Reply to Referee 1:

We’d like to thank the reviewer for her/his comments which helped to greatly improve the manuscript. In the following, we provide replies to the reviewer’s comments (typeset in bold).

**This manuscript examines biogenic and anthropogenic SOA surrogate particles for their ice nucleating ability.** The SOA particles were photochemically generated in the Manchester aerosol chamber (MAS) and then transferred to the Manchester Aerosol and Ice Cloud Chamber (MICC) where ice nucleation was probed between -20 C to -28.6 C at water saturation mimicking mixed-phase cloud formation conditions. Reference ice nucleation experiments employing ammonium sulfate and kaolinite particles were conducted. Under probed conditions only kaolinite particles initiated ice nucleation. The authors present a study of increasing interest, i.e. if and how organic, in particular, secondary organic aerosol (SOA) particles form ice in the atmosphere. This is an important topic and I am in support that new experimental results should be published.

We are happy about and thank the reviewer for this positive assessment.

However, I find that this manuscript lacks discussion of recent literature on ice nucleation and diffusion of SOA particles to set the new results in the right context. SOA ice nucleation or diffusion has been studied by several groups in recent years (among others, Wang et al., 2012, Ignatius et al. 2016, Mohler et al., 2008, Charnawskas et al., 2017, Price et al., 2015, Wagner et al., 2017, Lienhard et al., 2015, Kanji et al., 2017, Ladino et al., 2014, recent review by Knopf et al., 2018). These papers should be present in introduction and may be further discussed in other sections of the manuscript.

We gave the introduction a major overhaul and also revised the discussion to include more references and compare to the referenced works.

Furthermore, the SOA generation procedures may vary among this and other studies. This should be mentioned/discussed in places.

We agree that the SOA generation procedures can vary substantially among different studies. We mentioned this fact and included mentioning/discussion in the respective sections (i.e. mainly introduction and discussion).

I find the supplemental material should be better implemented within the main text. As is, there are some notes to it, but the supplement has a lot of important information. I feel the bounce experiments would be better situated in the main text, also to be more visible, but I leave this to the authors.

Following the reviewers suggestion, we moved the bounce experiments into the main text as new Section 3.1 and slightly adapted the text due to its new position.

The figures in text and supplement reporting ice nucleation experiments should also include the supersaturation of ice, $S_{\text{ice}}$. This is crucial information missing.

Unfortunately, the TDL system was malfunctioning during the experiments, thus only the CR4 provided humidity measurements. However, the CR4 can only sample at ambient pressure, which means, there are no humidity measurements during cloud activation runs. We provide initial $S_{\text{ice}}$ (i.e. measured just before a cloud activation run) for each cloud activation run. Due to the phase changes from water vapour into the particle phase, simulation of $S_{\text{ice}}$ would yield high uncertainties; therefore, we do not provide these. However, we included the initial $S_{\text{ice}}$ measurements in the overview in Table 1.
I recommend that the abstract states explicitly the particle systems investigated for ice nucleation.
We added: “These are namely alpha-pinene, heptadecane, and 1,3,5-trimethylbenzene.”

p. 2, l. 10-15: other studies mentioned above in general comment should be mentioned.
We have rewritten the introduction, and now it includes references to other studies as the ones you have mentioned above.

p. 3, l. 24-25: The 33 m transfer line. You show data later but please elaborate on particle losses due to diffusion, gravitational settling etc. What is the flow speed and pressure in this transfer line? Since this is a new experiment, it would be beneficial to know these parameters.
The flow speed and pressure in the transfer line are governed by the pressure (difference) in MICC and MAC. At the beginning of a transfer, the pressure in the transfer line close to MAC will be close to the pressure in MAC, while at the end close to MICC, it will be rather at MICC pressure. As the pressure difference reduces over time (when MICC is filling) the flow speed decreases. A typical flow speed time series for a refill from MAC after a MICC cloud activation is shown below.

![Figure: Volume flow in transfer pipe during refill of MICC from MAC after a cloud activation.](image_url)

The comparison between DMPS size distribution measurements from MAC just before transfer and SMPS size distributions measured in MICC just after the transfer can be used to infer how severe particle losses during transfer are: The figure below shows the respective size distributions for the different SOA experiments. In case of the alpha-pinene SOA, no significant change in the main particle mode diameter is apparent, while for the first heptadecane experiment and the TMB experiment growth in the main particle mode happened, possibly in MICC due to the colder temperatures there compared to Mac temperature which fosters the condensation of the organic vapours onto the particles.
p. 5, l. 4-8: Here, I would give the bounce experiments more exposure. “Bouncy” is not really a physical parameter, is it possible to use phase state definitions, such as semi-solid, solid etc.?
We moved the section about the particle bounce measurements into the main manuscript at the end of the introduction part of section 3 and modified it slightly to adapt to the new position.
We agree with the reviewer regarding the phase state definitions and use phase state definitions (semisolid or liquid) instead.

p. 5, l. 19: Here, the reader learns the first time the NOx is involved in SOA formation. This can be different from above mentioned studies. What does this mean for SOA composition, viscosity etc.? This could be important but is not discussed.
The effect of NOx on SOA viscosity is not studied (at least the authors are not aware of any publications on this). It should be noted though, that also the O:C of produced SOA was relatively low in these experiments. As shown in Pajunoja et al. (2015) the particle viscosity (or bounce behaviour) at elevated RHs depends strongly on O:C. This is because the particle hygroscopicity (i.e. the particle phase water content at certain humidity) increases with O:C. Hence, not only the NOx might affect the composition or viscosity, but also the oxidation conditions more generally.
The use of NOx in these experiments was to help initiate the photochemistry, and the work did not include a systematic investigation of the effect of NOx on particle composition or properties.
We added this discussion to the manuscript.

p. 5, l. 26 – p. 6, l. 8: Some details are not entirely clear to me: The SOA from MAC flows into evacuated MICC. Then MICC is filled with gas. Do you expect losing
SOA species due to evaporation (low pressure) and due to dilution? The VOCs then diffuse to the cold walls of MICC? Also going from a warm (MAC) to a cold environment (MICC), does this not affect RH fields, thus affecting organic phase state?

Correct, the evacuated MICC is refilled from MAC until ambient pressure is reached. Thus, there is no further dilution of the aerosol population other than by the air that remained in MICC prior to the transfer (it is not possible to evacuate MICC to vacuum, but the lowest pressure is 200hPa). As stated in the text, about 8m$^2$ air from MAC (which holds the aerosol) is diluted by the remaining 2m$^2$ of filtered air in MICC. The dilution leads to a tendency for components to evaporate. The transferred air cools in MICC and cooling leads to a tendency for the components to condense. Thus, there are opposing tendencies and any semi-volatile component in the aerosol will have a tendency to transfer between phases accordingly. The rate at which the components follow this tendency may possibly be influenced by the changes in condensed phase properties with temperature, since an increase in viscosity towards or across the glass transition may lead to a decrease in condensed phase diffusion and decrease in rate of bulk equilibration.

Effects of dilution and cooling can be investigated to a certain amount by comparing the SMPS and CPC measurements from directly following the transfer of air from MAC to MICC (when MICC temperatures were above the target temperature) and the repeated measurements once the target temperature was reached. For example, looking at the SMPS size distributions given in Figures 3 and 4 (and others in the supplement), which shows the size distribution directly “after transfer” in red and the two size distributions sampled when the target temperature was reached “S1/S2 before evacuation” in blue colours, no significant changes are apparent. Thus, it seems that enough organic vapour remained in the gas phase in MAC prior to transfer such that particles would not evaporate/shrink when entering MICC even if amounts of the vapour are lost to condensation on the chamber walls.

We added some explanation to the manuscript.

p. 6, l. 24-25: The air from MAC was humid and entered MICC. Are the particle RH trajectories known for the transfer? Does this impact phase state? See, e.g. discussion in Ignatius et al. (2016) and Knopf et al. (2018). The humid air condenses onto cold MICC walls?

The exact RH trajectories are not known. We do have information about the initial RH in MAC and the RH in MICC after transfer. Due to the not-ambient pressure it is not possible to measure the RH during transfer. MICC walls are ice coated from the humidity that entered the chamber during the cleaning cycles. Thus, any humidity in excess of $R_{\text{H,ice}} = 100\%$ would condense onto the walls after the transfer. However, this process will take some time, following a rough calculation assuming a gradient in saturation ratio of 0.15 over 0.5m (half the diameter of MICC), molecular diffusion of water vapour is really small and the supersaturation would stay there for maybe 1.5 hours. There will be turbulence in the chamber too (from the air stream filling the chamber), which should reduce this time, and the presence of particles (that have their own water content, eventually subsaturated wrt liquid water) will prolong the diffusion, too. Generally, RH can have an impact on the phase state of the SOA particles. From the bounce measurements presented here, we can estimate that even at low RH (and thus at high RH as well) the SOA particles from heptadecane precursor will be liquid, while TMB is in a semi-solid phase even at high RH.
p. 6, l. 30-31: Here and Fig. 4 case: Are activated droplet sizes what would be expected from Kohler theory and diffusional growth?
Generally, yes! However, the size distribution will be broader than theory predicts due to non-uniformities in the temperature and humidity fields in the chamber (see also reply to comment “p. 8, l. 16-21” below).

p. 7, l. 27-35: For this discussion it is crucial to know also the temperature and S_{ice} values during measurement of the activated fraction. At this point the discussion is confusing and one wonders about these results. Maybe at fast pumping speed, i.e. at high S_{ice}, the activated fraction of HD is not as sensitive compared to lower pumping speed and thus lower S_{ice}?
We modified Figure 6 which now also includes the temperature measurements during the cloud expansions and the initial S_{ice}. Due to the failure of the TDL system, we unfortunately, only have humidity measurements at ambient pressure, thus, not during the cloud expansion experiments. We included statements about the temperatures and initial S_{ice} in the manuscript.
“... it will take time for the cloud to extend downwards to the bottom and be sampled, see also discussion in Möhler et al. (2003) for similar effects in the AIDA cloud chamber. The observed cloud particle size distribution is wider than the simulated one. This could be due to effects of non-uniformity in temperature and humidity that lead to broadening of the size distribution. For example, as the chamber walls will stay at close to their initial temperature while the chamber centre cools adiabatically during an expansion, wall heating effects can create a temperature gradient within the chamber (warmer towards the walls and colder towards the chamber centre), which will induce a humidity gradient as well. The incoming air stream causes mixing which on the one hand side can reduce this gradient, but on the other side can induce inhomogeneous temperature and humidity fields leading to variation in the activation and growth of the cloud particles.”

