Reply to the referee #2

Referee's comment is typed in blue, authors' response is typed in black, and the change in the revised text is highlighted with red.

The authors have made a number of improvements to the original manuscript, and they have included additional details and raw data. In my opinion, the manuscript is now publishable without further review on my part. However, I do offer some additional comments for the authors to consider if they wish to clarify and revise any of the following remaining issues.

We appreciate the referee for his/her further constructive comments. We have revised the manuscript according to his/her suggestions.

Abstract: P1, L32-33: I suggest adding the very important clarification in caps: “These results FROM THE DEEP TROPICS suggest the following.”

Done.

Abstract: P1, L33-35 The authors state: “The time scale of horizontal mixing in the tropical middle stratosphere is sufficiently large for in-situ photolysis of N2O, mainly because of strong upwelling and transport barrier between the tropics and extratropics.” What does this sentence mean? Taken literally, it doesn’t make any sense to me and is oddly phrased. I am guessing that authors are trying to say that the epsilon values in the Rayleigh analysis for the N2O isotopocules are as large (or almost as large) as those for photolysis in a closed system because air in the middle tropical stratosphere is relatively isolated from the mixing in of older, photochemically-aged air from the extratropics (which serves to decrease epsilon values from the Rayleigh limit). If I were to just try to rewrite their sentence (which I think would not be as clear), then it would be more accurate to say something like: “The time scale for quasi-horizontal mixing between tropical and midlatitude air in the tropical middle stratosphere is sufficiently slow relative to the tropical upwelling rate that isotope fractionation approaches the Rayleigh limit for N2O photolysis.”

There is a similar problematic wording in the Conclusions (see below).

Revised as suggested.

P3, L32: The authors state that (Kaiser et al., 2002a) “estimated that a much larger fraction than 10% is removed by photooxidation at least in the lower stratosphere” Can the authors please give a number for the larger fraction that Kaiser et al suggested? How much larger than 10%?

We have revised the sentence as follows.

…they estimated that a much larger fraction (up to 100%) is removed by photooxidation at least in the lower stratosphere (N2O mixing ratios > 300 nmol mol-1) (Kaiser et al., 2006).

P3 L33: The authors state that “similar but a little simplified analyses by Park et al. (2004) and Toyoda et al. (2004)” were performed. Can the authors please be more descriptive in what they mean by ‘but a little
simplified relative to Kaiser et al”?
Since we described this in section 3.4, we have just added a reference to section 3.4 to the sentence.

P6, L4: The authors say that they used CO2 mixing ratios to estimate the mean age of air of an air sample and cite Engel 2009 for the measurements, but is this true for all flights (i.e., that CO2 mixing ratios were measured for all samples by Engel et al. (2009))? Or perhaps they just mean to state how a mean age can be obtained from CO2 mixing ratios? This is unclear and should be clarified in either case.
We have revised the sentence (changed the position of "Engel et al., 2009") to mean to state how a mean age can be obtained from CO2 mixing ratios.

P9, L11-12: The authors state: “The slope, which corresponds to the ratio of epsilon values, is very close to the one expected for photolysis. This confirms that photochemical decomposition of N2O is mainly caused by photolysis (Minshwaner et al., 1993)…” I think most stratospheric chemists will think it is a stretch that this isotope data needs to be used to confirm what has been known for some time. In other words, I don’t believe the fact that the majority of N2O is destroyed by photolysis needs to be confirmed in 2017. This should be reworded so that it doesn’t seem like this is an important, new, or controversial finding.
We have revised the sentence as follows.

This agrees with the fact that photochemical decomposition of N₂O is mainly caused by photolysis (Minshwaner et al., 1993), …

P9, L27-28 The authors state here: “Because the vertical ascent rate in the tropics is much faster than quasi-horizontal transport, there is an apparent transport barrier between the tropics and extratropics (Plumb, 2007)…” Sort of… It would be better to take out the ‘much’ from “much faster” and then qualify by saying “Because the vertical ascent rate in the tropics is faster than quasi-horizontal transport out to the extratropics and much faster than the quasi-horizontal transport of extratropical air into the tropics, there is an apparent transport barrier between the tropics and extratropics…” On the other hand, what one really wants to get across for this isotope study is that the tropics are relatively isolated than the rest of the stratosphere – especially the middle tropical stratosphere since little extratropical air is mixed back in (i.e., the vertical ascent rates and the entrainment of tropical air out to midlatitudes are both much faster than the transport of older air back into the tropics…).
The sentence has been revised as suggested.

P11, L11: The authors state: “Low values are obtained near the TTL over the Equator.” Note that the TTL is usually tropospheric air, not stratospheric. So are these samples in the troposphere (below the tropopause) or above the tropopause in the stratosphere?
The sentence has been revised as follows.

… low values are obtained just above the TTL over the Equator (EQP, z = 20 km) just as they are at
other latitudes.

P11, L11: The authors state: “This result confirms the indication by Kaiser et al. (2006) that the photooxidation sink has a much larger fraction than 10% in the lower stratosphere.” As I noted earlier, please give a number for ‘much larger’? And ‘confirms’? I would not agree yet that the analysis presented here confirms that at all. So I agree with the authors, who state below, that this will require more study. But, in light of this, perhaps they could use a word other than ‘confirms’ which carries a strong meaning scientifically, which is a bar I do not think they have met yet. It’s fine to publish this idea, and the case they present, but I think “confirm” is too strong a word to use just yet.

The sentence has been revised as follows. ”Number for ‘much larger’ ” has been added in p. 3 as described above.

This result is in accordance with the indication by Kaiser et al. (2006) ….

