dashed lines, almost overlapping with the 1:1 line).

These results are noteworthy given that the parameterization (Eq. 2) does not consider either explicit molecular structures or functional groups. Previous studies have shown that \( T_g \) can be especially sensitive to the number of OH groups, which interact strongly through hydrogen bonding. For example, Nakanishi et al., (2011) found a direct relationship between \( T_g \) and the number of hydroxyl groups in a molecule for sugar alcohols; \( T_g \) increases as the number of OH groups increases. They reported that the correlation between \( T_g \) and the number of OH groups was much stronger than the correlation between \( T_g \) and the number of carbons in a molecule. Such a trend is implicitly included in Eq. (1) and (2), which contain the O:C ratio and number of oxygen atoms as parameters, respectively. Recently, Rothfuss and Petters (2017) showed an approximately linear relationship between the number of OH groups and \( T_g \) for compounds with up to eight OH groups. Grayson et al. (2017) showed that addition of hydroxyl functional groups
increases viscosity, a conclusion supported by both the experimental data and quantitative structure-property relationship model. The correlation between $T_g$ and the number of carbon atoms is consistent with the free volume theory, in which molecular motion is restricted by the difference between the space required for a molecule to vibrate versus the space in which the molecule resides (i.e., the free volume) (White and Lipson, 2016). The correlation between $T_g$ and the number of OH groups is more consistent with the topological constraint theory, where the primary influence is the three dimensional structure of the molecule as determined by molecular bonds and hydrogen-bonding networks (Nakanishi and Nozaki, 2011; van der Sman, 2013). Future experiments targeting more comprehensive $T_g$ data, especially for higher molar mass compounds, would lead to further refinements of our $T_g$ parameterizations.

Comparing Eq. (1) and (2), the two parameterizations give similar performance for compounds with $M < 450$ g mol$^{-1}$ as shown in Fig. A2c. The statistical measures of correlation coefficient (R), mean bias (MB), and root mean square error (RMSE) are 0.93, $6.45$ K, and $25.64$ K, respectively, for the performance of Eq. (1), while for Eq. (2), they are 0.95, $3.15$ K, and $21.11$ K, respectively. It should be noted again that Eq. (1) cannot be used to predict $T_g$ for compounds with $M > 450$ g mol$^{-1}$. For example, $T_g$ of stachyose ($M = 667$ g mol$^{-1}$) predicted by Eq. (1) is 198 K, while that by Eq. (2) is 394 K, which agrees much better with the measured mean $T_g$ of 396 K (Rothfuss and Petters, 2017). Eq. (2) is more flexible than Eq. (1) and can be potentially expanded to include compounds containing hetero-atoms (e.g., nitrogen or sulfur), once substantial sets of experimental values of $T_g$ for such compounds become available. Regarding the application in air quality and climate models, Eq. (1) can be applied in the volatility basis set (VBS) (Donahue et al., 2006; Donahue et al., 2011) and the molecular corridor approach (Shiraiwa et al., 2014; Li et al., 2016) to predict the $T_g$ of SOA particles
(Shiraiwa et al., 2017), while the new parameterization may be suitable for coupling with the statistical oxidation model which characterizes the SOA evolution as a function of $n_C$ and $n_O$ (Cappa and Wilson, 2012; Jathar et al., 2015).

These parameterizations (Eqs. 1, 2) calculate $T_g$ based on the elemental composition of organic compounds. SOA particles contain a number of organic compounds as well as a variable amount of liquid water, which has low $T_g$ (136 K) and can act as a plasticizer (Mikhailov et al., 2009; Koop et al., 2011). Under humid conditions, SOA particles take up water by hygroscopic growth in response to RH, lowering $T_g$ and viscosity of SOA particles. Estimations of $T_g$ for SOA-water mixtures were discussed by Shiraiwa et al. (2017), who applied the Gordon-Taylor equation validated for a wide range of mixtures of organics, polymer, and water (Roos, 1993; Hancock and Zografi, 1994; Zobrist et al., 2008; Dette et al., 2014; Dette and Koop, 2015).

Briefly, $T_g$ of mixtures of SOA compounds under dry conditions ($T_{g,org}$) were calculated assuming the Gordon-Taylor constant ($k_{GT}$) of 1 (Dette et al., 2014): $T_{g,org} = \sum w_i T_{g,i}$, where $w_i$ is the mass fraction of organic compound $i$, which can be derived using mass concentrations of SOA products. The Gordon-Taylor equation can also be applied to calculate $T_g$ of organic-water mixtures considering the mass fraction of organics ($w_{org}$) in SOA particles (Koop et al., 2011):

$$T_g(w_{org}) = \frac{(1-w_{org})T_{gw} + \frac{1}{k_{GT}}w_{org}T_{g,org}}{(1-w_{org}) + \frac{1}{k_{GT}}w_{org}}$$

(3)