p. 8, l. 16-21: Is it possible to make this speculative discussion a bit more quantitative?
We expanded this discussion:

p. 8, l. 29-31: I find this too simplified and feel it needs more discussion. Please look at studies mentioned above in general comment.
We made significant changes to this section of the discussion, where we refer to other studies, comparing those results and conditions used during SOA generation with our experiments.

p. 9, l. 1-5: I find this needs more discussion. Please look at studies mentioned above in general comment. SOA particles are produced in different ways, different temperatures are probed etc.
We expanded the discussion and made significant changes, see comment above.
p. 9, l. 12-13: Different heptadecane properties due to different VOC/NOx ratio applied?
As mentioned above, the effect of NOx on SOA viscosity is not studied. It is difficult to speculate on this given the lack of any specific work on the issue. Also, given the relatively small difference in VOC/NOx ratios in our experiments, it is probably unlikely that this would be the main reason behind the difference in the bounce behaviour.

p. 9, l. 14-15: Not necessarily higher supersaturation are needed but longer times. The need of larger supersaturation may be “apparent”, i.e. disequilibrium between gas and condensed phase.
We rephrased: “Thus, it takes a longer time for these viscous SOA particles to take on water vapour and grow due to diffusion limitations.”

p. 9, l. 15-16: Indeed, different temperature in chambers or sampling lines can affect particle properties. See e.g. discussion in Knopf et al. (2018) and Ignatius et al. (2016).
True, we expanded the discussion by adding “Indeed, an effect of different temperatures in the chambers or sampling lines had been found and discussed by e.g. Ignatius et al. (2016) and Knopf et al. (2018).” to the end of this possible explanation.

p. 9, l. 28-30: Above mentioned literature may enhance this discussion.
We expanded “Thus, the phase state of the aerosol particles (represented by their bounciness) could play a role in the onset of activation, as hinted in measurements by e.g. Ignatius et al. (2016); Ladino et al. (2014); Wagner et al. (2014).” Furthermore, the discussion has been modified substantially, and we have referenced and discussed above mentioned literature in various places throughout the discussion now.

p. 10, l. 5-6: Please refer to, e.g., Wagner et al. (2014, 2012) articles.
We added at the end of this passage: “Pre-cooling of SOA particles has the potential to increase the aerosol particles' ability to act as INP (e.g. Ladino et al., 2014; Wagner et al., 2014). Thus, in the respective second cloud activation runs, there could have been a higher chance of ice formation. However, apparently the minimum temperatures reached during the first cloud runs here were not cold enough for such a pre-activation of the aerosol particles and hence, no ice had formed.”

p. 10, l. 16-18: Heptadecane is more viscous and therefore the activated fraction is lower?
Actually, based on the bounce measurements heptadecane is less viscous than alpha-pinene and TMB (mentioned p9, l13, see also bounce figure in supplement or Saukko et al., 2012). The heptadecane SOA behaves as liquid droplets even at dry RH.

Figures: 3-5 and similar ones in supplement: specific for figures in main text: particle images are not described in caption. Panel indicators are missing. As stated above, please include $S_{ice}$. It is confusing to have a legend in third panel that includes definitions for other panels. Please split legend to corresponding panels.
The figures have been altered as suggested. As mentioned before, we unfortunately can only state the initial $S_{ice}$ for these experiments. Due to the formation of cloud particles, i.e. phase change of vapour to particles, a calculation of $S_{ice}$ would be hampered by high uncertainties. The initial $S_{ice}$ is now included in Table 1 (alongside initial $S_{water}$).
Figure 5: What do you mean by “eating up”? A Wegener-Bergeron-Findeisen process? Please change expression.
We rephrased: "The data show formation of ice in a second mode, and the decrease and almost disappearance of particle numbers of smaller drops over time (Wegener-Bergeron-Findeisen process)."

Table 2: You mean MAC and not “aerosol chamber”? “Amount injected”: unit? Please elaborate. Have aqueous solutions been injected? What is the mass? The mole fraction or other information is needed. Units missing for gas species. The mass difference, last column, between pinene and TMB is correct?
MAC is the synonym for the Manchester Aerosol Chamber, thus, both would be correct. The gas species are in nmol mol⁻¹, we added that information to the table. The VOCs were injected as high purity chemical liquids into a heated glass bulb where it immediately evaporates. A continuous flow of nitrogen then flushes the gas phase VOCs into the aerosol chamber. (See description in original manuscript p3 l7-9 and p5 l18/19.) We now expanded: “To prepare the system for injection of relevant gases for particle formation in MAC the volatile organic compound (VOC) injection glass bulb is heated and continuously flushed with nitrogen. The precursors for the SOA are injected into the glass bulb in form of high purity liquids, where they evaporate immediately. The vapourised VOCs and NOₓ are then injected during the last filling of the MAC air bag.”
As we use pure liquids, their mole fraction is unity. To avoid confusion we changed the way we state the amount of VOCs injected: As we calculated the amount of liquid for the volume injection, taking into account the chamber bag volume, we now state the “nominal VOC mass” that should enter the chamber as gas. We also made a reference to the text, Sect. 3.1 Experimental Design.
Since we injected precursor gases with very different characteristics, the resulting aerosol differs not only by mass but also by e.g. their nucleation and growth characteristics and losses to the walls. TMB is much harder to produce and therefore, masses are smaller than for alpha-pinene, which contrary nucleates much faster. There was indeed an error in the TMB mass, but still the TMB mass is much smaller than e.g. the alpha-pinene mass.

Table 3: How can mass in MICC be larger than in MAC (mass_DMPS vs. mass_SPMS)?
Due to the differing size ranges of the DMPS and SMPS, the mass retrieved from these instruments can be different even if sampled from the same aerosol population. As the SMPS starts measuring at 13.8nm (vs 40nm DMPS) it will add mass from the small particles. If you look at the comparison of size distributions (figure above in the reply to your comment on the transfer pipe), in the α-pinene and TMB cases also larger particles are observed by the SMPS, which are absent in the DMPS measurements. These contribute to the SMPS mass accordingly.

Supplement: p. 1: change “cooking” to “processing” or other terminology.
Changed to: “...for any experiment performed on specified aerosol photochemically produced in the aerosol chamber.”

Figure S4: Please include pinene SOA bounce fraction.
Since the bounce measurements shown here were not from the same experiments but from a previous experiment, there were unfortunately, no measurements of pure alpha-pinene SOA. However, for example Saukko et al. (2012) and Pajunoja et al. (2015) did show by flow tube measurements that alpha-pinene is semi-solid. We state more clearly now in the main text that the bounce measurements and the ice nucleation
measurements were not made in the same experiment but the bounce measurements were part of an earlier experiment using the same set up as our measurements.

p. 4: Change “ingredients” to “species” or “compounds”, etc.
Changed to: “…all chemical substances as in a normal SOA experiment were used, without the actual precursor.”

What is the difference between S17 and S19 and S18 and S20 experiments? Maybe additional text is necessary?
Yes, it seems additional text should be provided. There were two experiments with ammonium sulfate aerosol, with two cloud activation runs each. Thus, the difference between S17 and S19/S18 and S20 is the actual experiment, S17/S18 are cloud activation runs from experiment 2, S19/S20 from experiment 9 (see also Table 1 in main manuscript). We included a reference to the respective experiment (and the table) for all cloud activation run figures in the supplement.

Technical corrections:
I suggest throughout manuscript and supplement to change the expression “cloud evacuation” to “cloud activation experiment” or something along those lines.
We changed according to the reviewer’s suggestion.

p. 7, l. 25: Change language. Avoid the term “sister run”.
Changed to: “…the already shown heptadecane […] and dust […] runs accompanied by the respective other runs in the same experiments, plus a further heptadecane experiment...”.

p. 8, l. 26: Maybe use “employed” or ”applied” instead of “used”.
Changed to “employed”.

p. 9, l. 8: Avoid “kicks in”. Change language.
Changed to “commences”.

p. 9, l. 30: Exchange “than” with “as”.
Done.

p. 9, l. 32: Instead of “sucking” use “pumping” or “evacuating”.
Changed to “pumping”.

p. 10, l. 6-7: It feels there is an error in this sentence.
It is not clear where the reviewer suspects an error. However, we added some information to the previous sentence and hopefully this will resolve the misunderstanding?
“Generally, cloud processing is thought to increase the efficiency of activation into cloud particles (e.g. Hoose et al., 2008), through changing the internal chemical structure and/or composition of the aerosol particles. However, as the experiments reported here exhibit pure SOA aerosol, and we expect no other organic and inorganic material (or vapours) in the chambers, cloud processing here will only change the aerosol mass, not aerosol chemistry.”

p. 10, l. 30: Exchange “no” for “not”.
Done.
p. 11, l. 22: Exchange “bump” to “maximum” or similar.
Rephrased sentence:
“The sharp increase in cloud particle numbers at 20 seconds (i.e. the major activation) coincides with the departure in the corrected temperature curve from the adiabatic curve.”

