Keywords: Climate sensitivity, climate variability, energy balance
Abstract: Our climate is constrained by the balance between solar energy absorbed by the Earth and terrestrial energy radiated to space. This energy balance has been widely used to infer equilibrium climate sensitivity (ECS) from observations of 20th-century warming. Such estimates yield lower values than other methods and these have been influential in pushing down the consensus ECS range in recent assessments. Here we test the method using a 100-member ensemble of the MPI-ESM1.1 climate model simulations of the period 1850-2005 with known forcing. We calculate ECS in each ensemble member using energy balance, yielding values ranging from 2.1 to 3.9 K. The spread in the ensemble is related to the central hypothesis in the energy budget framework: that global average surface temperature anomalies are indicative of anomalies in outgoing energy (either of terrestrial origin or reflected solar energy). We find that assumption is not well supported over the historical temperature record in the model ensemble or more recent satellite observations. We find that framing energy balance in terms of 500-hPa tropical temperature better describes the planet’s energy balance.
The problem

When an energy imbalance is imposed, such as by adding a greenhouse gas to the atmosphere, the climate will shift in such a way to eliminate the energy imbalance. This process is embodied in the traditional linearized energy balance equation:

\[ R = F + \lambda \Delta T_s \]  

(1)

where the forcing \( F \) is an imposed energy imbalance, \( T_s \) is the global average surface temperature, and \( \lambda \) relates changes in \( T_s \) to a change in net top-of-atmosphere (TOA) flux (Dessler and Zelinka, 2014). \( R \) is the resulting TOA flux imbalance from the combined forcing and response. All quantities are deviations from an equilibrium base state, usually the pre-industrial climate. Equilibrium climate sensitivity (hereafter ECS, the equilibrium warming in response to a doubling of \( \text{CO}_2 \)) is equal to \( -F_{2\times\text{CO}_2}/\lambda \), where \( F_{2\times\text{CO}_2} \) is the forcing from doubled \( \text{CO}_2 \).

Many investigators (e.g., Gregory et al., 2002; Annan and Hargreaves, 2006; Otto et al., 2013; Lewis and Curry, 2015; Aldrin et al., 2012; Skeie et al., 2014; Forster, 2016) have used Eq. 1 combined with estimates of \( R, F, \) and \( T_s \) to estimate \( \lambda \):

\[ \lambda = \frac{\Delta(R-F)}{\Delta T_s} \]  

(2)

where \( \Delta \) indicates the change between the start of the historical period (usually the mid to late nineteenth century) and a recent period. These calculations result in values of \( \lambda \) near -2 W/m\(^2\)/K and appear to rule out ECS larger than \( \sim 4 \) K (Stevens et al., 2016). The substantial likelihood of an ECS below 2 K implied by these calculations led the IPCC Fifth Assessment Report to extend their lower bound on likely values of ECS to 1.5 K (Collins et al., 2013).

We test this energy balance methodology through a perfect model experiment consisting of an analysis of a 100-member ensemble of runs of the MPI Earth System Model, MPI-ESM1.1. This is the latest coupled climate model from the Max Planck Institute for Meteorology and consists of the ECHAM6.3 atmosphere and land model coupled to the MPI-OM ocean model. The atmospheric resolution is T63 spectral truncation, corresponding to about 200 km, with 47
vertical levels, whereas the ocean has a nominal resolution of about 1.5 degrees and 40 vertical levels. MPI-ESM1.1 is a bug-fixed and improved version of the MPI-ESM used during CMIP5 (Giorgetta et al., 2013) and nearly identical to the MPI-ESM1.2 (Mauritsen et al., 2018) model being used to provide output to CMIP6, except that the historical forcings are from the MPI-ESM.

Each of the 100 members simulates the years 1850-2005 (Fig. 1) and use the same evolution of historical natural and anthropogenic forcings. The members differ only in their initial conditions — each starts from a different state sampled from a 2000-year control simulation. We calculate effective radiative forcing $F$ for the ensemble by subtracting top-of-atmosphere flux $R$ in a run with climatological sea surface temperatures (SSTs) and a constant pre-industrial atmosphere from average $R$ from an ensemble of three runs using the same SSTs but the time-varying atmospheric composition used in the historical runs (Hansen et al., 2005; Forster et al., 2016). The three-member ensemble begins with perturbed atmospheric states. We estimate $F_{2\times CO_2}$ using the same approach in a set of fixed SST runs in which CO$_2$ increases at 1% per year, which yields a $F_{2\times CO_2}$ value of 3.9 W/m$^2$.