$w_{org}$ can be calculated using the mass concentrations of water ($m_{H_2O}$) and SOA ($m_{SOA}$) as $w_{org} = m_{SOA} / (m_{SOA} + m_{H_2O})$. $m_{H_2O}$ can be estimated using the effective hygroscopicity parameter ($\kappa$) (Petters and Kreidenweis, 2007):

$$m_{H2O} = \frac{\kappa_p m_{SOA}}{\rho_{SOA}(\frac{1}{w_{H2O}} - 1)}$$

(4)
The density of water ($\rho_w$) is 1 g cm$^{-3}$, the density of SOA particles ($\rho_{SOA}$) is assumed to be 1.2 g cm$^{-3}$ (Kuwata et al., 2012), $m_{SOA}$ is the total mass concentrations of SOA, and $a_w$ is the water activity calculated as $a_w = RH/100$. Pajunoja et al. (2015) found that water uptake in subsaturated conditions is inhibited until RH is high enough for dissolution of water in SOA particles with relatively low O:C ratios. As oxidation of SOA increases, solubility of water increases and dissolution occurs at lower RH values. In both cases, the use of subsaturated hygroscopicity measurements was supported.

2.2 Viscosity

Temperature dependence of viscosity ($\eta$) was predicted using the modified Vogel-Tammann-Fulcher (VTF) equation (Angell, 1991):

$$\eta = \eta_\infty e^{D \frac{T_0}{T - T_0}} \quad (5)$$

where $\eta_\infty$ is viscosity at infinite temperature; $T_0$ is the Vogel temperature; $T$ is the ambient temperature. The fragility parameter, $D$, characterizes how rapidly the dynamics of a material slow down as $T$ approaches $T_g$, reflecting to what degree the temperature dependence of the viscosity deviates from Arrhenius behavior. When $T$ is close to $T_g$ ($T_g/T \approx 1$), smaller $D$ values indicate that viscosity is sensitive to temperature change (fragile behavior); while larger $D$ values indicate that viscosity is less sensitive to temperature change (strong or Arrhenius behavior).

Assuming $\eta_\infty = 10^{-5}$ Pa s (Angell, 1991):

$$\log \eta = -5 + 0.434 \frac{T_0 D}{T - T_0} \quad (6)$$

When $T = T_g$, $\eta = 10^{12}$ Pa s, which leads to (Angell, 1991; Angell, 2002):

$$T_0 = \frac{39.17 T_g}{D + 39.17} \quad (7)$$
As can be seen in Eq. (5), both $T_g$ and $D$ are required to calculate $\eta$ from Eq. (4) at a given temperature.

Figure 2 shows the $T_g$-scaled Arrhenius plot of fragility (viscosity versus $T_g/T$) referred to as an Angell plot (Angell, 1995). $D$ values of organic compounds are typically in the range of $\sim$5–30 (Angell, 1997). To estimate $D$ values that could be applied to SOA compounds, we compiled measured fragility values. Fragility was often measured in the form of the fragility steepness index ($m$), which represents the slope of the Arrhenius plot at the point where $T = T_g$ (Boehmer et al., 1993). Compounds with lower $m$ exhibit higher $D$ values, indicating stronger glass formers. The measured $m$ of 95 organic compounds are included in the Supplement. $m$ can be converted to $D$ using the following equation (see the full derivation of this equation in Appendix A):

$$D = \frac{665.89}{m - 17}$$

Figure 3 shows the measured $D$ as a function of (a) molar mass and (b) atomic O:C ratio of organic molecules. The molar mass exerts a stronger effect on fragility, while there is little dependence of $D$ on the O:C ratio. As molar mass increases, $D$ approaches a lower limit of 10.3 ($\pm$ 1.7), consistent with the value of 10 used in our recent study (Shiraiwa et al., 2017). To evaluate the impact of the variations of $D$ on viscosity prediction, sensitivity calculations were conducted as described in Sect. 3.

Besides the VTF equation, another commonly used equation for describing the temperature dependence of viscosity is the Williams-Landel-Ferry (WLF) equation: $\log \left( \frac{\eta(T)}{\eta(T_g)} \right) = \frac{-C_1(T - T_g)}{C_2 + (T - T_g)}$, where empirical parameters $C_1$ and $C_2$ are adopted as 17.44 and 51.6 K, respectively (Williams et al., 1955; Schill and Tolbert, 2013; Wang et al., 2015). The two equations are
mathematically equivalent, both defined with respect to a reference temperature, and their
dependence is assumed between temperature and free volume (O’Connell and McKenna, 1999; Huang and McKenna, 2001; Metatla and Soldera, 2007). For the VTF equation, the reference is the Vogel temperature ($T_0$)—a hypothetical temperature at which all non-vibrational motion ceases and viscosity becomes infinite and the theoretical foundation of the VTF equation includes both thermodynamic and kinetic considerations (O’Connell and McKenna, 1999; Huang and McKenna, 2001; Metatla and Soldera, 2007). The calculations of viscosity in this study are based mainly on the VTF equation and the difference between calculated results from the two equations will be briefly discussed in the following section.