Reply to Referee 2:

We would like to thank the reviewer for her/his comments, which helped to greatly improve the manuscript!
Please find our replies to the comments (which are typeset in bold) below:

The manuscript by Frey and co-workers investigates the ice nucleation ability of secondary organic aerosol (SOA) particles under so-called mixed-phase cloud conditions. SOA particles have been found to nucleate ice under so-called cold cloud conditions found at high atmospheric altitudes, an ability which is often ascribed to their glassy solid phase state, but their ability for cloud formation at much higher temperatures /lower altitudes has not yet been proven. This work is well-written and addresses this very relevant problem by connecting an aerosol formation vessel (Manchester Aerosol Chamber, MAC) and a vessel for probing the ice nucleation ability of particles (Manchester Ice Cloud Chamber, MICC) in an innovative experimental setup. The authors tested an array of different SOA particles by using three different precursors: one from biogenic and two from anthropogenic origin, making the work relevant for the ambient atmosphere and hence publication in ACP. The main result of this work is that none of the investigated organic aerosols facilitated ice nucleation in the observed temperature and RH region. Such negative results are important to direct future works on the relevance of these particles for cloud formation. However, in my understanding, there was no possibility that ice nucleation should be observed due to the way the experiments were operated. This greatly diminishes the value of this publication and might disincentivize further research on the topic if it won’t be stressed clearly by the authors why ice nucleation did not occur. I would like to outline my thoughts in the following and already encourage the author’s to disagree with me in their rebuttal in case I misunderstood the experimental setup. At this point, however, I cannot recommend the manuscript for publication.

The reviewer stresses a very important point and we are confident that we will be able to convince the reviewer to support the publication of our manuscript.
Generally, we tried to follow an experimental path that is as closely aligned with processes in nature as possible: The generation of SOA was performed at conditions which are close to realistic conditions in the lower boundary layer, where precursor gases for SOA formation are emitted (i.e. room temperature and relative humidities wrt water of 45-50%). Previous studies often did not follow such a realistic path, generating SOA at below 10% humidity, some even down to almost 0% humidity (e.g. Prenni et al., 2009, Baustian et al., 2013, Wagner et al., 2017). From ground the aerosol is lifted to regions, where mixed-phase clouds potentially form, implicating cooling of the aerosol and changes in humidity. The transfer of the aerosol in our experiments from the aerosol to the cloud chamber and the subsequent cooling of the transferred air including the aerosol could be seen to mimic those conditions. Then, first a water cloud is formed (therefore, water saturation is needed) from which ice nucleation could take place to form a mixed-phase cloud. This is achieved by quasi-adiabatically cooling of the chamber by performing a chamber expansion.

The modelling study by Shiraiwa et al., 2017 suggests that SOA already is in a semi-solid state over the mid-latitudes and semi-arid regions as Europe, India, Australia, Mexico, and western US. Going up to higher altitudes, the particle phase state becomes more frequently solid or semi-solid. According to Shiraiwa et al. almost all SOA will be solid at 500hPa, corresponding to about 5.5km or roughly -20°C (according to standard atmosphere). And -20°C is the starting temperature of our experiments. They mention convective uplifting of the air in their model, however, whether the RH follows a similar trajectory as in our measurements, we cannot say. Also Mikhailov et al. (2009), based on
measurements of hydration and dehydration with a hygroscopicity tandem differential mobility analyzer (H-TDMA), conclude that the (semi-) solid phases should not only be important at high altitudes but also influence cloud processes at the relative humidities and temperatures of the lower troposphere and the boundary layer. Therefore, our measurements seem relevant as some of the tested systems are known/shown to be semi-solid after formation in the aerosol chamber (see bounce measurements, and also Saukko et al., 2012, and Pajunoja et al, 2015) and we conduct our experiments under these conditions where, according to the above mentioned studies, SOA should exist in (semi-) solid phase state and behave in a way that influences cloud processes, as cloud formation and ice nucleation.

Our measurements start at (close to) water saturation, which facilitates a quick start of cloud formation. Furthermore, ice saturation is needed in order to nucleate ice, thus, being at ice supersaturation is prerequisite as well. According to Koop’s (schematic not representational) phase diagram (Koop et al., 2011), all particles (including the amorphous solid) are deliquesced at 90% RH. So the RH at which we operated in no way diminishes the general applicability of the results.

General critique
In the following I will assume that a glassy phase state is necessary for SOA particles to nucleate ice. If this is the case, a look at the phase diagram of glassy organic material should have sufficed to predict the lacking ice nucleation ability of the SOA particles observed in these experiments (e.g. Koop et al., 2011). The authors state that the MICC was at water saturation before expansion and during the filling of the vessel. At water saturation, a hygroscopic substance cannot be in a viscous or glassy phase state, no matter the glass transition temperature of the pure substance.

According to Koop’s schematical phase diagram (as mentioned above) all particles are deliquesced at about 70% RH (amorphous solid should be deliquesced at about 60%). Given that the schematic is correct and glassy aerosol needed for ice to nucleate from SOA, Ignatius et al., 2016 should not have observed ice nucleation at roughly -39°C and Sice of 1.3 (coldest example of their figure 5, showing alpha-pinene experiments), as RH_w would be about 89% in that case. Either, the particles in Ignatius et al.’s study were not glassy, or the schematic phase diagram might have a different look for varied SOA species.

If we assume water saturation in mixed-phase clouds (and according to e.g. Ansmann et al., (2009) the ice phase in mixed-phase clouds is observed after the liquid phase had been established) your argument above would mean that there will never be ice nucleation from SOA in any mixed-phase cloud. This should be tested as hypothesis in a future study. On the other hand, Shiraiwa et al. (2017) and Mikhailov et al. (2009) suggest that these particles should have an impact on cloud processes in the lower troposphere. Thus, we think that our experiments in the way they were conducted are relevant.

In previous chamber experiments showing the ice nucleation ability of organic aerosols (e.g. Murray et al. (2010), Wilson et al. (2012)), expansion was always initialized at around ice saturation, thus far below water saturation level. The only reason particles could be in a viscous state in the experiment at hand would be if they would cool faster than they could take up water upon entering MICC and hence maintain a non-equilibrium state. These dynamics however seem very difficult to predict since the exact temperature and humidity profiles between MAC and MICC are probably difficult to obtain. Hence, the authors investigated in this study not only if organic aerosols could induce ice nucleation at higher
temperatures than expected, but also when initialized at higher humidities than in previous studies. Ice nucleation by organic aerosols under mixed-phase cloud conditions should only be possible if the glassy state is somehow maintained despite the high temperatures and humidities.

Please see reply above. Correct, most studies generate their SOA particles in very dry conditions, except Wang et al. (2012), who also generated their SOA in more humid conditions at 35±5%.

In general, the authors miss to mention that not only temperature is important to determine aerosol phase state, but also humidity. A study by Berkemeier et al. (2014) investigating the kinetics of water uptake of viscous organic particles shows that there is a sensitive interplay between temperature, initial humidity and humidification rate that enables organic aerosols to be in the glassy state at humidities relevant for ice nucleation.

The reviewer has a good point here; we now mention the importance of relative humidity for the aerosol phase state in according places (mainly introduction and discussion).

If it was not the goal to use the glassy phase state of organic aerosols to trigger ice nucleation this has to be stated more clearly in this manuscript. In this case however, the discussion devoted to bounciness of particles would be superfluous (or even misleading) and a different incentive to discuss organic aerosols as ice nuclei would have to be presented. It is hard to imagine ice nucleation on liquid aerosol particles.

First of all, we aimed at characterising the ice nucleation (or lack thereof) in terms of SOA phase state. Here, we show that deposition nucleation is not happening to the SOA particles under the conditions of our experiments. Also immersion freezing does not happen to the SOA generated in our experiments, which means that there are no efficient solid/insoluble IN inclusions in the liquid droplets we see. As stated in Berkemeier et al. (2014), solid inclusions in liquid SOA particles can well be realistic in the atmosphere (we added to the discussion accordingly):

“Berkemeier et al. (2014) further state that humidification in typical atmospheric updrafts (or cloud chamber experiments) may be fast enough to cause a difference in phase state from that of equilibrium, as the time for diffusion of the water into the particle is longer than the time for humidification. This can result in a particle that has a liquid outer shell but still contains solid inclusions/a solid core even at RH above the quasi-equilibrium glass transition. Thus, SOA particiles could potentially act as immersion freezing nuclei in conditions where they are supposed to be liquid, if in equilibrium.”

Specific remarks
• In the introduction, it seems worth mentioning that many more studies have investigated ice formation from organic aerosols. Examples here are works from the Knopf group (e.g. Wang et al., 2012; Charnawskas et al., 2017), the Tolbert group (Baustian et al., 2013) or at the AIDA chamber (e.g. Wilson et al., 2012). Overall the number of references in this paper is very lacking and too much focused on the author’s own work.

We gave the introduction a major overhaul and also revised the discussion to include more references and compare to the referenced works.

• As mentioned above, the introduction too much focused on temperatures, too little on relative humidities. The biggest problem with ice nucleation and glassy SOA are the high relative humidities necessary to nucleate ice on the particles, which in turn leads to non-viscous phase states. A discussion on this competition
process can be found in Berkemeier et al. (2014)."p. 4, l.11 – Out of curiosity, why would the oxidation be conducted with ozone and not also under irradiation with UV light to generate OH radicals? Most products of SOA formation should not be susceptible to reaction with ozone."

We have moved the section about ‘Particle bounce measurements’ from the supplement into the main manuscript. These measurements show that TMB and alpha-pinene do exist in a semi-solid phase state even at high relative humidities. Heptadecane indeed is in a liquid phase even at very low relative humidities. We enhanced the discussion to account for the effect of relative humidity on phase state.

Regarding your question about the cleaning procedure: We regularly also perform SOA background experiments, which include UV radiation. Based on experience with the chamber, we found that regular weekly background experiments are sufficient to keep the chamber walls clean enough, such that the daily cleaning (overnight) between two experiments can be performed without irradiation. This combination of cleaning and background cycles furthermore allows enough time to run the actual SOA experiments and not stretch the time frame for experiments too far. We have expanded the cleaning section in this regard.

• The usage of the words “bouncy” and “non-bouncy” in this study are misleading. What the author’s should say are the conditions under which these particles bounce (RH and T). Do they bounce at -20°C and water saturation? Hence, in the context of p.8, l.23, this is not a meaningful statement.