P11, L13-15: Figure S6: It is an important new figure component that the authors now provide in this revised manuscript the total loss rate for N2O in relevant regions in the stratosphere. I still believe they are not interpreting it nor their data in as rigorous a way as they could, but, as they note, they leave further work up to future studies. However, in the authors’ response to review they note “[we] deleted a part of the plots of tropics and all the plots of February Arctic region so that the plots show the parameters in the region where photochemical N2O loss really occurs.” I do see tropical parameters in their Fig S6, so I am wondering what 'part' was deleted. I think it is very important to include a complete Fig S6 so that readers can evaluate and follow up on the arguments that the authors are making here.

The part of plots deleted from the tropical profiles are those below 17 km, which was the lowest height of cold point tropopause during our observations.

Conclusions:

P 11, L28-29 “Unlike other region of the stratosphere, enrichment factors for isotopocules in the middle equatorial stratosphere (25–30 km, or [N2O] < 260 nmol mol-1) agreed with those obtained with laboratory photolysis experiments, suggesting that the isotopocule ratios are determined mainly by photolysis because of weak vertical or horizontal mixing in the tropical upwelling…” As I noted in a comment to the authors above, the wording seems to mix up cause and effect. The middle tropical stratosphere is relatively isolated; the lack of transport of air of many different transport time histories makes the isotope fractionation appear almost Rayleigh (as in an -- almost -- closed system). The specific arguments about weak vertical and horizontal mixing are not especially accurate, nor are they really needed.

The sentence has been revised as follows.

Unlike other region of the stratosphere, enrichment factors for isotopocules in the middle equatorial stratosphere (25–30 km, or [N2O] < 260 nmol mol⁻¹) agreed with those obtained with laboratory photolysis experiments because the middle tropical stratosphere is relatively isolated than the rest of the stratosphere.
P12, L3-5: The authors state: “Further observations of temporal variations and comparison with ACTM simulation will be needed to examine the change in the meridional circulation…” What change in the meridional circulation? This is the first time the authors have brought this up as a motivation or next step. There is a vast literature on this hot topic but no context is presented here at all, and no references are given. If the authors wish to motivate that this is something that N2O isotopocules could provide insight into, they should provide at least a sentence or two of context as well as some references, and a more complete argument of how N2O isotopocules could help.

The sentence has been revised as follows.

Further observations of temporal variations and comparison with ACTM simulation will be needed to obtain the quantitative estimate of the importance of photooxidation pathway and to examine the possible change in the meridional circulation predicted by model simulations (Li et al., 2008; McLandress and Shepherd, 2009) because such a change might affect $e$ values of stratospheric N$_2$O by perturbing mixing of air with different transport time histories.

Even more minor comments:

Polishing of the English usage of definite (the’s) and indefinite (a’s) articles could be helpful for readers. The first version of our manuscript had been edited by a commercial English editing service. We have checked the revised sentences carefully and tried our best to polish the English.

Pg2, L24; “transportation” should be replaced with “transport”

We forgot to correct this in the previous revision, thank you.

Pg 3, L8-9: “Although these observations are limited to ca. 20 km altitude, vertical profiles can be obtained for horizontally wide areas such as Arctic polar vortexes (pg 3, L8-9).” It is unclear what is meant by this nor why this is an important distinction.

We intended to mean that aircraft observations have a limitation of altitude and have the advantage in obtaining horizontal distributions of trace gasses and their isotopocules. We have revised the sentence as follows.

Although these observations are limited to up to ca. 20 km altitude, mean vertical profiles can be obtained from horizontally wide areas such as Arctic polar vortexes.

P7, L25-28: “The height of the tropical tropopause layer (TTL) was 14–18.5 km (Fueglistaler et al., 2009). I presume since the measurements were made in 2015, then the authors are using Fueglistaler to mean “typically,” and what the TTL is rather than a reference that has the actual tropopause measurements for these flights in it. So saying ‘typically’ and putting an “e.g.,” in the reference could clarify this.

The sentence has been revised as follows, with correction of table number.
The height of the tropical tropopause layer (TTL) is typically 14–18.5 km (e.g., Fueglistaler et al., 2009), whereas the tropopause height was 12–16 km over Japan and 9 or 10 km over Sweden and Antarctica (Table S2).

P8, L19: The authors state: “The equatorial values of epsilon almost coincide with those of photolysis…”
If the authors mean “almost as large as” it would be more clear to state it that way (since it gives the direction, and what is expected); if it is noisy, then I suppose “almost coincide” would be ok.
Revised as suggested.

P8, L21-22: The authors state “latitudinal and year-to-year or seasonal variation are slight compared to those of the middle stratosphere in the lower stratosphere”: I had to read this several times, as the order is confusing. I think the authors mean mean: “latitudinal and year-to-year or seasonal variation are slight IN THE LOWER STRATOSPHERE compared to VARIATIONS IN the middle stratosphere”
Revised as suggested.

P8, L22-25 The authors state: “Although the similar latitudinal and altitudinal dependence of epsilon has been reported previously for the latitudes ranging from 18°N to 89°N (Park et al., 2004; Kaiser et al., 2006), our equatorial data showed that the change in epsilon at altitude with higher N2O mixing ratio and the epsilon value is exactly what would be expected during the N2O photolysis.” I have several suggestions to make this sentence more clear. First, putting “show” in present tense (instead of past tense “showed”) clarifies that the authors are referring to the new deep tropical data presented here. In addition, the very last part of the sentence I think is a preview of what will be discussed in the next section, not a statement that needs to be supported here.
The sentence has been divided in two and revised as follows.

…, our equatorial data show that the change in ε at altitude with higher N2O mixing ratio. The ε value is exactly what would be expected during the N2O photolysis as discussed below.