3. Comparison of predicted viscosity with measurements

3.1. SOA formed from α-pinene and isoprene

The purpose of this section is to demonstrate that viscosity of SOA material can be predicted over a broad range of RH values from four parameters: $T_g$ of dry SOA ($T_{g,\text{org}}$), fragility ($D$), hygroscopicity ($\kappa$), and the Gordon-Taylor constant for mixing SOA and water ($k_{GT}$). Viscosity of α-pinene SOA has been measured as a function of RH by several groups using multiple experimental techniques as shown in Fig. 4(a) (Abramson et al., 2013; Renbaum-Wolff et al., 2013; Kidd et al., 2014; Pajunoja et al., 2014; Bateman et al., 2015; Zhang et al., 2015; Grayson et al., 2016). The wide range of experimentally measured viscosities reported for α-pinene SOA, particularly from 30-60% RH is most likely a consequence of the different experimental approaches, mass loadings and O:C ratios for each experiment. For instance,
Grayson et al. (2016) used mass loadings of 121 to 14000 µg m$^3$ and observed that viscosity decreased as mass loading increased. Higher mass loadings would lead to greater partitioning of semi-volatile and lower molar mass compounds into the particle phase, which would lead to the decrease of $T_g$ and viscosity of the resulting SOA mixture. They concluded that their results should be considered a lower limit for viscosity of α-pinene SOA in the atmosphere. It should also be noted that the viscosity measurements from Renbaum-Wolff et al. (2013) were for the water-soluble portion of the SOA. These datasets suggest that viscosity of α-pinene SOA approaches very high values (~$>10^8$ Pa s) below 20-30% RH and decreases with an increase in RH reaching a value of ~10 Pa s at 80% RH. As can be seen in Fig. 4(b), isoprene SOA is less viscous with $\eta < 10^6$ Pa s even under dry conditions, undergoing a phase transition from a semi-solid phase to a liquid phase at ~55% RH (Bateman et al., 2015; Song et al., 2015).

The solid lines with the shaded areas in Figure 4 are viscosity values predicted using $T_{g,\text{org}}$, $D$, $\kappa$, $k_{GT}$. $T_{g,\text{org}}$ values were adopted by Berkemeier et al. (2014) who estimated $T_{g,\text{org}}$ with the Boyer-Kauzmann rule using the melting point of representative SOA oxidation products. Note that Eq. (1) or (2) were not used to estimate $T_{g,\text{org}}$, which should be done in future studies by obtaining their elemental composition using high resolution mass spectrometry. For α-pinene, $T_{g,\text{org}}$ was assumed to be 278 K corresponding to an O:C ratio of 0.5 (Berkemeier et al., 2014), which is a typical O:C ratio of α-pinene SOA (Aiken et al., 2008; Chen et al., 2011; Putman et al., 2012).

The $T_{g,\text{org}}$ selected for isoprene SOA was 255 K, corresponding to the O:C ratio of 0.6. Although no measurements of the O:C ratio for the experimental isoprene SOA data were reported, Song et al. (2015) estimated O:C of 0.64-1.1 based on literature values. As O:C ratios are useful in estimating $T_{g,\text{org}}$, we encourage the measurement of the O:C ratio of SOA when
conducting viscosity measurements. In contrast to α-pinene SOA, there are limited viscosity measurements for isoprene SOA. While the predicted viscosity is consistent with the experimental data, comparison of our model predictions to additional measurements is strongly recommended. Song et al. (2015) prepared their samples in a potential aerosol mass (PAM) reactor while those investigated by Bateman et al. (2015) were generated in a smog chamber. It has been suggested that under ambient conditions, the majority of isoprene-derived SOA can be derived through heterogeneous interactions with acidic sulfate particles forming oligomers (Lin et al., 2013; Surratt et al., 2010; Gaston et al., 2014), which may increase viscosity. Further studies are warranted to compare laboratory-generated and ambient isoprene SOA, and to investigate the effect of the acidic seed on the viscosity.

For both α-pinene and isoprene SOA, $D$ was set to 10 based on the analysis presented in Fig. 3(a). $\kappa$ was set to 0.1 based on field and laboratory measurements (Gunthe et al., 2009; Lambe et al., 2011b; Pajunoja et al., 2014; Petters et al., 2017) and $k_{GT}$ was assumed to be 2.5 (Zobrist et al., 2008; Koop et al., 2011). Using these parameters, the predicted viscosities match well the magnitude and the RH-dependence of the measured viscosity of α-pinene and isoprene SOA. Figure 4 also shows predicted viscosities (dotted lines) using the WLF equation, which shows similar values as the VTF equation, but slightly underestimates the viscosity of α-pinene SOA at low RH and overestimates the viscosity of isoprene SOA at high RH.