Considering the comments by the other reviewer, we changed wording here since bouncy/non-bouncy is not really a physical parameter. We now use the phase state definitions instead (in our experiments ‘semi-solid’ and ‘liquid’). Furthermore, we moved the section about ‘Particle bounce measurements’ from the supplement into the main manuscript. From those measurements it becomes clear that heptadecane is in a liquid phase and alpha-pinene and TMB are semi-solid even at high RH, see reply above.

• The effects of cloud processing in the TMB vs heptadecane SOA experiment are an interesting finding. Is the picture of TMB SOA showing lower activated fractions in the second chamber evacuation run consistent among repetitions of the experiment?

There was, unfortunately, only one TMB experiment day. Thus, we only have those evacuations shown.

Minor and technical comments
• p. 4, l.2 – boiling point of water
Done.

• p. 4, l.11 – Out of curiosity, why would the oxidation be conducted with ozone and not also under irradiation with UV light to generate OH radicals? Most products of SOA formation should not be susceptible to reaction with ozone.

See our reply to this point above (section starting with “As mentioned above, the introduction ...”

• p.5, l.11 – A closing parenthesis “)” is missing here.
Parenthesis added.

• p.5, l.17 – It is not entirely clear what is meant with “to achieve this”. I assume it refers to the cleaning of the chamber, not the particle formation described in the previous sentence.
It actually refers to the particle formation. We rephrased the sentences:
“To prepare the system for injection of relevant gases for particle formation in MAC the volatile organic compound (VOC) injection glass bulb is heated and flushed with nitrogen. The precursor gases for the SOA and NOx are then injected during the last filling of the MAC air bag.”

• p. 7, l.6 – I believe the word “one” is superfluous here.
The sentence should use the singular of “particles” as there really only was one particle imaged by the CPI.
“Only one spherical particle was imaged by the CPI.”

• p.9, l.12 – Not the precursors are bouncy, the SOA from these precursors are, at a specific RH and T.
Rephrased: “The aerosol particles formed from these precursors are both in a semi-solid phase state, i.e. more viscous than the heptadecane particles at the same temperature and relative humidity.”

• p. 9, l.13 – The statement confuses kinetics and thermodynamics, please clarify that not a higher supersaturation is needed to activate viscous particles, it just takes longer time.
We rephrased: “Thus, it takes a longer time for these viscous precursors to take on water vapour and grow due to diffusion limitations.”

Abstract. Secondary Organic Aerosol (SOA) particles have been found to be efficient ice nucleating particles under the cold conditions of (tropical) upper tropospheric cirrus clouds. Whether they also are efficient at initiating freezing at slightly warmer conditions as found in mixed-phase clouds remains undetermined. Here, we study the ice nucleating ability of photochemically produced SOA particles with the combination of the Manchester Aerosol and Ice Cloud Chambers. Three SOA systems were tested resembling biogenic/anthropogenic particles and particles of different phase state. These are namely α-pinene, heptadecane, and 1,3,5-trimethylbenzene. After the aerosol particles were formed, they were transferred into the cloud chamber where subsequent quasi-adiabatic cloud activation experiments were performed. Additionally, the ice forming abilities of ammonium sulfate and kaolinite were investigated as a reference to test the experimental setup. Clouds were formed in the temperature range of -20°C to -28.6°C. Only the reference experiment using dust particles showed evidence of ice nucleation. No ice particles were observed in any other experiment. Thus, we conclude that SOA particles produced under the conditions of the reported experiments are not efficient ice nucleating particles starting at liquid saturation under mixed-phase cloud conditions.

1 Introduction

Clouds and their feedbacks are major sources of uncertainty in future climate predictions. Aerosol particles determine the condensation of water to form liquid droplets and ice crystals. The transition into the ice phase is particularly important, e.g. for formation of precipitation, but is yet poorly understood in detail. While certain aerosol particles such as dust are known to be important ice nucleating particles (INP), others are highly abundant, yet their ice forming abilities remain poorly understood. One example for such particles are secondary organic aerosol (SOA; see also a recent review about the role of organic aerosol as INP by Knopf et al., 2018). They originate from biogenic and anthropogenic sources, e.g. from the oxidation of plant, biomass burning, and combustion emissions. SOA particles can ex-
ist in different phase states. The traditional understanding conceived them as homogeneous well-mixed liquids but they can occur in amorphous semi-solid or solid (also termed glassy) states (Virtanen et al., 2010). The state of the particles is dependent on the relative humidity and temperature (Koop et al., 2011). Amorphous solid, also termed glassy, particles have been observed to bounce in an aerosol impactor, thus, the bounce of particles can be used to infer their phase state (Virtanen et al., 2010) (Koop et al., 2011; Berkemeier et al., 2014). The amorphous phase state of these glassy particles has been shown to influence their ability to act as ice nucleating particles. For example Murray et al. (2010) have found glassy organic particles to be efficient ice nucleating particles INPs in the depositional mode in the tropical tropopause layer. In their experiments, Murray et al. (2010) found that glassy aerosol particles nucleated ice crystals at lower relative humidities (with respect to ice) than the same aerosol in a non-glassy phase state. Furthermore, fewer particles nucleated on the glassy particles, allowing higher in-cloud humidities. Shiraiwa et al. (2017) state that in the middle and upper troposphere SOA should be mostly in the glassy state, which may promote ice nucleation. They found SOA to undergo their glass transition above 2 km altitude. Similarly, Mikhailov et al. (2009) state that a moisture induced glass transition may play a role in the lower troposphere, depending on the relative humidity. Several studies have Several further studies have investigated the ice forming capability of different SOA particles (e.g. Prenni et al. 2009; Wang et al. 2012; Ladino et al. 2014; Schill et al. 2014; Ignatius et al. 2016; Wagner et al., 2017) in the laboratory. The procedures for generation of the SOA particles as well as the methods to initiate ice nucleation do vary substantially among these experiments. E.g. SOA formation was initiated by dark ozonolysis (Prenni et al., 2009; Wagner et al., 2017) or photochemical reactions (Ladino et al., 2014; Ignatius et al., 2016), using gas-phase reactions (Wang et al., 2012; Ignatius et al., 2016) or aqueous processing (Wilson et al., 2012; Baustian et al., 2013; Schill et al., 2014). Ice nucleation was tested e.g. in expansion chambers (Murray et al., 2010; Wilson et al., 2012; Wagner et al., 2017), continuous flow diffusion chambers and flow tubes (Ladino et al., 2014; Ignatius et al., 2016), and in microscope systems (Wang et al., 2012; Baustian et al. 2013). Whether these formation pathways and ice nucleation initiation methods have an impact on the ice nucleation ability of the SOA particles is not clear. In addition to the different particle generation procedures, the resulting particle sizes vary, too, which certainly alters the ice nucleation capability (larger particles provide a larger surface area and are more likely to form ice). The findings of the above mentioned studies can be summarised as follows: Wang et al. (2012) and Ignatius et al. (2016) find that atmospheric SOA particles are potentially important for ice nucleation due to their semi-solid or solid phase states by investigating SOA from naphtalene and α-pinene, respectively, whereas Ladino et al. (2014) and Wagner et al. (2017) found that α-pinene SOA at first is an inefficient INP at cirrus temperatures, but after precociling of the SOA particles, ice nucleation ability is increased. Schill et al. (2014) found that semi-solid or glassy SOA from aqueous processing of methylglyoxal with methlamine is a poor depositional INP, however, Wilson et al. (2012) found other aqueous glassy aerosol to nucleate ice heterogeneously at temperatures relevant for cirrus formation in the tropical tropopause layer. All these studies investigated the ice forming capability of different SOA particles; however, the majority of these studies looked at cirrus temperatures. Abilities of the SOA particles at temperatures in the cirrus regime (i.e. below -40°C) and only few investigations look at the temperature range of. Investigations of the ice nucleation potential of SOA in mixed-phase clouds cloud conditions are scarce. One example of such a study a study conducted at mixed-phase cloud temperatures is reported by Prenni et al. (2009). They looked at the ice nucleating ability of alkenes at -30°C and found them to be unlikely
to participate in heterogeneous nucleation. However, they formed the SOA particles by dark ozonolysis of precursors. To our knowledge, the efficiency of photo-chemically produced SOA particles as ice nucleating particles under mixed-phase cloud conditions has not been determined.

Modelling studies generally predict that SOA particles are efficient INP under cirrus conditions, i.e. low temperature and humidities (e.g. Koop et al., 2011; Berkemeier et al., 2014; Price et al., 2015) as the SOA particles are in a glassy phase state under those conditions. Furthermore, Shiraiwa et al. (2017) state that also in the middle troposphere SOA should be mostly in the glassy state, which may promote ice nucleation. They found SOA to undergo their glass transition above 2km altitude. Similarly, Mikhailov et al. (2009) state that a moisture-induced glass transition may play a role in the lower troposphere, depending on the relative humidity. Thus, SOA might play a role as INP in mixed-phase clouds, too.

The freezing and eventual sublimation of ice from the aerosol particle may change its properties (e.g. Adler et al., 2014): so called cloud processing. Thus, such a freeze-drying cycle might increase their ice nucleating abilities. Wagner et al. (2014) for example, found that pre-activated aerosol particles, i.e. temporarily cooled particles, have an increased ability for heterogeneous ice nucleation. Cloud processing also happens in warm clouds (e.g. Hoose et al., 2008), where the aerosol particle characteristics can be changed e.g. through additional uptake of atmospheric gases and chemical reactions with the soluble part of the contained aerosol particle take place in the aqueous phase. Upon evaporation of the cloud, aerosol particles are re-emitted and these particles have changed chemical properties and are larger than the initial particles (Pruppacher and Klett, 1997); therefore, the aerosol size distribution is also affected by cloud processing. Comparison of the size distribution of interstitial aerosol within the cloud with the size distribution below the cloud clearly indicates that the processing of the aerosol through (nonprecipitating) stratus can lead to increased mass of the subset of particles which had served as cloud condensation nuclei (CCN; Hoppel et al., 1994).