P8, L29: We NOW discuss causes (not ‘then’).
Done.
Vertical distributions of N₂O isotopocules in the equatorial stratosphere

Abstract. Vertical profiles of nitrous oxide (N₂O) and its isotopocules, isotopically substituted molecules, were obtained over the equator at altitudes of 16–30 km. Whole air samples were collected using newly developed balloon-borne compact cryogenic samplers over the Eastern Equatorial Pacific in 2012 and Biak Island, Indonesia in 2015. They were examined in the laboratory using gas chromatography and mass spectrometry. The mixing ratio and isotopocule ratios of N₂O in the equatorial stratosphere showed a weaker vertical gradient than the previously reported profiles in the subtropical and mid-latitude and high-latitude stratosphere. From the relation between the mixing ratio and isotopocule ratios, further distinct characteristics were found over the equator: (1) Observed isotopocule enrichment factors (ε values) in the middle stratosphere (25–30 km or [N₂O] < ca. 260 nmol mol⁻¹) are almost equal to ε values reported from broadband photolysis experiments conducted in the laboratory. (2) ε values in the lower stratosphere (< ca. 25 km or [N₂O] > ca. 260 nmol mol⁻¹) are about half of the experimentally obtained values, being slightly larger than those observed in the mid-latitude and high-latitude lower stratosphere ([N₂O] > ca. 170 nmol mol⁻¹). These results from the deep tropics suggest the following. (1) The time scale for quasi-horizontal mixing between tropical and midlatitude air in the tropical middle stratosphere is sufficiently slow relative to the tropical upwelling rate that isotope fractionation approaches the Rayleigh limit for N₂O photolysis. The time scale of
horizontal mixing in the tropical middle stratosphere is sufficiently large for in-situ photolysis of N₂O, mainly because of strong upwelling and transport barrier between the tropics and extratropics. (2) The air in the tropical lower stratosphere is exchanged with extratropical air on a time scale that is shorter than that of photochemical decomposition of N₂O. Previously observed $\varepsilon$ values, which are invariably smaller than those of photolysis, can be explained qualitatively using a three-dimensional chemical transport model and using a simple model that assumes mixing of ‘aged’ tropical air and extratropical air during residual circulation. Results show that isotopocule ratios are useful to examine the stratospheric transport scheme deduced from tracer–tracer relations.

Keywords. nitrous oxide, stable isotopes, tropical stratosphere, cryogenic sampling, stratospheric transport, stratospheric photochemistry

1 Introduction

Nitrous oxide (N₂O) is a potent greenhouse gas and stratospheric ozone depleting substance emitted from various sources on the Earth surface. It is injected into the stratosphere in tropical upwelling regions. In the stratosphere, it is transported meridionally by so-called Brewer–Dobson circulation and is decomposed by photolysis (Eq. 1) and photooxidation (Eq. 2) with approximate shares of 90% and 10%, respectively (Minschwaner et al., 1993).

\[
\begin{align*}
\text{N}_2\text{O} + \text{hv} & \rightarrow \text{N}_2 + \text{O}(^1\text{D}) \\
\text{N}_2\text{O} + \text{O}(^1\text{D}) & \rightarrow \text{2NO} \\
& \rightarrow \text{N}_2 + \text{O}_2
\end{align*}
\] (1) (2a) (2b)

Mixing ratios of trace gases such as N₂O and their interrelationships are regarded as useful tools to establish a detailed picture of stratospheric circulation (Plumb, 2007), and previous observations showed compact tracer relationships that depend on the latitude (e.g., Michelsen et al., 1998). Natural abundance ratios of N₂O isotopocules, molecular species that only differ in the number or position of isotopic substitutions (Coplen, 2011), are useful tracers for elucidating the sources and physicochemical records of N₂O because isotopocule ratios reflect the isotopic compositions of source materials, isotope effects specific to each chemical and physical process relevant to formation, transportation, and decomposition of N₂O, and mixing of various air and water masses (Toyoda et al., 2015). In the context of stratospheric distribution, isotopocule ratios are unique in their ability to provide the degree of photochemical decomposition and the relative
importance of the above-mentioned two decomposition pathways (Toyoda et al., 2001; Röckmann et al., 2001).

Stratospheric distributions of N$_2$O isotopocules have been studied using scientific balloons and aircraft. For balloon observations, (a) whole air samples are collected using cryogenic samplers and are evaluated using isotope ratio monitoring mass spectrometry (IRMS) (Kim and Craig, 1993; Rahn and Wahlen, 1997; Röckmann et al., 2001; Toyoda et al., 2001; Toyoda et al., 2004; Kaiser et al., 2006); alternatively, (b) remote measurements are conducted using Fourier-transform infrared spectrometry (Griffith et al., 2000). Such observations have revealed vertical profiles up to 35 km altitude. For aircraft observations, whole air samples are collected using pressurizing pumps, with subsequent evaluation by IRMS (Rahn and Wahlen, 1997; Park et al., 2004; Kaiser et al., 2006). Although these observations are limited to up to ca. 20 km altitude, mean vertical profiles can be obtained from or horizontally wide areas such as Arctic polar vortexes.