Sensitivity studies were conducted to examine the effects of $T_{g,org}$, $D$, $\kappa$ and $k_{GT}$, on the calculated viscosity. In these studies, $T_{g,org}$ of α-pinene and isoprene SOA were varied within 229-328 K and 255-316 K, respectively, representing $T_{g,org}$ of different oxidation states (Berkemeier et al., 2014). $D$ was varied between 5 and 30, which is the range characteristic for organic compounds (see Fig. 3a). $\kappa$ of 0.05-0.15 were used for α-pinene and isoprene SOA
(Lambe et al., 2011b; Pajunoja et al., 2015). For the Gordon-Taylor constant, values of 2.5±1.5 were considered (Zobrist et al., 2008; Koop et al., 2011; Dette et al., 2014; Dette and Koop, 2015).

The effect of varying each parameter on the calculated viscosity of α-pinene SOA is illustrated in Fig. 5. Variations of ±50 K in $T_{g,\text{org}}$ result in 3-6 orders of magnitude difference in calculated values at dry conditions, indicating that $T_{g,\text{org}}$ is a critical parameter for viscosity estimations. Decreasing $D$ from 10 to 5 led to a decrease of calculated values by more than one order of magnitude. The calculated results were within the upper limit of measurements when increasing $D$ from 10 to 20, and the predicted values were only slightly enhanced when further increasing $D$ from 20 to 30. Calculated values with variations in $\kappa$ from 0.05 to 0.15 and $k_{GT}$ from 1.0 to 4.0 were all within the measured ranges.

For isoprene SOA, an increase of $T_{g,\text{org}}$ to 287 K, which represents a higher oxidation state (Berkemeier et al., 2014), led to calculated values to be several orders of magnitude higher than the upper limit of measurements (Fig. 6a). When $T_{g,\text{org}}$ reaches 316 K, isoprene SOA can occur as a solid for RH lower than ~40%. Compared to α-pinene SOA, a variation in $D$ has a larger effect on the calculated viscosity (Fig. 6b). For a range of 5 - 30 for $D$, calculations with the $D$ value of 10 agreed well with the measurements, while other $D$ values resulted in calculated viscosity outside of the measured ranges. Figures 6c and 6d show that decreasing $\kappa$ and $k_{GT}$ below the reference values, the predictions overestimate the measured $\eta$ by one or two orders of magnitude. The latter is most evident at RH > 60%, where the calculated values were higher than the upper limit of measurements. Modeling results with $\kappa$ and $k_{GT}$ increasing to 0.15 and 4.0, respectively, were within the lower limit of measurements.
The above comparison between the measured and predicted viscosity demonstrates that the method described in this study can reproduce reasonably well the measured RH-dependent viscosity of SOA formed from α-pinene and isoprene. The sensitivity calculations showed that $T_{g,org}$ contributed the most to the uncertainty in the viscosity estimates. Previous studies have shown that the experimental conditions such as particle mass concentrations (Grayson et al., 2016) and RH upon SOA formation (Kidd et al., 2014; Hinks et al., 2018) can impact chemical composition of SOA and hence the phase state and viscosity. Further efforts to constrain the uncertainties are needed both in experiments and parameterizations.

### 3.2. SOA formed from toluene

In this and the following sections, we examine the feasibility of calculating the value of $T_{g,org}$ from mass spectrometry data on SOA. Hinks et al. (2017) measured the elemental composition of toluene SOA using nanospray desorption electrospray ionization high-resolution mass spectrometry (nano-DESI-HRMS) (Roach et al., 2010a, b). Toluene SOA were formed by OH photooxidation in an aerosol smog chamber at <2% RH (mass loading = 23 μg m$^{-3}$) and 75% RH (mass loading = 8 μg m$^{-3}$) to investigate the effect of RH on the chemical composition of toluene SOA formed under low-NO$_x$ conditions. Measurements revealed a significant reduction in the fraction of oligomers present in toluene SOA generated under high RH conditions compared to SOA generated under low RH conditions (Hinks et al., 2017). The detected molar mass of individual oxidation products spanned a range of 102 - 570 g mol$^{-1}$ at high RH, which increased up to 726 g mol$^{-1}$ at low RH.

Figure 7(a) shows the interdependence of glass transition temperature, volatility, and molar mass of the detected toluene SOA compounds. Glass transition temperatures were
calculated using Eq. (2). Saturation mass concentrations or volatilities of detected compounds were estimated from the elemental composition by using the parameterization of Li et al. (2016). The analysis is based on the molecular corridor approach—a two-dimensional framework of volatility and molar mass of SOA components constrained by boundary lines of low and high atomic O:C ratio, corresponding to \( n \)-alkanes \( (C_nH_{2n+2}, \text{O:C} = 0) \) and sugar alcohols \( (C_nH_{2n+2}O_n, \text{O:C} = 1) \), respectively (Shiraiwa et al., 2014; Li et al., 2016). The toluene SOA constituents are well constrained by the molecular corridor and \( T_g \) are higher for compounds with higher molar mass and lower volatility.