We calculate $\lambda$ using Eq. 2 for each ensemble member, producing values ranging from -1.88 to -1.01 W/m$^2$/K, with an ensemble average of -1.43 W/m$^2$/K (Fig. 2a). In this calculation, $\Delta(R-F)$ and $\Delta T_1$ are the average difference between the first and last decade of each run. We also calculate ECS = $-F_{2\times CO_2}/\lambda$ for each ensemble member, producing values ranging from 2.08 to 3.87 K (Fig. 2b), with an ensemble average of 2.76 K.

With respect to precision of the estimates, our analysis shows that $\lambda$ and ECS estimated from the historical record can vary widely simply due to internal variability. Given that we have only a single realization of the 20$^{th}$ century, we should not consider estimates based on the historical period to be precise — even with perfect observations. This supports previous work that also emphasized the impact of internal variability on estimates of $\lambda$ and ECS (Huber et al., 2014; Andrews et al., 2015; Zhou et al., 2016; Gregory and Andrews, 2016).
Previous researchers have questioned whether the historical record provides an accurate measure of $\lambda$ and ECS, and we can check this by comparing the ensemble average values to ECS estimates from a 2xCO$_2$ run of the MPI-ESM1.2, which is physically very close to MPI-ESM1.1 and the changes between the MPI-ESM1.1 and MPI-ESM1.2 are not believed to be important for its climate sensitivity. An abrupt 2xCO$_2$ run yields an ECS of 2.93 K in response to an abrupt doubling of CO$_2$ (estimated by regressing years 100-1000 of a 1000-year run) — 6% larger than the ensemble average. This is in line with the 10% difference in ECS estimated by Mauritsen and Pincus (2017) to arise from the average CMIP5 model time-dependent feedback, but is smaller than suggested in other recent studies of ECS in transient climate runs (e.g., Armour, 2017; Proistosescu and Huybers, 2017).

Thus, there are a number of issues that need to be considered when interpreting estimates of $\lambda$ and ECS derived from the historical period. In addition to the precision and accuracy issues discussed above, it also includes the large and evolving uncertainty in forcing over the 20$^{th}$ century (Forster, 2016), different forcing efficacies of greenhouse gases and aerosols (Shindell, 2014; Kummer and Dessler, 2014), and geographically incomplete or inhomogeneous observations (Richardson et al., 2016).

Why are estimates using the traditional energy balance approach imprecise?

In this section, we explain the physical process by which internal variability leads to the large spread in $\lambda$ and ECS estimated from the ensemble. We begin by observing that Eqs. 1 and 2 parameterize R-F in terms of $T_S$. In model runs with strong forcing driving large warming, such as abrupt 4xCO$_2$ simulations, there is indeed a strong correlation between these variables (e.g., Gregory et al., 2004). However, because R-F in such runs is dominated by a monotonic trend, correlations will exist with any geophysical field that also exhibits a monotonic trend, regardless of whether there is a physical connection between the fields. Thus, one should not take the correlation between R-F and $T_S$ in these runs as proving causality.

If $T_S$ is a good proxy for the response R-F, we would expect to also see a correlation in measurements dominated by interannual variations. Observational data allow us to test this
hypothesis. We use observations of $R$ from the Clouds and the Earth’s Radiant Energy System (CERES) Energy Balanced and Filled product (ed. 4) (Loeb et al., 2009), which cover the period March 2000 to July 2017. Our sign convention throughout the paper is that downward fluxes are positive. Temperatures come from the European Centre for Medium Range Weather Forecasts (ECMWF) Interim Re-Analysis (ERAi) (Dee et al., 2011). We assume forcing changes linearly over this time period and account for it by detrending $\Delta R$ and $\Delta T$ anomaly time series using a linear least-squares fit to remove the long-term trend.