Earlier studies showed that a decrease in the mixing ratio of N$_2$O with altitude is accompanied by enrichment of isotopocules of N$_2$O heavier than the major one ($^{14}$N$^{14}$N$^{16}$O) (Kim and Craig, 1993; Rahn and Wahlen, 1997). The results were consistent with the expected isotopolecule fractionation during photolysis (Yung and Miller, 1997), but the apparent degrees of fractionation (isotopolecule enrichment factor, $\varepsilon$) differed between those of the lower (< 20–25 km where N$_2$O mixing ratio > 180-250 nmol mol$^{-1}$) and middle (> 20–25 km or < 180-250 nmol mol$^{-1}$) stratosphere (Toyoda et al., 2001; Röckmann et al., 2001; Kaiser et al., 2006; Park et al., 2004). They are always smaller than that obtained from laboratory photolysis experiments (Röckmann et al., 2000; Turatti et al., 2000; Zhang et al., 2000; Kaiser et al., 2002b; 2003) or absorption spectra (von Hessberg et al., 2004). Moreover, the values of $\varepsilon$ for the middle stratosphere were found to depend on the latitude and season (Toyoda et al., 2004; Kaiser et al., 2006; Park et al., 2004). Such variation has been regarded as a result of photochemical and transport processes (McLinden et al., 2003; Park et al., 2004; Kaiser et al., 2006), but it has not been fully examined because of the lack of measurements taken over the tropical upwelling regions. As noted above, tropical stratosphere is the starting point of meridional transportation of N$_2$O injected from the tropopause and the rates of photochemical reactions are faster than those in the extratropics because of stronger actinic flux. Although there are a few reports on vertical profiles of N$_2$O isotopocules over India (18°N) (Röckmann et al., 2001; Kaiser et al., 2006), isotopic composition of N$_2$O in upwelling tropical air has not been characterized.

Another controversial problem about the stratospheric N$_2$O is whether the photooxidation sink (Eq. 2) has a larger contribution than 10% in the lower stratosphere. Kaiser and coworkers found that the ratios of
enrichment factors of isotopocule during photolysis and photooxidation are distinct (Kaiser et al., 2002a) and they estimated that a much larger fraction than (up to 100%) is removed by photooxidation at least in the lower stratosphere (N₂O mixing ratios > 300 nmol mol⁻¹) (Kaiser et al., 2006). However, similar but a little simplified analyses by Park et al. (2004) and Toyoda et al. (2004) (see Sect. 3.4) could not detect significant differences in the enrichment factor ratios between the lower and middle stratospheres, and Park et al. (2004) speculated that the enrichment factor ratios could be affected not only by the relative share of the two sink pathways but also by other factors such as transport.

This study was conducted to ascertain the vertical profiles of N₂O and its isotopocules over the equator and to examine the factors that control the apparent isotopic fractionation in the stratosphere by comparing results from earlier studies and three-dimensional chemical transport model simulation.

2 Experiments and model simulation

2.1 Whole air sampling over the equator

Stratospheric air samples were collected using balloon-borne compact cryogenic samplers (J-T samplers) (Morimoto et al., 2009). The sampler consists of an evacuated 800 cm³ stainless steel sample flask (SUS304), a cooling device called a Joule–Thomson (J-T) mini cooler, a two-liter high-pressure neon gas cylinder, pneumatic valves, solenoid valves, a 100 cm³ high-pressure N₂ gas cylinder for actuation of pneumatic valves, an electronic controller with a GPS receiver, a telemetry transmitter, and batteries. The J-T mini cooler can produce liquid neon from high-pressure neon gas that is pre-cooled by liquid nitrogen. The liquid neon is used as refrigerant to solidify or liquefy the stratospheric air. Contrasted against the larger sampling system used in our previous observations, which was about 250 kg with 12 sample flasks in a Dewar flask filled with liquid helium, the J-T sampler is ca. 20 kg, with operational and logistic advantages at remote sites such as remote islands or polar regions.

Sampling over the eastern equatorial Pacific (0°N, 105°W–115°W) was conducted on February 4, 5, 7, and 8, 2012 during the KH-12-1 cruise of R/V Hakuho-maru, JAMSTEC as a part of the Equatorial Pacific Ocean and Stratospheric/tropospheric Atmosphere Study Program. For each balloon flight, a 5–8 L STP of air sample was collected by a single sampler at programmed altitude of 19–29 km. The sampler then descended by parachute. It was later recovered on the sea.
Another sampling campaign was conducted at Biak Island, Indonesia (1°S, 136°E) on February 22, 24, 26, and 28, 2015 as a part of Small-Size Project by ISAS / JAXA (Hasebe et al., submitted). For each balloon flight, two samplers integrated into a single gondola were launched from the observatory of National Institute of Aeronautics and Space of the Republic of Indonesia (LAPAN). Samples were collected at two altitudes. Therefore, in total, we obtained seven samples: two samples on each of four flights, with one failed sampling.

Locations of launching sites are shown in Figure Fig. 1. Balloon trajectories are portrayed in Figure Fig. S2. Sampling was conducted while the balloon was ascending except the flight on Feb 5, 2012. Typical altitude range was about 2 km, and we took the central value of the range as the sampling altitude.

### 2.2 Analysis of mixing ratio and isotopocule ratios

At Tohoku University, the mixing ratio of N2O was measured using gas chromatography with electron capture detection (GC-ECD) with precision of 1 nmol mol⁻¹ (Ishijima et al., 2001). The isotopocule ratios, defined as follows, were measured at Tokyo Institute of Technology using gas chromatography – isotope ratio mass spectrometry (Toyoda et al., 2004; Toyoda and Yoshida, 2016).

\[ \delta X = \frac{R_{\text{sample}} - R_{\text{standard}}}{R_{\text{standard}}} \]  

Therein, \( X \) denotes \( ^{15}N^\alpha \), \( ^{15}N^\beta \) or \( ^{18}O \), and where \( R \) denotes \( ^{14}N^{15}N^{16}O/^{14}N^{14}N^{16}O \), \( ^{15}N^{14}N^{16}O/^{14}N^{14}N^{16}O \) or \( ^{14}N^{14}N^{18}O/^{14}N^{14}N^{16}O \) of the sample and standards (Toyoda and Yoshida, 1999). The \( \delta \) value is expressed as the permil (‰) deviation relative to atmospheric N\(_2\), and Vienna Standard Mean Ocean Water (VSMOW), respectively, for nitrogen and oxygen. In addition to \( \delta^{15}N^\alpha \) and \( \delta^{15}N^\beta \), the \( \delta \) value for bulk N and \( ^{15}N \)-site preference (SP) are often used as illustrative parameters:

\[ \delta^{15}N^{\text{bulk}} = \frac{\delta^{15}N^\alpha + \delta^{15}N^\beta}{2} \]  

\[ \text{SP} = \delta^{15}N^\alpha - \delta^{15}N^\beta. \]  