Eq. (1) was used to calculate \( T_g \) for individual compounds with \( M < 450 \text{ g mol}^{-1} \), while excluding compounds with molar mass higher than \( 450 \text{ g mol}^{-1} \). This approach was deemed reasonable as such high molar mass compounds account for \(< 10\% \) of all toluene SOA products formed at low RH, and for \( < 2\% \) formed at high RH. Eq. (2) was used to calculate \( T_g \) for all the detected compounds. \( T_g \) of dry toluene SOA \( (T_{g,\text{org}}) \) was then computed using the Gordon-Taylor approach with \( k_{GT} = 1 \) (Sect. 2.1). The relative mass concentrations of individual components were assumed to be proportional to their relative abundance in the nano-DESI-HRMS spectrum. This assumption has a number of caveats (Bateman et al., 2012; Nguyen et al., 2013), and as we will see below, it results in deviations between the predicted and measured viscosity. Table 2 summarizes the results of such calculations, showing that the \( T_{g,\text{org}} \) by Eq. (1) – excluding high molar mass compounds – is about 10 K lower as compared to \( T_{g,\text{org}} \) by Eq. (2). \( T_{g,\text{org}} \) at low RH is predicted to be higher than \( T_{g,\text{org}} \) at high RH, which results from a lower abundance of high molar mass compounds observed at high RH. This trend is consistent with Kidd et al. (2014), who showed that SOA material formed under dry conditions is more viscous than that formed under wet conditions.
Figure 7(b) shows the predicted viscosity of toluene SOA as a function of RH, as compared to the measured viscosity of toluene SOA formed in an oxidation flow reactor at 13% RH (Song et al., 2016a). Indirect viscosity measurements are also included in shaded boxes (Bateman et al., 2015; Li et al., 2015). Lines with shaded areas are calculated viscosities using \( T_{g,\text{org}} \) as described above. \( \kappa \) was assumed to be 0.25 based on laboratory measurements (Lambe et al., 2011a; Hildebrandt Ruiz et al., 2015). To achieve good fit, \( D \) was set to 13 and \( k_{GT} \) was assumed to be 3.0 (Dette et al., 2014). Estimations with Eq. (1) match the measured viscosity values very well over the entire RH range. Predictions with Eq. (2) overestimated the measurements by one or two orders of magnitude at moderate RH between 30% and 50%, while they agreed with the measurements derived at RH ≥ 60% and at the dry conditions.

There are several possible reasons for the difference between the measurements and predictions. First, the relative abundance of high molar mass compounds observed in HRMS measurements may be overestimated, as high molar mass compounds tend to have higher (yet generally unknown) ionization efficiencies compared to lower molar mass compounds. Second, the nano-DESI-HRMS analysis of toluene SOA was limited to \( m/z \) range of 100 -1000 (Hinks et al., 2017). It is possible that some SOA products with lower molar mass were present in particles but not detected, which would lead to an overestimation of \( T_g \). Third, the chemical composition of toluene SOA are likely different between Hinks et al. (2017) and Song et al. (2016) because of the differences in the experimental conditions. Specifically, toluene SOA was formed in a Teflon chamber in Hinks et al., while Song et al. used an oxidation flow reactor to generate toluene SOA. The O:C ratios are 0.71 at low RH and 0.63 at high RH based on nano-DESI-HRMS measurements in Hinks et al. (2017), while it was 1.06 based on the aerosol mass spectrometry (AMS) measurements in Song et al. (2016).
In addition, different mass loadings may have affected viscosity. Song et al. (2016) measured viscosity at two different mass loadings (60-100 and 600-1000 \( \mu g \ m^{-3} \)) and compared their results to Bateman et al. (2015) (30-50 \( \mu g \ m^{-3} \)) and Li et al. (2015) (44-125 \( \mu g \ m^{-3} \)), observing little impact of mass loadings on viscosity. We carried out a sensitivity study of mass loadings on viscosity using a set of compounds detected by HRMS. The saturation mass concentration was predicted for each component using the molecular corridor approach (Li et al., 2016). Assuming that the mass signal intensity is proportional to the total mass concentration of the compound in the mixture, and applying the absorptive partitioning theory (Pankow, 1994), particle-phase concentrations of each compound were predicted to estimate \( T_g \) at different organic aerosol mass loading values (1-1000 \( \mu g \ m^{-3} \)). The glass transition temperature of the SOA mixture decreases as mass loading increases. Viscosity decreases up to two orders of magnitude at low RH, while at high RH they have little difference as shown in Fig. A3. Simultaneous measurements of viscosity and chemical composition with different mass loadings should be performed in future studies.

### 3.3 Biomass Burning Particles

To further explore the applicability of our viscosity prediction method using elemental composition as measured by HRMS, we performed similar calculations for biomass burning organic particles emitted from test facility burns of subalpine fir and lodgepole pine trees, conducted as a part of the FIREX 2016 campaign (Selimovic et al., 2017). These samples were analyzed by HRMS using two different ionization sources: electrospray ionization (ESI) and atmospheric pressure photoionization (APPI). Mass spectra shown in Fig. 8(a) and (b) indicate that a substantial number of compounds were detected by both methods (109 and 170...
compounds for subalpine fur and lodgepole pine, respectively). However, pronounced
differences are also observed between the ESI and APPI spectra both in terms of the identity and
signal intensities of the detected compounds.