This work aims to investigate the ice nucleating ability of photo-chemically produced SOA particles at mixed-phase cloud conditions in the Manchester Aerosol and Ice Cloud Chambers. Here, we report on the results of the measurements (Sect. 3, including the experimental setup), after an introduction of the chambers and instrumentation (Sect. 2). The results are discussed in relation to previous studies and their impact for atmospheric processes (Sect. 4) and summarised in the conclusions (Sect. 5).

2 Facilities and Instrumentation

For the current study the Manchester Ice Cloud Chamber (MICC) and Manchester Aerosol Chamber (MAC) were used, which are connected by a transfer pipe. The chambers and their instrumentation are described in the following. An overview is given in Fig. 1.

2.1 Manchester Aerosol Chamber (MAC)

The Manchester Aerosol Chamber (MAC) is a photochemical aerosol chamber comprising a 18m³ teflon bag (Hamilton et al., 2011; Alfarra et al., 2013) surrounded by a temperature and relative humidity controlled housing. The teflon bag is held by
three frames such that the upper and lower frame can freely move to allow expansion and collapsing of the chamber during fill cycles or sampling (and thus removing air) from the chamber. Attached to the chamber is an air system that contains a series of filters (Purafil, Purafil Inc., USA; charcoal; HEPA, Donaldson Filtration, USA), a humidifier, an ozoniser, and a seed drum. NO\textsubscript{x} can be added (as NO\textsubscript{2}) as well as the target volatile organic compounds (VOCs) for SOA formation. The precursors are introduced through injection into a heated glass bulb and transferred into the chamber by a flow of filtered, high purity nitrogen (ECD grade, 99.997\%). Thus, the composition of gaseous precursors and relative humidity can be controlled. Two 6kW Xenon arc lamps and further halogen bulbs are mounted on the inside of the bag’s housing to simulate the solar spectrum and enable photochemistry. Furthermore, the housing is covered with reflective space blanket, in order to maximise the irradiance in the bag and to ensure even illumination. The Xenon arc lamps are mounted on two opposite sides of the enclosure at different heights. The illumination setup has been tuned to mimic the atmospheric actinic spectrum over the wavelength range 290–800\text{nm}. Air conditioning ensures that the chamber is kept at an operating temperature of typically 25°\text{C} during experiments (under illumination). Further details on the chamber and illumination can be found in Alfarra et al. (2013).

The aerosol chamber is equipped with a set of instruments to measure temperature, humidity, aerosol number, particle size distribution, mass concentration, and chemical composition. Relative humidity and temperature are measured at the centre and on the side of the chamber by a dewpoint hygrometer, a thermocouple, and a resistance probe. A water condensation particle counter (WCPC 3785, TSI Inc., USA; with a cut-off diameter at 5 nm) is used to measure the aerosol number concentrations. A Differential Mobility Particle Sizer (DMPS, custom made) observes particle size and mass distributions for sizes between 40–640 nm with the sheath flow taken from the chamber as well. A chemiluminescence gas analyser (Model 42i, Thermo Scientific, USA) is used for measuring NO and NO\textsubscript{2} mixing ratios and ozone was measured by a UV photometric gas detector (Model 49C, Thermo Scientific, USA).

A transfer pipe connects the aerosol chamber to the cloud chamber (as indicated in Fig. 1). The pipe has a diameter of one inch and is approximately 33 m long.

### 2.2 Manchester Ice Cloud Chamber (MICC)

The Manchester Ice Cloud Chamber (MICC) is a 10 m high stainless steel tube of 1 m diameter which is contained in three cold rooms (spanning over three floors; Connolly et al., 2012; Emersic et al., 2015). The cold rooms can be temperature controlled from room temperature to about approximately -50°\text{C}. Two scroll pumps are used to evacuate the chamber in order to form clouds in these experiments. The chamber can be refilled, e.g. with filtered air or air from the aerosol chamber, via the transfer pipe (cf. Fig. 1).

MICC is instrumented to measure ambient conditions such as temperature, pressure, and humidity, and furthermore, cloud particle and aerosol particle concentrations. The following instruments are in use: eight thermocouples (K type) at different heights, reaching alternating 10 cm (thermocouples Tc1, Tc3, Tc5, Tc7) or 50 cm (thermocouples Tc2, Tc4, Tc6, Tc8) into the chamber. The thermocouples were calibrated before the experiments at temperatures between -78.5°\text{C} (dry ice) and 100°\text{C} (boiling point of water). The thermocouples have a time constant of about 60 s, see appendix for more detail. A modified (for lower temperatures) Keller Lex1 pressure sensor with accuracy of 0.2\%FS monitors the chamber pressure. Humidity can
be measured at ambient pressure by a CR-4 hygrometer. For the measurements of cloud particle properties such as number concentrations, size distributions, and shapes, a Forward Scattering Spectrometer Probe (FSSP Dye and Baumgardner, 1984) and a Cloud Particle Imager (CPI, version 1.0; Connolly et al., 2007) were deployed.

2.3 Cleaning procedures

In order to clean the chambers the attached air system accommodates three filters (see description in Sect. 2.1 and Fig. 1) to remove any particles and reactive gases. The aerosol chamber is cleaned by several cycles of filling and flushing (at least 5 times) until the aerosol number concentrations stayed constant below 5 cm$^{-3}$ (dark concentration). The cleaning procedure includes flushing the pipes around the seed drum and ozoniser. After the last flushing cycle ozone is added into the chamber and left overnight in order to oxidise any left-over reactants. Typically for this purpose, ozone concentrations are about 500-600 nmol mol$^{-1}$. The content of the chamber is then replaced with clean air using a series of fill/flush cycles prior to the experiment. Once a week a SOA background experiment (see Sect. 3.2 for details) is conducted where the UV lights are switched on. These background experiments could be seen as ‘harsh’ cleaning procedures, and the combination of the daily cleaning (fill/flush cycles and ozone overnight) and background cycles has been found to keep the chamber sufficiently clean.

The cloud chamber is cleaned by repeated evacuations of the chamber to 200 hPa followed by refilling from the air system with filtered air until aerosol concentrations stayed constant below 1 cm$^{-3}$. The number of necessary cleaning cycles is dependent on the aerosol number concentrations left from a previous experiment. As the cloud chamber is fitted with several outlets/openings, which for evacuation are sealed off, there are sources for leakages. These have been measured by evacuating the chamber to 200 hPa and leaving it at this pressure for approximately two hours. A leakage rate of 0.12 hPa min$^{-1}$ was found, which should only allow introduction of a small number of unspecified aerosol from the lab air. An estimate including previous leak checks and concurrent aerosol concentration measurements suggests an introduction of less than 1.5 cm$^{-3}$ when leaving the chamber 5 minutes at 200 hPa. (Less aerosol is introduced through leakages at higher pressures in the cloud chamber.) The leak check included the transfer pipe, i.e. the valve to the transfer pipe on the cloud chamber side was open and just closed at the entrance to the air system. The refilling of the cloud chamber with air from the aerosol chamber was performed as quickly as possible, to reduce time when MICC and transfer pipe are underpressured and can potentially be contaminated (typically started within 1 minute). A transfer, i.e. the refilling of the cloud chamber from the aerosol chamber to ambient pressure, takes about 10 minutes. The air system itself is a complex system with various fittings; therefore, it presents a further potential source for contamination during transfers. This was tested by “clean bag” transfers, where both chambers are cleaned and a transfer is performed with (almost) particle free air from the aerosol chamber bag (measurements are shown in supplementary material).

In addition to the cleaning procedures, MICC is regularly defrosted to avoid build-up of ice on the sample line outlets to the cloud particle instrumentation that would eventually lead to particle losses.
3 Experiments

The experimental programme was constructed to test the efficiency of SOA to act as ice nucleating particles at −20°C to around −28°C, i.e. under conditions roughly resembling mixed-phase clouds where dust starts to become important as ice nucleating particle. Experiments were started at −20°C and close to water saturation to allow formation of liquid clouds which then glaciate. Thus, the setup also allows for testing of immersion freezing, i.e. whether the activated cloud droplets contain efficient (semi-) solid INclusions. Three different SOA systems were used to perform the experiments. They were chosen to be representative of a typical range of SOA particles of varying sources found in the atmosphere, including anthropogenic/biogenic as well as particles of different phase state (bouncy/non-bouncy particles; Virtanen et al., 2010) (here liquid and semi-solid particles; Virtanen et al., 2010, see also Sect. 3.1). The SOA were photochemically formed from the following precursors: α-pinene (biogenic and bouncy semi-solid phase state), 1,3,5-trimethylbenzene (TMB; anthropogenic and bouncy semi-solid), and heptadecane (anthropogenic and non-bouncy liquid). In order to test the experimental setup, the experiments using SOA particles for cloud formation were accompanied with experiments using ammonium sulfate. Ammonium sulfate was chosen as it is a well known system that does not nucleate ice under the chosen experimental conditions. Furthermore, it can easily be tested with a model to assess whether the ammonium sulfate measurements are meaningful (see Sec. 3.4). A further control experiment was performed using dust (kaolinite) as this is known to be an ice nucleating particle at the given temperature. Some systems have been tested with two different pump speeds during evacuation the cloud activation experiments which alters the cooling rate. Cooling rates were about approximately 10.1K min⁻¹ and 6.2K min⁻¹ for fast and slow pump speed, respectively. An overview of the performed experiments is given in Table 1.