Duplicate analyses were made for a set of two runs: monitoring of molecular ion for determination of \( \delta^{15}N^{\text{bulk}} \) and \( \delta^{18}O \) and NO\(^+\) fragment ion for determination of \( \delta^{15}N^\alpha \). A 300–400 cm\(^3\) STP aliquot of the sample air was introduced into the analytical system from the sample flask in a single run. Typical precisions of the isotopic analyses are < 0.1‰ for \( \delta^{15}N^{\text{bulk}} \), < 0.2‰ for \( \delta^{18}O \), and < 0.5‰ for \( \delta^{15}N^\alpha \), although they were slightly worse for samples collected at higher altitudes because of the lower N\(_2\)O mixing ratio.
To analyze the relation between the N$_2$O mixing ratio ([N$_2$O]) and isotopocule ratio (δ) in a Rayleigh fractionation scheme (Eq. 6), measured values must be normalized with respect to the values before the air mass enters the stratosphere.

\[
\frac{(1+\delta)/(1+\delta_0)}{[N_2O]/[N_2O]_0} = \varepsilon
\]

In Eq. 6, subscript 0 signifies a tropospheric value; ε is the enrichment factor. Because the tropospheric mixing ratio and isotopocule ratios are known to have secular trends, [N$_2$O]$_0$ and δ$_0$ were estimated as follows. First, the age of the measured air mass was estimated based on the mixing ratio of CO$_2$ (Engel et al., 2009), which was also measured for the same air sample (Engel et al., 2009). Then, the N$_2$O mixing ratio at the time when the air mass was in the troposphere was calculated using the estimated age of air and the secular trend of tropospheric mixing ratio observed by the ALE/GAGE/AGAGE project (Prinn et al., 2000). We used AGAGE data from Mace Head (Ireland) to calculate [N$_2$O]$_0$ for stratospheric air in the tropics (this study) and the Northern Hemisphere (in which our previous observations were conducted) and those from Cape Grim (Tasmania) for the Southern Hemisphere (our previous observation in Antarctica). For calculating δ$_0$, the secular trends observed at Hateruma island, Japan (Toyoda et al., 2013) and Cape Grim (Park et al., 2012) were used, respectively, for the tropics/Northern Hemisphere and the Southern Hemisphere. In Table S3 we compare how much this correction regarding the age of air changed the position of each data point in Figs. 3 and 5.Typically, the term related to mixing ratio (−ln{[N$_2$O]/[N$_2$O]$_{trp}$}) is decreased by 0.2–3% when we use [N$_2$O]$_0$, the value when the air mass actually entered into the stratosphere, instead of the value at the same time of the observation, [N$_2$O]$_{trp}$. The isotopic terms (ln{(1+δ)/(1+δ$_{trp}$)}) are either increased or decreased depending on their secular trends, and they are changed by 0.2–3%.

2.3 Simulation using a three-dimensional chemical transport model

To examine the factors controlling the stratospheric distributions of N$_2$O isotopocules, a numerical simulation was conducted using the Center for Climate System Research/National Institute for Environmental Studies/Frontier Research Center for Global Change atmospheric general circulation model with chemical reactions (CCSR/NIES/FRCGC ACTM) (Ishijima et al., 2010; Ishijima et al., 2015). Because Ishijima et al. (2015) have already given a detailed description of the N$_2$O isotopocule model, we briefly explain it here.

The N$_2$O photolysis rate was calculated for 15 bins from 178 to 200 nm and for 3 bins from 200 to 278 nm using a scheme incorporating the parameterization of Minschwaner et al. (1993) (Akiyoshi et al., 2009) and by a main radiation–photolysis scheme of the ACTM (Sekiguchi and Nakajima, 2008). Fractionation of N$_2$O isotopocules was simulated using wavelength-dependent and temperature-dependent enrichment factors (ε)
for $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ and $^{15}\text{N}^{14}\text{N}^{16}\text{O}$ reported by von Hessberg et al. (2004) although the $\varepsilon$ for $^{14}\text{N}^{14}\text{N}^{18}\text{O}$ was estimated from the relation between apparent $\varepsilon$ for each isotopologue observed in the stratosphere due to the lack of suitable experimental reports. The model transport was nudged to ERA-interim reanalysis (Dee et al., 2011) for horizontal winds and temperature at 6-hourly time intervals. Regarding the photooxidation sink of N$_2$O, the concentration of O($^1\text{D}$) was calculated online in the ACTM; $\varepsilon$ values were calculated as described by Kaiser et al. (2002a).

While both the surface emissions and the photolytic isotopologue fractionations were optimized in the earlier work by Ishijima et al. (2015), only the former was optimized in the present study. This is because we considered that it would be better to keep the experimentally determined original isotopologue enrichment factors for the purpose of comparison between the model and the observations in the stratosphere. Moreover, we found that apparent isotopologue enrichment factors obtained by the model simulation become much closer to those by the balloon observations by replacing the meteorological data from JRA-25 (Onogi et al., 2007) with those from ERA-interim. This is probably because dynamics and chemical reactions in the model was improved by the replacement of the meteorological reanalysis data for nudging. Surface emissions of the four N$_2$O isotopologues were optimized in the manner described in an earlier report (Ishijima et al., 2015), with emissions modified to reproduce observed trends (Röckmann and Levin, 2005) and interhemispheric differences (Ishijima et al., 2007) of atmospheric N$_2$O isotopologue mixing ratios. Consequently, the estimated emissions were used for a forward simulation of four N$_2$O isotopologues in the atmosphere from the surface to the stratosphere in this study. The emissions and tropospheric values are reasonable (see Supplemental Information) compared to those of past studies (e.g., Toyoda et al., 2013; Toyoda et al., 2015) in terms of the necessary order of precision for analysis of the large vertical profiles in the stratosphere in this study.