Glass transition temperatures for the assigned CH and CHO compounds were computed
using Eq. (2). Nitrogen and sulfur containing compounds (CHON and CHOS) are not yet
covered by Eq. (2) and were therefore excluded from the analysis. CHON and CHOS compounds
comprised less than 10% of the detected ion intensity and <15% of the assigned compounds.
Please note that we do not intend to provide accurate estimates of ambient biomass burning
particles (as inorganic components are also not included in this analysis), but we investigate how
the use of different ionization methods would lead to variations in our viscosity predictions. $T_g$ of
organic mixtures ($T_{g,org}$) were then calculated using the Gordon-Taylor approach with $k_{GT} = 1$,
assuming that the relative concentration of each compound is proportional to its MS signal
intensity. The calculated $T_{g,org}$ values for the mixtures are specified in the legend of Figure 9. For
both types of mixtures, the calculated $T_{g,org}$ for the APPI MS data is lower than the value
calculated based on the ESI MS data with a difference of 32 K for subalpine fir and 11 K for the
lodgepole pine. Figure 9 shows the predicted viscosity as a function of RH, assuming $D = 10$, $\kappa$
= 0.10 and $k_{GT} = 2.5$. The difference in $T_{g,org}$ derived from ESI and APPI results in a variation of
predicted viscosity at low RH by up to five and two orders of magnitude for subalpine fir and
lodgepole pine, respectively.

The difference in the calculated $T_{g,org}$ values is attributed to the chemical profile of the
species detected using different ionization techniques as shown in mass spectra in Fig. 8(a) and
(b). Van Krevelen diagrams in Fig. 8(c) and (d) illustrate these compositional differences
between chemical species detected by ESI and APPI. ESI is more efficient at detection of polar
compounds (Kiontke et al., 2016), which typically have higher O:C ratios and therefore would result in higher predicted values of viscosity (Koop et al., 2011; Saukko et al., 2012). APPI enables the detection of nonpolar compounds with lower O:C ratios, in particular polycyclic aromatic hydrocarbons (PAHs), that have low ionization efficiencies when analyzed by ESI MS (Raffaelli and Saba, 2003; Itoh et al., 2006). Due to the complementary nature of these ionization methods, it is most likely that the actual glass transition temperature and viscosity of each type of SOA are somewhere in between the values inferred from ESI and APPI data sets: ESI MS may be viewed as providing the upper limit of viscosity, while APPI MS gives the lower limit. Our results indicate that the use of complementary ionization techniques may help evaluate the associated uncertainty for the prediction of viscosity values based on the elemental composition as measured by HRMS.

4 Conclusions

We have developed a parameterization for calculation of the glass transition temperature of individual SOA compounds with molar mass up to ~1100 g mol\(^{-1}\) using the number of carbon, oxygen, and hydrogen atoms. Viscosity of SOA was estimated using the \(T_g\)-scaled Arrhenius plot of viscosity versus \(T_g/T\) and the Gordon-Taylor approach to account for mixtures of SOA and water. The fragility parameter \(D\) was compiled for organic compounds and we found that \(D\) approaches a lower limit of ~10 (+/- 1.7) as the molar mass increases. The resulting viscosity estimations agree well with measured viscosity of \(\alpha\)-pinene and isoprene SOA, validating our method. Using HRMS data, glass transition temperatures of individual components and viscosity of toluene SOA were predicted, also resulting in a good agreement with measurements. However, we note that the predicted viscosities were slightly higher than the measured values.
suggesting that additional considerations may need to be taken into account. For example, the ionization efficiency of both low and high molar mass compounds may have a pronounced effect on the relative abundance of different classes of compounds in HRMS data. The viscosity prediction method was also applied to biomass burning particles, whose elemental composition was measured using HRMS with two different ionization techniques. Substantial differences in viscosity estimations were obtained using ESI and APPI mass spectra.

Figure 10 summarizes the predicted range of viscosity of α-pinene SOA, isoprene SOA, toluene SOA, and biomass burning particles. Isoprene SOA has lower viscosity, reflecting lower glass transition temperature due to relatively low molar mass of isoprene oxidation products. α-pinene and toluene SOA have much higher viscosity with a different shape of the RH dependence due to differences in glass transition temperatures and hygroscopicity. Biomass burning particles have moderate viscosity between the two extreme cases. Currently, both predictions and measurements are subject to large uncertainties and variations. Complementary measurements of viscosity and chemical composition employing different ionization techniques are desired to further constrain RH-dependent viscosity in future studies. Current $T_g$ parameterizations do not consider functionality or molecular structure explicitly and further measurements of $T_g$ and viscosity of SOA would allow us to refine the method presented in this study. Nevertheless, current results offer a promising starting point and such simple parameterizations are practical for predicting viscosity of particles as measured by HRMS. The developed viscosity prediction method should also be useful in recent efforts of simulating the distribution of SOA phase state and related properties in regional or global air quality models (e.g., Maclean et al., 2017; Shiraiwa et al., 2017).
Appendix A: Conversion of fragility steepness index ($m$) to fragility ($D$)