These data show that $\Delta R$ is poorly correlated with $\Delta T$, in response to interannual variability (Fig. 3a), as has been noted many times in the literature; see, e.g., Sect. 5 of Forster (2016). In particular, the low correlation coefficient tells us that $\Delta T$ explains little of the variance in $\Delta R$.

Using explicit estimates of forcing or other temperature datasets (e.g., MERRA-2) yield the same result.

GCMs that submitted output to the 5th phase of the Coupled Model Intercomparison Project (CMIP5) (Taylor et al., 2012) also show this poor correlation. To demonstrate this, we have calculated the correlation coefficient between $\Delta T_S$ and $\Delta R$ in CMIP5 pre-industrial control runs (these are runs for which forcing $F = 0$). To facilitate comparison with the CERES data, as well as avoid any issues with long-term drift in the control runs, we break each run into 16-year segments and calculate the correlation coefficient of monthly anomalies of $\Delta R$ and $\Delta T_S$ for each segment. Fig. 4 shows that the correlation between $\Delta R$ and $\Delta T_S$ in the models is similar to that from the CERES analysis.

Recent work provides an explanation: the response of $\Delta(R-F)$ to a particular $\Delta T_S$ is determined not only by the global average magnitude, but also by the pattern of warming (Armour et al., 2013; Andrews et al., 2015; Gregory and Andrews, 2016; Zhou et al., 2016, 2017; Andrews and Webb, 2018). During El Nino cycles that dominate the observations in Fig. 3, the spatial pattern of warm and cool regions changes, leading to responses in $\Delta(R-F)$ that do not scale cleanly with $\Delta T_S$ — something Stevens et al. (2016) refer to as “pattern effects”
To demonstrate how this also generates the spread in $\lambda$ in the model ensemble (Fig. 2a), we calculate the local response $\lambda_r$ in three equal-area regions (90°S-19.4°S, 19.4°S-19.4°N, 19.4°N-90°N). We define $\lambda_r$ as the regional analog to $\lambda$ (Eq. 2):

$$\lambda_r = \Delta (R-F)/\Delta T_{S,r}$$  \hspace{1cm} (3)

where the “r” subscript indicates a regional average value.

We find that $\lambda_r$ varies between the regions (Fig. 5). This means that different ensemble members with similar global average $\Delta T_S$ but different patterns of surface warming produce different values of global average $\Delta (R-F)$, thereby leading to spread in the estimated $\lambda$ among the ensemble members. We also see strong variability in $\lambda_r$ within each region, suggesting that how the warming is distributed within the region also drives some of the spread in estimated $\lambda$ in the ensemble.

This explanation is consistent with analyses showing that $\lambda$ changes during transient runs as the pattern of surface temperature evolves (Senior and Mitchell, 2000; Armour et al., 2013; Andrews et al., 2015; Gregory and Andrews, 2016; Stevens et al., 2016). In our model ensemble, however, the pattern changes are caused by internal variability rather than differing regional heat capacities that cause some regions to warm more slowly than others during forced warming.

**A better way to describe energy balance**

Our analysis demonstrates limitations of the conventional energy balance framework (Eq. 1). It has been previously noted that $\Delta R$ correlates better with tropospheric temperatures than $\Delta T_S$ (Murphy, 2010; Spencer and Braswell, 2010; Trenberth et al., 2015). Recent analyses have also stressed the importance of atmospheric temperatures — through its influence on lapse rate — as providing a fundamental control on the planet’s energy budget (Zhou et al., 2016; Ceppi and Gregory, 2017). Based on this, we test a new energy balance framework constructed using the temperature of the tropical atmosphere:
\[ R - F = \Theta T_A \quad (4) \]

where \( T_A \) is the tropical average (30°N-30°S) 500-hPa temperature and \( \Theta \) relates this quantity to R-F. R and F are the same global average quantities they were in equation 1. ECS can be expressed in terms of \( \Theta \):

\[ ECS = - \frac{\Delta F_{2\times CO_2}}{\Theta} \frac{\Delta T_S}{\Delta T_A} \quad (5) \]

where \( \Delta T_S \) and \( \Delta T_A \) are the equilibrium changes in these quantities in response to doubled \( CO_2 \);

the CMIP5 ensemble average ratio \( \Delta T_S/\Delta T_A \) is 0.86±0.10 (±1σ), where \( \Delta \) represents the average difference between the first and last decades of the abrupt 4x\( CO_2 \) runs.