3 Results and discussion

3.1 Vertical profiles of the N$_2$O mixing ratio and isotopologue ratios over the Equator

In all, 11 samples (4 from the eastern Pacific, 7 at Biak Island) were collected at target altitudes; of them, 10 were measured for N$_2$O isotopologues. Figure 2 presents vertical profiles of the N$_2$O mixing ratio, $\delta^{15}\text{N}^{\text{bulk}}$, SP, and $\delta^{18}\text{O}$ observed over the equator. Data from our previous observations over Japan, Sweden, and Antarctica and those from observations by Röckmann et al. (2000) and Kaiser et al. (2006) conducted over India are also shown. The height of the tropical tropopause layer (TTL) was typically 14–18.5 km (e.g., Fueglistaler et al., 2009), whereas the tropopause height was 12–16 km over Japan and 9 or 10 km over Sweden and Antarctica (Table S4S2). As observed at mid-latitudes and high latitudes, the mixing ratio decreases with height;
isotopocule ratios increase with height over the equator. However, the vertical gradient is weaker at lower latitudes. Our observation over the equator shows the weakest gradient. Although a slight difference in mixing ratio was observed for 20–25 km, the two equatorial profiles obtained at different longitudes over the equator agreed quite well. We combined the two datasets as a single one for further examinations.

3.2 Correlation between mixing ratio and isotopocule ratios: apparent isotopocule enrichment factors

In Fig. 3 and Figs. S3–S5, the isotopocule ratios are shown against the N\textsubscript{2}O mixing ratio after the normalization described in Eq. 6 (Rayleigh plot). The equatorial data for lower altitudes (−\ln\{[N\textsubscript{2}O]/[N\textsubscript{2}O]_0\} < 0.2 or [N\textsubscript{2}O] > ca. 260 nmol mol\(^{-1}\)) are on the line defined by the data for lower altitudes (−\ln\{[N\textsubscript{2}O]/[N\textsubscript{2}O]_0\} < 0.6 or [N\textsubscript{2}O] > 170 nmol mol\(^{-1}\)) over middle latitudes and high latitudes. The linear relation is consistent with isotopocule fractionation during the decomposition of N\textsubscript{2}O in a closed system, although the slope of the line, which corresponds to isotopic enrichment factor (\(\varepsilon\)), is markedly lower than that obtained by laboratory photolysis experiments (see below). However, the three data points obtained at altitudes corresponding to −\ln\{[N\textsubscript{2}O]/[N\textsubscript{2}O]_0\} > 0.2 ([N\textsubscript{2}O] < ca. 260 nmol mol\(^{-1}\)) show systematic deviation from the line and seem to define another line (Fig. 3b). A similar deviation or bending structure of the Rayleigh plot has also been observed at middle to high latitudes (Fig. 3a, from the points where the x axis value is ca. 0.5) (Toyoda et al., 2004). We therefore compare the slope of the lines obtained for observations at various latitudes and for laboratory simulation experiments.

As portrayed in Fig. 4, absolute values of \(\varepsilon\) (|\(\varepsilon\)|) for \(^{15}\text{N}\text{bulk}^{\text{a}}, \(^{15}\text{N}\alpha\), and \(^{18}\text{O}\) in the equatorial lower stratosphere are slightly higher than those of middle latitude and high latitude lower stratosphere, but they are still only about half of the \(\varepsilon\) obtained by broadband photolysis experiments (Kaiser et al., 2002b; Kaiser et al., 2003). In contrast, |\(\varepsilon\)| in the higher region (or middle stratosphere) show larger values. They are the largest over the equator except for \(\varepsilon(\text{18O})\). The equatorial values of \(\varepsilon\) almost coincide with as large as those of photolysis. It is also noteworthy that |\(\varepsilon\)| in the middle stratosphere in the arctic polar vortex (Sweden) is as small as that in the lower stratosphere and that latitudinal and year-to-year or seasonal variation are slight in the lower stratosphere compared to those of variations in the middle stratosphere in the lower stratosphere. Although the similar latitudinal and altitudinal dependence of \(\varepsilon\) has been reported previously for the latitudes ranging from 18°N to 89°N (Park et al., 2004; Kaiser et al., 2006), our equatorial data showed that the change in \(\varepsilon\) at altitude with higher N\textsubscript{2}O mixing ratio and the \(\varepsilon\) value is exactly what would be expected during the N\textsubscript{2}O photolysis as discussed below.
3.3 Cause of the variation of stratospheric $\varepsilon$

We then now discuss causes of (1) lower $|\varepsilon|$ value in the lower stratosphere, (2) increase of $|\varepsilon|$ in the middle stratosphere, and (3) the largest $|\varepsilon|$ in the equatorial middle stratosphere based on two factors: photochemical and transport processes.