3.1 Particle bounce measurements

Amorphous solid particles have been observed to bounce in an aerosol impactor, thus, the bounce of particles can be used to infer their phase state (Virtanen et al., 2010). In a previous experiment using the combination of MAC and MICC, transfer experiments on some of the same (and some additional) systems were performed and the phase state of particles were determined by particle bounce measurements (see Saukko et al., 2012b, a, for a detailed description of the methods). Here an upgraded version of the bounce system, the Aerosol Bounce Instrument (ABI Pajunoja et al., 2015), was employed. ABI consists of a particle size selection unit (neutralizer containing bipolar 210Po strip and Vienna type long DMA), a humidification unit (Permapure PD-240-12SS, Nation multtube), impactor unit (MOUDI stage #14 with upstream pressure \(p_{\text{initial}} = 0.85\text{bar}\), and downstream pressure \(p_{\text{final}} = 0.7\text{bar}\), leading to a cut-off aerodynamic diameter \(d_a = 67.09\text{nm}\), and two CPCs (TSI, model 3010) for measuring the particle number concentration before and after the impactor. ABI determines a bounced fraction (BF) of particles which is used as an indicator of the phase state of particles; particles with BF 0 are mechanically liquid whereas particles with \(0.1 < BF < 1\) are mechanically solid or semi-solid. Calculation and calibration of bounce measurements are described in more detail by Saukko et al. (2012a).

In Fig. 2, the bounced fractions measured for TMB, heptadecane, α-pinene/limonene and limonene experiments as a function of

---

\(^1\)see supplement for more information on particle bounce--
RH are shown. In general higher bounce fractions are found at lower relative humidity. For TMB, limonene and α-pinene/lime cases the bounced fractions are high at dry conditions and stay elevated (BF > 0.4) up to RH 80% indicating semi-solid phase of the particles at elevated humidities. It can clearly be seen that SOA from the heptadecane experiment exhibit very different behaviour, maintaining a bounced fraction of less than 0.012 even at the lowest available RH indicating liquid phase state already at dry conditions. Similar liquid behaviour was observed for heptadecane earlier by Saukko et al. (2012b). The heptadecane experiment also shows a much lower m/z=44 fraction than in other experiments. Even though these bounce measurements were not performed simultaneously to the ice nucleation experiments we report here, the bounce measurements were conducted under very similar conditions in the same chamber using the same particle generation procedures. Therefore, we believe that the results are applicable to the SOA particles formed in our recent experiments. Unfortunately, no bounce measurements with pure α-pinene were performed, however, several studies (e.g. Saukko et al. 2012a, Pajunoja et al. 2015, Ignatius et al., 2016) have shown that α-pinene SOA is semi-solid under the conditions relevant here.

3.2 Experimental design

An experiment always followed the outlined procedure: After careful cleaning of the chambers and the air inlet system, the desired particles are created in MAC. To achieve this prepare the system for injection of relevant gases for particle formation in MAC the volatile organic compound (VOC) injection glass bulb is heated and continuously flushed with nitrogen. During The precursors for the SOA are injected into the glass bulb in form of high purity liquids, where they evaporate immediately. The vapourised VOCs and NOx are then injected during the last filling of the MAC air bag, the precursor gases for the SOA and are injected. By filling through the humidifier water vapour is added. Mixing within the bag is ensured by the main filling air stream. Photochemistry is started by switching on the lights. Ozone is injected as well just after the lights are switched on as a source of OH to speed up aerosol nucleation and to increase particle numbers. After sufficient time for the photochemistry, the lights are switched off and the cloud chamber is evacuated to prepare for the transfer. Table 2 shows the initial concentrations and other chamber conditions used for the formation of SOA particles. A typical development of the formation of a SOA system is shown in Figure 3.

When total aerosol particle mass reached equilibrium in MAC, a transfer was performed from MAC to MICC. For the transfer MICC was evacuated to 200hPa and then refilled from MAC to ambient pressure. Thus, the desired aerosol population is transferred into the cloud chamber and slightly diluted by the remaining air in MICC, i.e. approximately 8m³ air from MAC is transferred to MICC and mixed with the approximately 2m³ remaining clean air. The dilution leads to a tendency for the semi-volatile components of the aerosol to evaporate. Since the air is cooled at the same time, there also is the opposing tendency of condensation and any semi-volatile component in the aerosol will have a tendency to transfer between phases accordingly. As there is no humidity nor organic vapour measurement during the transfer, the exact state of the aerosol is unknown. The transfer was then followed by measuring aerosol total number concentration and size distribution in MICC (using the CPC and SMPS). Temperatures in MICC fluctuate during a transfer, decreasing during chamber evacuation and increasing during refill, even above the target temperature of 253K, as the aerosol chamber is operated at room temperature, and the transferred air needs time to cool. Therefore, further aerosol measurements were obtained after MICC temperatures
settled back to the target temperature. Immediately following these aerosol measurements, a cloud activation experiment, i.e. after the temperatures have settled, reveal that there is no significant change. Therefore, we conclude that either no significant evaporation and condensation took place or both effects cancel each other. As the chamber walls were ice coated, any humidity in excess of RH\textsubscript{ice} would have condensed onto the chamber walls following the transfer. However, given the dimensions of the chamber and the low speed of the diffusion process supersaturation was not depleted until the start of the experiments: Immediately following the later aerosol measurements, a cloud expansion activation run was performed, i.e. MICC was pumped down to 700hPa with the cloud probes sampling from the chamber as well. Two different pump speeds were tested, a faster pump speed using both main pumps and the pumps attached to the cloud probes, and a slower pump speed using one of the main pumps only in addition to the cloud probes. A faster pump speed, assuming adiabaticity, will lead to a faster cooling rate and higher supersaturations. MICC was refilled again from MAC, to avoid further dilution of the aerosol by mixing with filtered air. Again, aerosol number concentrations and size distributions were measured in MICC two times and a further cloud expansion was performed. If there was still enough air remaining in MAC, it was used to refill MICC which allowed a third cloud run.

Additionally, cloud expansion activation experiments on background transfers were performed. The background experiments normally contain all of the ingredients used chemical substances as in a typical SOA experiment, with the exception of the main precursor. They are conducted to quantify the contribution of background VOCs and oxidants to the overall SOA formation and to ensure that the SOA formed during actual experiments is a result of the oxidation of the precursors being studied (i.e. not originating from compounds coming off the chamber walls or from the air used to fill the chamber).

### 3.3 Results

Instead of showing data for all cloud expansions here, we will only illustrate in detail two examples, one using heptadecane as precursor and one \(\alpha\)-pinene, as the latter looks fairly similar to the TMB experiment. For the sake of completeness, figures for all other expansions cloud activation runs can be found in the supplementary material. An example for a cloud expansion activation run on SOA formed on heptadecane precursor with the faster pump speed is shown in Fig. 4. The uppermost panel shows the aerosol size distribution measured by the SMPS prior to the chamber evacuation, along with the numbers for total aerosol concentration as observed by the SMPS. Agreement of the size distributions observed after transfer and before expansion shows that there is no significant alteration of the aerosol size distribution as a result of the transfer and the time spent in MICC while the temperatures settle. The mean mode diameter of the aerosol is located at about 370nm, while the second mode diameter is at about 200nm. Thus, these aerosol particles are large enough to potentially act as ice nucleating particles. Simultaneously with the aerosol measurements, humidity was scanned in MICC. These observations show that MICC was almost saturated with respect to water (RH\textsubscript{w} = 96%, supersaturated with respect to ice), the dew point was at 252.6K after the transfer and at 252.7K before the expansion. The further panels in Fig. 4 show the time series of the cloud development, with the size distribution and mean volume diameter (MVD) of cloud particles (panel b) observed by the FSSP, total water content (TWC) and number concentration (N; panel c), pressure and temperature (panel d), and some example images taken by the CPI (panel e). Cloud particles observed just at the start of the expansion potentially stem from opening the valve to the
At the beginning of the expansion cloud activation run (first 20 seconds) a small number of aerosol particles (approx. 30 cm$^{-3}$) activate to cloud particles with sizes mostly below 10µm. The main activation takes place at 21 seconds, apparent from the cloud particle size distribution time series. High numbers of small hydrometeors are observed that subsequently grow to slightly larger sizes (cf. yellow colours showing the main particle size mode and superimposed mean volume diameter (MVD, light blue) in the plot). The CPI only detected spherical particles during the expansion. We would expect that potential ice particles would grow to larger sizes than the observed sizes. Taking the sizes and the imaged spherical shapes into consideration, it can be comfortably reasonably assumed that the observed particles were water droplets.

Fig. 5 shows the example of a cloud evacuation activation run performed with a slow pump speed on SOA generated from α-pinene as the SOA precursor. The mean mode diameter of the aerosol is at approximately 210nm. Activation of aerosol to cloud particles starts at 30s into the cloud run. Particle sizes stay below 20µm, the mean volume diameter reaches about 9µm at about 90 seconds into the evacuation cloud activation run and stays fairly constant until the cloud diminishes. Only one spherical particle had been imaged by the CPI. Given that there was no further growth in particle size and particle sizes are rather small, we conclude that the particles were in the liquid phase and not frozen. In the case of frozen particles, we would have expected those to grow more quickly to larger sizes, e.g. as in the dust example below.

In order to show that ice can be formed under the experimental conditions, kaolinite dust particles were injected into the cloud chamber. The kaolinite dust (KGa-1b) was injected into the cloud chamber with the help of a dust generator (PALAS RBG1000) directly attached to the chamber (not via the air system). To ensure proper mixing of the dust and air in the chamber an evacuation to 700 hPa was performed directly after the injection. The results of the dust run using the high pump speed is shown in Fig. 6. Dust particles of a wide range of sizes were present (see SMPS size distribution). At first, small particles with mean volume diameters between 4µm and 10µm were observed that were presumably large (swollen) dust particles. Upon activation at 21 seconds, small particles activated in the droplet mode (cf. yellow colours in the size distribution time series), followed by particle growth and a diminishing of the small droplet mode. The drop of cloud particle numbers at about 80s into the evacuation are caused by the growth of the larger ice particles, at the expense of the small droplets (Wegener-Bergeron-Findeisen process). The CPI images show the presence of non-spherical particles, i.e. ice particles.