Fragility steepness index ($m$) is defined as:

$$m = \lim_{T \to T_g} \frac{d \log \eta}{d(T_g/T)}$$  \hspace{1cm} (A1)

Combining Eq. (A1) with Eq. (4) gives:

$$m = \lim_{T \to T_g} \frac{d}{d(T_g/T)} \left( -5 + 0.434 \frac{T_g D}{T - T_0} \right)$$  \hspace{1cm} (A2)

Considering that $\eta = 10^{12}$ Pa s at $T = T_g$ (Angell, 1991), and by defining $\Delta x = 1 - T_g/T$, and a combination with Eq. (5) leads to:

$$m = \lim_{\Delta x \to 0} \frac{1}{\Delta x} \left( 12 - \left( -5 + 0.434 \frac{39.17 T_g D}{D + 39.17} \right) \right)$$

$$= \lim_{\Delta x \to 0} \frac{1}{\Delta x} \left( 17 - 0.434 \frac{39.17 T_g D (1 - \Delta x)}{DT_g + 39.17 T_g \Delta x} \right)$$

$$= \lim_{\Delta x \to 0} \frac{665.89 + 17D}{D + 39.17 \Delta x}$$

$$= \frac{665.89 + 17D}{D}$$  \hspace{1cm} (A3)

Note that Eq. (A3) is derived assuming the high temperature limit of viscosity $\eta_\infty$ is equal to $10^5$ Pa s (Angell, 1991) in the VTF equation (Eq. 3). Similar equations for the relation between $m$ and $D$ were given by previous studies using different $\eta_\infty$ and units (Angell et al., 1994; Angell, 2002; Bones et al., 2012) and applying those gave very similar results in our study.

Figure 1. Characteristic relationships between molecular properties and the glass transition temperature ($T_g$) of organic compounds. (a) $T_g$ of organic compounds as measured (circles) and estimated with the Boyer-Kauzmann rule (squares) plotted against molar mass. The markers are color-coded by atomic O:C ratio. (b) Measured (circles) and estimated (squares) $T_g$ of organic compounds plotted against O:C ratio. The markers are color-coded by molar mass. (c) Predicted $T_g$ for CHO compounds using a parameterization (Eq. 2) developed in this study compared to measured (circles) and estimated $T_g$ by the Boyer-Kauzmann rule (squares). The solid line shows 1:1 line and the dashed and dotted lines show 68% confidence and prediction bands, respectively.