3.3.1 Photochemical processes

During photochemical decomposition of N$_2$O, $\varepsilon$ reportedly depends on the wavelength that photolyzes N$_2$O, the relative share of photolysis and photooxidation pathways (Eqs. 1 and 2), and temperature (Toyoda et al., 2004; Kaiser et al., 2006). Moreover, because of transport processes the stratosphere cannot be always treated as an isolated system which is a prerequisite for Rayleigh fractionation model. The ratio of $\varepsilon$ values for independent isotopocules (e.g., $\varepsilon^{(15N_{\text{bulk}})}/\varepsilon^{(18O)}$), however, has been identified as a useful parameter to distinguish photolysis and photooxidation (Kaiser et al., 2002a) because its sensitivity to wavelength and temperature is small and it is not affected by mixing process. Figure 5 shows the data obtained in this study and some previous ones in $\delta$–$\delta$ space after the normalization described in Eq. 6. Especially in Fig. 5b, almost all data show a compact linear relation without bending or curved structure apparent in the Rayleigh diagram. The slope, which corresponds to the ratio of $\varepsilon$ values, is very close to the one expected for photolysis. This agrees with the fact confirms that photochemical decomposition of N$_2$O is mainly caused by photolysis (Minshwaner et al., 1993), although the small fluctuation in the lower left region in Fig. 5a will be discussed later.

3.3.2 Transport processes

Transport processes accompanied by mixing of variously aged stratospheric air has been considered as the major cause of lower $|\varepsilon|$ value in the stratosphere than in the laboratory photochemical decomposition (Park et al., 2004; Kaiser et al., 2006). Our new observation revealed that all the N$_2$O isotopocules are fractionated by the almost ideal Rayleigh process in the middle stratosphere over the deep tropics where the stratosphere is effectively the most isolated relative to all other regions. This underlines how much transport and mixing affect the apparent $\varepsilon$ value.

We then consider the effect of transport on the apparent $\varepsilon$ at different latitudes with a conceptual two-dimensional circulation model in the tropical and extra-tropical stratosphere that was proposed to explain tracer–tracer correlation (Plumb, 2002). In the tropics, N$_2$O is decomposed gradually during upwelling of the air mass injected from the troposphere. The uppermost tropical air mass $X_0$ is then transported to middle
latitudes and higher latitudes, where it begins downwelling. Because the vertical ascent rate in the tropics is much faster than quasi-horizontal transport out to the extratropics and much faster than the quasi-horizontal transport of extratropical air into the tropics, there is an apparent transport barrier between the tropics and extratropics (Plumb, 2007). Nevertheless, entrainment of air mass $Y_i$ across the subtropical edge separating the two regions must occur to compensate mass flux in the lower region (Fig. 6).

If we assume tropical profiles of $N_2O$ and its isotopocule ratios (e.g., $\delta^{15}N_{\text{bulk}}$) are determined purely by photochemistry with initial mixing ratio of 320 ppb, a delta value of 0‰ and a $\epsilon_{\text{sink}}$ of $-50$‰, then tropical air masses vertically divided from $Y_8$ through $Y_1$ and $X_0$ are expected to line up on a solid line as portrayed in Fig. 7. Next, let us consider that air mass $X_0$ is mixed with $Y_1$ to form $X_1$. Based on the mass balance of isotopocules before and after mixing, the resulting composition of $X_1$ is obtained as a curve, as shown in red in Fig. 7. Assuming arbitrarily that the mixing ratio of $Y_1$ to $X_1$ is 0.1, and repeating such mixing stepwise, then we obtain mixing ratio and isotope ratios of $N_2O$ in $X_1$ through $X_8$ as black stars in Fig. 6. This hypothetical, continuous mixing produces a curve that is qualitatively consistent with observations made over the mid-latitudes or high latitudes.

The mixing effect must also be the cause of smaller $\epsilon$ in the equatorial lower stratosphere (Fig. 4). The mean age of air deduced from $CO_2$ mixing ratio is known to be significantly larger than the phase lag of the water vapor mixing ratio, a so-called tape recorder signal, in the tropical stratosphere, which is explainable by mixing of old air from the extratropics into the tropics (Waugh and Hall, 2002). In addition, the difference in age between the equator and mid-latitude (over Japan) decreases concomitantly with decreasing altitude (Sugawara et al., unpublished data), suggesting that the time scale of meridional mixing or transport is smaller in the lower stratosphere than in the middle stratosphere, as suggested by results of an earlier study (Boering et al., 1996).

### 3.3.3 Comparison with chemical transport model (ACTM) simulation

We further examined the importance of transport using ACTM. Figure 8 presents results of ACTM simulation with observational data. Although the model approximates the photolysis of $N_2O$ in the longer wavelength region ($\lambda > 200$ nm) with lower spectral resolution, profiles of the $N_2O$ mixing ratio and isotopocule ratios were reproduced well, except in the winter polar stratosphere, where dynamic processes specific to the polar vortex might not be simulated appropriately in the model. In Fig. 9, the model simulation and observations are compared on a Rayleigh plot. Again, the model reproduced the difference between tropical and
mid-latitudes or high latitudes. Because in situ $\varepsilon_{\text{photolysis}}$ used in the model calculation is nearly the same between low and high latitudes (Fig. S6c), this agreement supports the inference that the major causes of the difference are transport and mixing, which was previously suggested by observations in the high latitudes (Park et al., 2004) and by 1D or 3D model studies (McLinden et al., 2003; Morgan et al., 2003).