Support for Eq. 4 can be found in the observations: \( \Delta R \) shows a tighter correlation with \( \Delta T_A \) than with \( \Delta T_S \) in observations (Figs. 3a vs. 3b). Given that the slope of these plots can be taken as estimates of \( \Theta \) and \( \lambda \), the tighter correlation leads to more accurate estimates of \( \Theta \) than \( \lambda \), both in absolute and relative terms.

Turning to the model ensemble, we next demonstrate that \( \Theta \) is a more precise metric than \( \lambda \).

We do this by calculating \( \Theta \) [= \( \Delta (R-F)/\Delta T_A \)] in each ensemble member, yielding values ranging from -1.18 to -0.89 W/m\(^2\)/K, with an ensemble average of -1.04 W/m\(^2\)/K (Fig. 2a). There is clearly less variability in \( \Theta \) among the ensemble members than for \( \lambda \). This reflects less variability in the regional response \( \Theta_r \) (= \( \Delta (R-F)/\Delta T_{A,r} \)) than \( \lambda_r \) (Fig. 5), as well as less variability within the regions. We therefore conclude that interannual variability has less of an impact on \( \Theta \) than \( \lambda \). We show additional evidence for the superior precision of \( \Theta \) in the Appendix.

As far as accuracy goes, we can compare \( \Theta \) in the ensemble over the historical period to \( \Theta \) in response to much larger warming. The ensemble average \( \Theta \) from the historic period, -1.04 W/m\(^2\)/K, is close to the value obtained from an analysis of the first 150 years of an abrupt 4x\( CO_2 \) run of the same model, \( \Theta = -1.03 \) W/m\(^2\)/K, as well as \( \Theta \) calculated from all 2600 years of this run, \( \Theta = -1.04 \) W/m\(^2\)/K. On the other hand, \( \lambda \) changes substantially in the 4x\( CO_2 \) run as the climate warms: \( \lambda = -1.36 \) W/m\(^2\)/K when calculated from the first 150 years, but \( \lambda = -0.95 \) W/m\(^2\)/K from all 2600 years of that run.
We can verify this result in the CMIP5 abrupt 4xCO$_2$ ensemble. It has been previously demonstrated that plots of R-F vs. $T_5$ do not trace straight lines as the climate warms (Andrews et al., 2015; Rugenstein et al., 2016; Rose and Rayborn, 2016; Armour, 2017), so $\lambda$ and ECS calculated in a single model run may depend on the portion of the run selected. In the CMIP5 abrupt 4xCO$_2$ ensemble, for example, average $\lambda$ calculated by regressing years 10-30 ($\lambda_{10-30}$) is more negative than $\lambda$ calculated from years 30-150 ($\lambda_{30-150}$) by 0.50 W/m$^2$/K (Fig. 6).

Several explanations for this have been advanced, most prominently that $\lambda$ is a function of the pattern of surface warming (Senior and Mitchell, 2000; Armour et al., 2013; Andrews et al., 2015; Gregory and Andrews, 2016; Zhou et al., 2016; Stevens et al., 2016). Using $\Theta$ largely eliminates this pattern effect: $\Theta_{10-30}$ and $\Theta_{30-150}$ have an average difference of 0.16 W/m$^2$/K for the CMIP5 ensemble (Fig. 6). Thus, we find additional evidence that $\Theta$ tends to be similar for different amounts and patterns of warming.

Finally, one of our ultimate goals for this revised framework is to help produce better estimates of ECS. We are working on a detailed analysis of ECS based on this framework and will publish that in a follow-on paper, but we briefly show here how the advantages of the revised energy balance framework may be leveraged to do this. Fig. 7a shows $\Theta$ calculated from control runs of 25 CMIP5 models. To calculate $\Theta$ in the control runs, we break each control run into 16-year segments and calculate monthly anomalies of $\Delta R$ and $\Delta T_A$ during each segment. Then, we calculate $\Theta$ for each segment as the slope of the regression of $\Delta R$ vs. $\Delta T_A$ for that segment. Thus, for each control run, we generate a large number of estimates of $\Theta$. The value in Fig. 7a is the average of these individual values.