The two successive cloud activation runs in each experiment can be used to look at activated fractions in order to see whether the aerosol properties change after one activation/deactivation cycle (cloud processing). The activated fraction here is simply calculated by dividing the pre-expansion aerosol number concentration by the peak cloud particle number concentration. Furthermore, when a second experiment is available with a different pump speed, this can be used to determine the effect of the cooling rate on the activation of the aerosol. Fig. 7 shows the activated fractions of five experiments: the already shown heptadecane (upper left panel), α-pinene (middle right panel), and dust (lower right panel) activation runs accompanied by their respective other runs in the same experiments, plus a further heptadecane experiment with altered pump speed (lower left panel) and the TMB experiment (upper right panel). Instrument error margins may lead to an activated fraction of more than 1. The fast pump speed heptadecane experiment shows no significant cloud processing, activated fractions of both runs are very similar. In the slower pump speed experiment, however, the second heptadecane run shows a higher activated
fraction than the first run, though initial ice supersaturation are the same and temperatures in both runs are within 0.2° C. Thus, the aerosol becomes more efficient at activating to cloud droplets. The first run here exhibits lower activated fractions as the fast pump speed runs, the second run peak activated fraction is about the same as in the fast pump speed runs. The α-pinene slow pump speed experiment shows the opposite behaviour, the second cloud run has slightly lower activated fractions as the first. The same is true for the TMB slow pump speed runs. However, the initial temperatures differ by about 0.7° C in the TMB case resulting in a less strong temperature drop during the expansion, and also the initial ice supersaturation differs. Caution needs to be taken with the outliers in the first α-pinene run, which might be due to oversampling in the FSSP. The dust runs were performed at different pump speeds, the second run using the slower pump speed shows slightly lower activated fractions as than the fast pump speed run.

3.4 Model comparison for ammonium sulfate control experiment

The Aerosol-Cloud and Precipitation Interactions Model (ACPIM; Connolly et al., 2012) has been chosen for testing of the experimental data of the ammonium sulfate control runs. The model is adapted to be used with chamber measurement data as the ones reported here. The observed temperature and pressure curves as well as the initial relative humidity and aerosol size distribution and number concentrations are used to initialise the model. Figure 8 shows the results of the ACPIM simulation in comparison to the measurements of cloud droplet number concentrations, LWC, and size distribution of the cloud activation run 2 of Experiment 9. The model predicts complete activation of the aerosol particles. The measurements show some outliers which might indicate that the capacity of the instrument for measuring particle numbers has been reached, i.e. too many particles lead to overcounting which is apparent in the outliers. Apart from the outliers, the measured cloud particle numbers are a little smaller than the modelled numbers, again in high concentrations the instrument is prone to measurement coincidence errors, not only overcounting but also multiple particles in the sample volume at one time leading to a general undercounting.

As all aerosol particles in ACPIM activate, they grow subsequently into a very narrow (theoretical) size distribution as theory predicts. The simulated sizes are somewhat smaller than the mean volume diameter measured by the FSSP. This could be the reason for the smaller LWC predicted than measured as well. The simulation predicts cloud particle appearance earlier than the observations show, this is certainly thought to be due to boundary layer effects in the cloud chamber.

Due to e.g. wall heating, the air next to the walls may stay cloud free for longer than the interior of the chamber where the cloud forms earlier on. As the sample lines are attached to the bottom and will first suck air from the boundary layer, it will take time for the cloud to extend downwards to the bottom and be sampled—see also discussion in Möhler et al. (2003) for similar effects in the AIDA cloud chamber.

The observed cloud particle size distribution is wider than the simulated one. Some aerosol particles might nucleate and subsequently activate into cloud drops during the evacuation, leading to the widening of the size distribution to the smaller sizes. Further This could be due to effects of non-uniformity in temperature and humidity might lead to further that lead to broadening of the size distribution. For example, as the chamber walls will stay at close to their initial temperature while the chamber centre cools adiabatically during an expansion, wall heating effects can create a temperature gradient within the chamber (warmer towards the walls and colder towards the chamber centre), which will induce a humidity gradient as
Three different precursors were chosen for SOA formation in this study, to cover biogenic and anthropogenic sources. The photo-oxidised SOA particles were transferred into a cloud chamber to study and their ice nucleating abilities were tested at temperatures of -20°C to about -28°C. The chamber was at close to water saturation at the start of the measurements, thus, providing the environment for cloud formation. The most important finding from this study is that the SOA particles were not efficient ice nucleating particles at the chosen temperature and relative humidity range (i.e. in the mixed-phase clouds regime). While the sensitivity runs performed on kaolinite dust particles, clearly show nucleation of ice, ice nucleation was not measurable in any of the other SOA or ammonium sulfate runs. Thus, even though abundant, SOA particles might not play a role in ice formation at lower altitudes, contrary to previous findings at lower temperatures, where SOA particles were found to nucleate ice (see Hoose and Möhler, 2012, and references therein). Measurements of ice nucleation (or lack of ice nucleation) at higher temperatures (temperatures above the cirrus regime) are scarce. Prenni et al. (2009) in their study, found no measurable ice nucleation in continuous flow chamber measurements at -30°C. However, the residence time of the aerosol particles in Prenni et al.'s measurements in the continuous flow chamber are in the order of seconds, compared to several minutes here. Furthermore, they formed the SOA particles through dark ozonolysis of precursors using excessive amounts of ozone, whereas in this study photo-oxidation of precursors with less ozone were used. While our results are in line with the findings e.g. from Prenni et al. (2009) and Schill et al. (2014) who concluded that their aqueous SOA is a poor depositional ice nucleus though the aerosol particles in Prenni et al.'s measurements in the continuous flow chamber are in the order of seconds, compared to several minutes here, were in a semi-solid or glassy phase state, other studies at lower temperatures found SOA to be an efficient INP (e.g. Wang et al., 2012; Ignatius et al., 2016) and thus potentially important for atmospheric ice nucleation. Further studies found that SOA from α-pinene is initially an inefficient INP at cirrus cloud conditions and shows an increased ice nucleation ability when precooled or preactivated, i.e. after cloud processing where the aerosol first activated to supercooled cloud droplets and then froze homogeneously (Ladino et al., 2014; Wagner et al., 2017). These and other studies on the ice nucleating ability of SOA particles are summarised in Hoose and Möhler (2012) and Knopf et al. (2018). It has to be stressed that in the above mentioned studies and our study the SOA generation procedures and conditions can vary significantly, as well as the methods used to measure ice nucleation, see the Introduction for details. The precise impact the different SOA formation procedures and conditions have on the ability of the SOA as INP, e.g. whether SOA formed by dark or
light ozonolysis would behave differently if temperatures and humidities during the generation are the same is not clear. In order to help initiate the photochemistry NOx was used in the SOA formation here, which might be different to other SOA formation conditions. However, to the authors knowledge, there is no systematic study of the effect of NOx on particle composition or properties, so whether this has an effect on the ice nucleating ability of the formed SOA is not known. It should be noted though, that also the O:C of produced SOA was relatively low in our experiments. As shown in Pajunoja et al. (2015) the particle viscosity (or bounce behaviour) at elevated RHs depends strongly on O:C. This is because the particle hygroscopicity (i.e. the particle phase water content at certain humidity) increases with O:C. Hence, not only the NOx might affect the composition or viscosity, but also the oxidation conditions more generally. Furthermore, the main sizes of the produced SOA particles show large differences, ranging from below 100 nm to 40 µm, which will impact on their ice nucleating ability due to the available surface area. While most studies generate their SOA particles at room temperature and (almost) 0% RH, only Wang et al. (2012) and our experiments stand out with 35±5% and 45-50% RH, respectively. SOA generated at different temperatures and humidities might exhibit different IN potential, as such conditions impact on the phase state of the particles (see e.g. discussion in Berkemeier et al., 2014). We aimed at generating SOA in our experiments under conditions which are close to realistic conditions in the lower boundary layer, where precursor gases for SOA formation are emitted (here: room temperature and relative humidities wrt water of 45-50%). Berkemeier et al. (2014) further state that humidification in typical atmospheric updrafts (or cloud chamber experiments) may be fast enough to cause a difference in phase state from that of equilibrium, as the time for diffusion of the water into the particle is longer than the time for humidification. This can result in a particle that has a liquid outer shell but still contains solid inclusions/a solid core even at RH above the quasi-equilibrium glass transition. Thus, SOA particles could potentially act as immersion freezing nuclei in conditions where they are supposed to be liquid, if in equilibrium. Even if Mikhailov et al. (2009) and Shiraiwa et al. (2017) are correct in assuming that glass transition plays a role at ambient temperatures in the lower troposphere (above roughly 2 km), these SOA particles according to this study and Prenni et al. (2009) will not be (efficient) ice nucleating particles, neither as depositional nor as immersion freezing nucleus. Thus, even though they are abundant, SOA particles might not play a role in ice formation at lower altitudes. There seems to be a twofold activation of cloud droplets in the heptadecane experiments. Upon the onset of activation a few seconds after start of the evacuation, a smaller amount of cloud particles are observed with the FSSP with a low LWC, until the second mode of activation kicks in and larger numbers of particles activate and the LWC peaks. The mean volume diameter of the cloud particles in the first activation mode is a little smaller than in the second mode, though not always clearly apparent. Also in the kaolinite dust experiments two modes were observed in the size distribution. Here, however, it is likely that the first mode comprises larger (possibly swollen) dust particles and not cloud particles. The latter appear in the second mode. The experiments with SOA particles from α-pinene and TMB precursors show a different behaviour with only the main activation mode. The aerosol particles formed from these precursors are both more in a semi-solid phase state, i.e. more viscous than the heptadecane particles generated from heptadecane at the same temperature and relative humidity. Thus, larger supersaturations are needed for these precursors it takes a longer time for these viscous SOA particles to take on water vapour and grow due to diffusion limitations. A speculative explanation for this the behaviour of the heptadecane SOA particles could be that the heptadecane particles, or rather a subset thereof, already start activating during the transfer. The relatively
warm air from the aerosol chamber flows into the cold cloud chamber and starts cooling, the relative humidity increases accordingly. Some vapour will condense onto the walls, but the relative humidity might increase enough to start activation of aerosol particles that already made it into the chamber. These activated particles then grow, while further later arriving particles may stay unactivated. When the evacuation of the cloud chamber starts, cooling will be much higher and all other heptadecane particles will activate as well. **Indeed, an effect of different temperatures in the chambers or sampling lines had been found and discussed by e.g. Ignatius et al. (2016) and Knopf et al. (2018).** However, the aerosol chamber DMPS and cloud chamber SMPS aerosol size distributions do not indicate major growth of particles between transfer and cloud evacuation. A different explanation for our observations could be that larger heptadecane particles were present (and similarly larger dust particles in the dust experiment) before the evacuation started. Such particles could have swollen or already activated into cloud particles sooner than the main mode. The SMPS size distributions only extend to 615 nm, thus, we cannot say whether larger particles were indeed present. Another explanation that cannot be ruled out completely is, that other aerosol particles from background contamination are activated and cause the first activation mode. However, it is not clear why contamination should only be existent in the heptadecane experiments and not in the α-pinene and TMB experiments as well.