Figure 2. The Angell plot of viscosity ($\eta$) vs. $T_g/T$. The lines represent different fragility parameter ($D$) values in the range of 5 - 100, with $D = 10$ (the solid line) used as a base case for this study. A large fragility parameter value is associated with a strong glass former, while fragile materials are associated with lower values. The black dashed line at viscosity of $10^2 \text{ Pa s}$ indicates the approximate threshold between liquid and semi-solid states.
Figure 3. Fragility parameter of organic compounds ($D$) plotted against (a) molar mass and (b) atomic O:C ratio. Error bars are standard deviations. The solid red lines represent the fitted curves with fitted equations for (a) $D = 602.6/M + 10.3$ and (b) $D = 14.4 - 2.3(O:C)$ respectively. Dashed red lines indicate the 95% confidence band.
Figure 4. Comparison of measured and predicted viscosity of (a) α-pinene SOA and (b) isoprene SOA at 295 K as a function of RH. The solid lines represent base simulations with the VTF equation, while the dotted line represents viscosity predicted using the WLF equation [parameters: glass transition temperature of dry SOA ($T_{g,\text{org}}$), fragility ($D$), hygroscopicity ($\kappa$) and Gordon-Taylor constant ($k_{GT}$)]: (a) 278.5 K, 0.1, 10 and 2.5; (b) 255 K, 0.1, 10 and 2.5. The shaded regions were determined by varying these parameters (a) upper (lower) limit: $T_{g,\text{org}} = 300$ K (278.5 K), $\kappa = 0.1$ (0.1), $D = 20$ (10), $k_{GT} = 2.5$ (2.0); (b) upper (lower limit): $T_{g,\text{org}} = 255$ K (255 K), $\kappa = 0.10$ (0.15), $D = 15$ (8), $k_{GT} = 2.5$ (4.0). Panel (a): Renbaum-Wolff et al. (2013) data represents viscosity for water-soluble portion of SOA; Grayson et al. (2016) data in the panel (a) represents two different mass loadings (121 µg m$^{-3}$; 520 µg m$^{-3}$). Panel (b): The gray box in panel (b) represents estimated viscosity based on bounce measurements of Bateman et al. (2015).
Figure 5. Sensitivity calculations for viscosity of α-pinene SOA at 295 K as a function of RH by varying: (a) glass transition temperature of dry SOA ($T_{g,\text{org}}$), (b) fragility ($D$), (c) hygroscopicity ($\kappa$), and (d) Gordon-Taylor constant ($k_{GT}$).
Figure 6. Sensitivity calculations for viscosity of isoprene SOA at 295 K as a function of RH by varying: (a) glass transition temperature of dry SOA ($T_{g,\text{org}}$), (b) fragility ($D$), (c) hygroscopicity ($\kappa$), and (d) Gordon-Taylor constant ($k_{GT}$). Data points are measured viscosity by Song et al. (2015) and the gray box represents estimated viscosity based on bounce measurements of Bateman et al. (2015).
Figure 7. (a) Molecular corridor of molar mass plotted against volatility of toluene SOA formed under dry conditions (Hinks et al., 2017) color-coded by glass transition temperature ($T_g$) estimated using Eq. (2). The upper dashed line indicates the low O:C bound of the molecular corridor (linear alkanes $C_nH_{2n+2}$ with O:C = 0), and the lower dotted line indicates the high O:C bound (sugar alcohols $C_nH_{2n+2}O_n$ with O:C = 1). (b) Comparison of measured (markers) and modeled (lines) viscosity of toluene SOA at 295 K as a function of RH. Viscosities were calculated using fragility ($D$) of 13, the hygroscopicity ($\kappa$) of 0.25 and the Gordon-Taylor constant ($k_{GT}$) of 3.0 with different glass transition temperatures of dry SOA ($T_{g,\text{org}}$) as estimated using Eq. (1) or (2) under low and high RH conditions. The shaded regions were calculated by varying those parameters: $T_{g,\text{org}} = 313$ K (295 K), $\kappa = 0.20$ (0.25), $D = 13$ (10), $k_{GT} = 2.5$ (3.5) for the upper (lower) limit. Mass loadings were 23 $\mu$g m$^{-3}$ for LRH and 8 $\mu$g m$^{-3}$ for HRH (Hinks et al., 2017).
Figure 8. Mass spectra of biomass burning organic particles collected from test burns of (a) subalpine fir and (b) lodgepole pine as measured by high resolution mass spectrometry with two ionization techniques: electron spray ionization (ESI, red) and atmospheric pressure photoionization (APPI; blue). Numbers of elemental formulas identified by ESI (red), APPI (blue) and both modes (black) are also specified. Van Krevelen plots of the compounds identified by ESI (red) and APPI (blue) mode in BBOA from burning of (c) subalpine fir and (d) lodgepole pine.
Figure 9. Predicted viscosity for biomass burning particles of (a) subalpine fir and (b) lodgepole pine trees as measured by high resolution mass spectrometry with two ionization techniques: electrospray ionization (ESI, red) and atmospheric pressure photoionization (APPI; blue). $T_{g,\text{org}}$ are specified in the figure legend and other used parameters are fixed to $\kappa = 0.1, D = 10, k_{GT} = 2.5$.

Figure 10. Summary of predicted range of viscosity of $\alpha$-pinene SOA (red), isoprene SOA (blue), toluene SOA (purple), and biomass burning particles (green).
Figure A1. (a) $T_g$ of organic compounds as measured (circles) and estimated with the Boyer-Kauzmann rule (squares) plotted against the inverse molar mass. The markers are color-coded by atomic O:C ratio. (b) Predicted $T_g$ for CHO compounds using a parameterization (Eq. 2) developed in this study compared to measured $T_g$ (circles). The solid line shows 1:1 line and the dashed and dotted lines show 68% confidence and prediction bands, respectively.

Figure A2. (a) Comparison of measured and estimated $T_g$ by the Boyer-Kauzmann rule for 251 organic compounds (Koop et al., 2011; Dette et al., 2014; Rothfuss and Petters 2017) with their measured $T_m$ available. The markers are color-coded by molar mass. (b, c) Predicted $T_g$ using Eq. (2) compared with (b) measured $T_g$ for CH compounds and (c) predicted $T_g$ using Eq. (1) for CHO compounds. The solid line shows 1:1 line. Solid circle markers represent organic compounds as compiled in Koop et al. (2011) and open square marker represent SOA oxidation products in Shiraiwa et al. (2014) in panel (c).
Figure A3. Effect of mass loading on predicted viscosity for toluene SOA. Solid lines represent the predicted viscosity with Eq. (2) using chemical composition of toluene SOA formed at low RH. Viscosity was predicted with different mass loadings ranging from 1-1000 µg m$^{-3}$. Markers and shaded boxes represent experimentally measured viscosity values. Song et al. (2016) mass loadings were 60-100 and 600-1000 µg m$^{-3}$. Bateman et al., (2015) and Li et al., (2015) mass loadings were 30-50 µg m$^{-3}$ and 44-125 µg m$^{-3}$, respectively.