Fig. 7b shows the ECS of these models, calculated from the first 150 years of the abrupt 4xCO$_2$ runs using the Gregory method (Gregory et al., 2004). If we assume that models with more accurate simulation of short-term $\Theta$ produce more accurate estimates of ECS (Brown and Caldeira, 2017; Wu and North, 2002), then we can use Figs. 7a and 7b to constrain ECS. We find that the 15 models whose short-term $\Theta$ agrees with the CERES observations have ECS values ranging from 2.0-3.9 K, with an average of 2.9 K. This excludes many of the highest ECS models.
It would not have been possible to draw this conclusion with the conventional energy balance framework. Fig. 7c shows the comparison between $\lambda$ from the control runs (calculated the same way $\Theta$ was calculated) and CERES observations. Because of the much larger uncertainty in the observational estimate of short-term $\lambda$, almost all models fall within the observational range, thereby prohibiting any constraint on the ECS range.

Conclusions

We have estimated ECS in each of a 100-member climate model ensemble using the same energy-balance constraint used by many investigators to estimate ECS from 20th-century historical observations. We find that the method is imprecise — the estimates of ECS range from 2.1 to 3.9 K (Fig. 2), with some ensemble members far from the model’s true value of 2.9 K. Given that we only have a single ensemble of reality, this suggests that some skepticism is appropriate when considering estimates of ECS derived from the historical record.

The source of the imprecision relates to the construction of the traditional energy balance equation (Eq. 1). In it, the response of TOA net flux (R-F) is parameterized in terms of global average surface temperature ($T_s$). Recent research has suggested that the response is not just determined by the magnitude of $T_s$, but includes other factors, such as the pattern of $T_s$ (e.g., Armour et al., 2013; Andrews et al., 2015; Gregory and Andrews, 2016; Zhou et al., 2017) or the lapse rate (e.g., Zhou et al., 2017; Ceppi and Gregory, 2017). As a result, two ensemble members with the same $\Delta T_s$ can have different climate responses, $\Delta (R-F)$, leading to spread in the inferred $\lambda$.

The lack of a direct relationship between $T_s$ and radiation balance suggests that it may be profitable to investigate alternative formulations. We test parameterizing the response in terms of 500-hPa tropical temperature (Eq. 4) and find that it is superior in many ways. Ultimately, how investigators describe the energy balance of the planet will depend on the problem and the available data. The surface temperature is indeed special, so the traditional framework may be preferred for some problems. But investigators may find that the alternatives are superior for certain problems, for instance constraining Earth’s climate sensitivity.
Appendix

It has been previously noted in analyses of the historical record that $\lambda$ exhibits significant interdecadal variability (Andrews et al., 2015; Gregory and Andrews, 2016; Zhou et al., 2016). We can reproduce this in a 2000-year control run (a run with fixed pre-industrial boundary conditions) of the MPI-ESM1.1 model. Fig. 8 shows $\lambda$ calculated in a sliding 16-year window and confirms significant temporal variability in $\lambda$. We can similarly calculate $\Theta$ and find that temporal variability in $\Theta$ is substantially smaller (Fig. 8).

This result is reproduced in the CMIP5 control models. Fig. 9 plots the standard deviation of each CMIP5 model’s set of short-term $\lambda$ divided by the standard deviation of that model’s set of short-term $\Theta$ (as described previously, we calculate time series of short-term $\lambda$ and $\Theta$ values for each model by regressing anomalies in a 16-year sliding window of the control runs). All of the models fall above 1, demonstrating that there is less variability in the $\Theta$ time series than in the $\lambda$ time series in every climate model. This confirms that $\Theta$ is more robust with respect to internal variability than $\lambda$. It also suggests that $\Theta$ estimated from the satellite data (Fig. 3) should be considered a better estimate of the climate system’s long-term value than $\lambda$ estimated from the same data set.