As Mikhailov et al. (2009) point out, organic (semi-)solid amorphous particles can kinetically limit the water uptake and may thus influence the growth activation as cloud condensation nuclei. Thus, the phase state of the aerosol particles (represented by their bounciness) could play a role in the onset of activation, as hinted in measurements by Ignatius et al. (2016); Ladino et al. (2014); Wagner et al. (2014). As the cloud chamber is generally at about close to water saturation at the beginning of each expansion, an earlier activation to cloud particles would be expected than seen here. It is likely, that the observation of cloud particles is delayed due to wall heating effects, i.e. the cloud forms in the middle of the chamber but when starting pumping air into the sample lines to the cloud particle instrumentation, air from the boundary layer between wall and chamber interior is drawn into the lines first which might be at slightly higher temperatures and therefore at lower relative humidity and cloud free. Such wall effects have been observed in other cloud chambers as the AIDA chamber as well (Möhler et al., 2003). The comparison of activated fractions shows some differences between the investigated aerosol particles: while most experiments show no or only little signs of cloud processing in terms of a changed activated fraction of aerosol particles to cloud particles, TMB activated fractions in the second run are lower than in the first run. Thus, after the first cloud cycle the TMB particles are less likely to form cloud droplets, though the mean mode diameter shifted slightly to larger sizes which should foster faster droplet activation. α-pinene shows a similar behaviour, though less obvious. Generally, cloud processing is thought to increase the efficiency of activation into cloud particles (e.g. Hoose et al., 2008), **through changing the internal chemical structure and/or composition of the aerosol particles.** However, as the experiments reported here exhibit pure SOA aerosol, and we expect no other organic and inorganic material (or vapours) in the chambers, cloud processing here will only change the aerosol mass, not aerosol chemistry. Only remaining organic vapour can condense into the droplets. Uptake of organic vapours during the first cloud cycle and thus, less vapour available during the second cloud cycle could lead to a smaller effect of co-condensation (Topping et al., 2013) and thus, smaller cloud particle numbers and reduced activated fractions. Dust as well showed a higher activated fraction during the first run, however, one has to bear in mind the higher pump speed used in that run. Heptadecane shows a contrary behaviour to the other SOA compounds: In the slow pump speed experiment, the
second cloud cycle exhibits higher activated fractions than the first cycle with numbers comparable to those in the cloud cycles of the fast pump speed experiment. In the latter no significant difference in activated fractions between the two cloud runs can be distinguished. It has to be noted that the mean mode diameter of the aerosol in the runs using the fast pump speed were about 400nm, but approximately 500nm in the slow runs. In general, the heptadecane runs show significantly smaller activated fractions than the runs using the bouncy compounds in semi-solid phase state, even though the aerosol mean mode diameters are larger than in the TMB and α-pinene experiments. Therefore, we speculate that the phase state of the SOA particles shows an impact on cloud activation here.

Pre-cooling of SOA particles has the potential to increase the aerosol particles’ ability to act as INP (e.g. Ladino et al. 2014, Wagner et al., 2014). Thus, there could have been a higher chance of ice formation in the respective second cloud activation runs. However, apparently the minimum temperatures reached during the first cloud runs here were not cold enough for such a pre-activation of the aerosol particles and hence, no ice had formed.

A further small difference between the bouncy and non-bouncy compounds is the growth of particle sizes during cloud evacuation runs. While in the heptadecane runs (non-bouncy-liquid) the MVD increases slightly with time, it stays fairly constant in the α-pinene and TMB runs. This might be due to the smaller activated fractions in the heptadecane experiments which leave more water vapour for further growth of the particles further into the cloud evacuation.

5 Conclusions

The coupled system of the Manchester Aerosol and Ice Cloud Chamber have has been used to investigate the ice nucleating ability of SOA particles at temperatures resembling and relative humidities that are relevant to mixed-phase clouds. SOA particles were formed on precursors in the aerosol chamber by photo-oxidation. Clouds were formed by evacuation of the cloud chamber that led to a quasi-adiabatic drop in temperature from approximately -20°C to about -28°C/-25.5°C (fast/slow pump speed, respectively) fostering cloud formation. At the start of the chamber evacuation the humidity inside the chamber was at about close to water saturation, allowing for a speedy onset of cloud formation. The measurements show that the photo-oxidised SOA particles are not efficient ice nucleating particles in the tested temperature range: No ice formation was observed, irrespective of the type of SOA particles that were used (from α-pinene, heptadecane, and TMB precursors), resembling biogenic/anthropogenic and bouncy semi-solid/non-bouncy-liquid compounds. A sensitivity experiment using kaolinite showed that ice formation was possible with the given setup.

While the bounciness (which basically represents the phase state (which is represented by the particles bounciness, see Sect. 3.1) of the particles has no measurable impact on ice nucleation under the reported conditions, the SOA particles of different bounciness phase state show differences in activation and cloud processing. The semi-solid SOA particles from TMB and α-pinene show precursors show (slightly) reduced activated fractions in a subsequent cloud cycle, the less bouncy compound heptadecane liquid SOA particles from heptadecane precursor reveals increased activated fractions. The exact rea-
sons can only be speculated on as for example no measurements of organic vapours in the chambers are available. Furthermore, heptadecane shows the heptadecane experiments show a two-fold cloud activation feature that is absent in the TMB and α-pinene experiments. Again, these cannot be fully explained here as measurements which would be able to support or disapprove the speculations are missing.

5 The main conclusions from these experiments are that the tested photo-oxidised SOA particles do not nucleate ice under the mixed-phase cloud regime, neither in depositional nor immersion freezing mode. Thus, even in their high abundance in nature, SOA particles will rather act as cloud condensation nuclei and only as ice nucleating particles when cold enough (below likely below the homogeneous freezing threshold).

6 Data availability

10 As the chambers are part of the EUROCHAMP consortium, the data will be made available at the EUROCHAMP data centre. Until then, they will be distributed upon request.

Appendix A: Temperature correction

During evacuations the temperature change in the cloud chamber is supposed to be quasi-adiabatic, if no clouds form. By considering the time constant, a quasi-adiabatic temperature drop can be seen at the beginning of the expansion, while heating effects become stronger later on from wall heating and latent heat release from droplet formation. Fig. A1 shows the temperatures during a cloud expansion (in the lower panel): measured temperature in red, calculated adiabatic temperature in blue, and the corrected temperature considering the time constant in orange and dashed. The corrected temperature is smoothed with a 20 seconds running mean due to the small scale fluctuations in the temperature measurements that otherwise propagate into the corrected temperature. Additionally, the plot shows the pressure. In the upper panel the measured cloud particle number concentrations are displayed in green triangles. They give a good indication for the bump in the corrected temperature. The sharp increase in cloud particle numbers at 20 seconds (i.e. the major activation) coincides with the temperature deviation departure in the corrected temperature curve from the adiabatic curve. By calculating the theoretically available humidity from these retrieved temperatures we find a good match with our LWC observations, as the calculated available LWCs in the upper panel show.

Figure 2. Composition and bounced fraction of SOA particles in MAC. Open symbols represent data collected in experiments where there was no quantitative ice nucleation data. Panel a shows the mass fraction of the AMS fragments measured at m/z=44 throughout their growth in the aerosol chamber. Panel b shows bounced fractions for heptadecane, α-pinene/limonene and limonene experiments as a function of RH at the latest available time before transfer. In general higher bounce fractions are found at lower relative humidity. It can clearly be seen that SOA from the heptadecane experiment exhibit very different behaviour, maintaining a bounced fraction of less than 0.012 even at the lowest available RH. All other bounced fraction data is similar to the other examples shown. The heptadecane experiment also shows a much lower m/z=44 fraction than in other experiments.
Figure 3. Development of SOA particles in the aerosol chamber. The blue dashed line indicates the injection of the SOA precursors, the grey dash-dotted line the beginning of the transfer to the cloud chamber. The grey shading indicates the time with the lights switched on. This example shows the development of SOA from the heptadecane precursor (experiment 8, see Table 1).
Figure 4. Example of a cloud evacuation performed on heptadecane precursor aerosol (experiment 10, see Table 1). The uppermost panel shows the SMPS size distributions obtained before the expansion, followed by timeseries of FSSP measurements, size distribution and mean volume diameter (MVD, panel b), total water content (TWC) and number concentration (N, panel c), and temperature and pressure (panel d) during evacuation. Below the time series images captured by the CPI are shown. This was the second run on the aerosol population with a fast pump speed.
Figure 5. As Fig. 4 but using α-pinene as SOA precursor (experiment 8, see Table 1). This evacuation was the second run on the aerosol population, performed with a slow pump speed. Only one image was sampled by the CPI.
Figure 6. Control experiment using kaolinite dust (experiment 11, see Table 1). Panels as in Fig. 4, the data shown here stem from the first run, using a high pump speed. The data show formation of ice in a second mode, and the eating up decrease and almost disappearance of particle numbers of smaller drops over time (Wegener-Bergeron-Finnigan process).