3.4 Share of photolysis and photooxidation

Kaiser et al. (2006) used the ratio of $\varepsilon$ values for $^{15}\text{N}_{\text{bulk}}$ and $^{18}\text{O}$ ($\psi$) and the ratio of $\varepsilon$ values for $^{15}\text{N}^\alpha$ and $^{15}\text{N}^\beta$ ($\eta$) to estimate the relative share of photolysis and photooxidation based on the fact that $\psi$ and $\eta$ are almost independent of transport processes and are significantly different between the two decomposition processes. They computed $\psi$ and $\eta$ values directly for each individual sample in order to avoid statistical errors associated with linear regression to the $\delta$–$\delta$ plot which was adopted by Toyoda et al. (2004) and Park et al. (2004). In Fig. 10, we show $\psi$ and $\eta$ values calculated using the data presented in Fig. 2 in the manner similar to that of Kaiser et al. (2006) except that we used individual date of stratospheric entry for each data to normalize the $\delta$ values instead of using a single tropopause date. Although it is noteworthy that errors in $\psi$ and $\eta$ values increase concomitantly with decreasing altitude because of the decrease in the $\delta$ values, low values are obtained near just above the TTL over the Equator (EQP, $z = 20 \text{ km}$) just as they are at other latitudes. This result confirms is in accordance with the indication by Kaiser et al. (2006) that the photooxidation sink has a much larger fraction than 10% in the lower stratosphere. Although the loss rate of N$_2$O in the lower stratosphere is very slow and the majority of N$_2$O injected into the stratosphere is photolyzed in the middle stratosphere as noted by Park et al. (2004), the share of photooxidation in in situ total loss increases in the lower stratosphere (Fig. S6b). Therefore, there is a possibility of additional decomposition of remaining N$_2$O during the transport (which should be slower than that of the tropical upwelling) and the isotopic signature of O(1D) pathway could be imprinted, and the photochemically aged air mass must be transported into the lower stratosphere of the tropics and extratropics. However, Morgan et al. (2003) reported that inclusion of isotope fractionation for photooxidation into their 2D model does not make a significant contribution to overall fractionation in the stratosphere, and Park et al. (2004) discussed an alternative modelling approach with and without O(1D) sink to test the importance of O(1D) reaction. Further studies using 3D model would be necessary to solve this controversial problem.
4 Conclusions

Vertical profiles of isotopocule ratios of N$_2$O in the equatorial stratosphere are found using balloon-borne compact cryogenic samplers and mass spectrometry in the laboratory. This report of the relevant literature is the first describing observations of them over the equator. Unlike other region of the stratosphere, enrichment factors for isotopocules in the middle equatorial stratosphere (25–30 km, or [N$_2$O] < 260 nmol mol$^{-1}$) agreed with those obtained with laboratory photolysis experiments, suggesting because the middle tropical stratosphere is relatively isolated than the rest of the stratosphere that the isotopocule ratios are determined mainly by photolysis because of weak vertical or horizontal mixing in the tropical upwelling. In the lower equatorial stratosphere (< ca. 25 km or [N$_2$O] > 260 nmol mol$^{-1}$), isotopocule ratios suggest that differently aged air masses are mixed because of the meridional transport and that decomposition by photooxidation might also plays a significant role. Vertical and latitudinal distributions of N$_2$O and its isotopocules are found to be a unique tool to diagnose the relationship between photochemistry and transport in the stratosphere.

Further observations of temporal variations and comparison with ACTM simulation will be needed to obtain the quantitative estimate of the importance of photooxidation pathway and to examine the possible change in the meridional circulation predicted by model simulations (Li et al., 2008; McLandress and Shepherd, 2009) because such a change might affect $\varepsilon$ values of stratospheric N$_2$O by perturbing mixing of air with different transport time histories and obtain the quantitative estimate of the importance of photooxidation pathway.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgments. We thank researchers and crew of R/V Hakuho-maru KH-12-1 cruise for sampling over the eastern equatorial Pacific, and researchers and technical staff of LAPAN for the sampling over Biak. This work was supported by JSPS KAKENHI Grant Numbers 23224013 and 26220101 and also by JAXA as its Small-Size Project.

See also Table S2 for details.

Figure 3: Correlation between mixing ratio and $\delta^{15}N_{\text{bulk}}$ of N$_2$O (Rayleigh plot). The high mixing ratio range (> ca. 120 nmol mol$^{-1}$) in (a) is enlarged in (b). Both parameters are normalized to their values at the time when the corresponding air mass entered the stratosphere (see Eq. 6 in the text). Grey solid and broken lines show slopes obtained respectively from laboratory broadband photolysis experiments (Kaiser et al., 2002; 2003) and photooxidation experiments (Kaiser et al., 2002; Toyoda et al., 2004).

Figure 4: Comparison of absolute values of the isotopocule enrichment factor ($|\varepsilon|$) for $^{15}N_{\text{bulk}},^{15}N^\alpha,$ and $^{18}O$ of N$_2$O between observations and laboratory experiments. L and M respectively refer to the lower and middle stratosphere with boundary mixing ratio of about 170 nmol mol$^{-1}$ ($-\ln(\left[N_2O]/[N_2O]_0\right) = 0.6$) and 260 nmol mol$^{-1}$ ($-\ln(\left[N_2O]/[N_2O]_0\right) = 0.2)$ for extratropics and tropics, respectively, based on the Rayleigh plot shape (Fig. 3). The respective $|\varepsilon|$ for Japan, Sweden, and Antarctica are from Toyoda et al. (2004). Those for photolysis and photooxidation experiments are referred from reports by Kaiser et al. (2002; 2003) and Toyoda et al. (2004). Error bars show either the standard deviation for the mean value (observation over Japan and photooxidation experiments), standard error associated with linear regression in Rayleigh plot (observations except Japan), or the possible range for stratospheric conditions (photolysis experiments).

Figure 5: Correlations between $\delta^{15}N^\beta$ and $\delta^{15}N^\alpha$ of N$_2$O (a) and between $\delta^{18}O$ and $\delta^{15}N_{\text{bulk}}$ of N$_2$O (b). The $\delta$ values are normalized as noted in the text. Grey solid and broken lines show slopes obtained respectively from laboratory broadband photolysis experiments (Kaiser et al., 2002; 2003) and photooxidation experiments (Kaiser et al., 2002; Toyoda et al., 2004).

Figure 6: Conceptual two-dimensional circulation model to analyze mixing processes between tropics and extratropics (from Plumb, 2002). The $X_0$ is the uppermost tropical stratospheric air mass, $X_i$ ($i = 1$–8) are air masses formed by mixing of $X_{i-1}$ and $Y_i$. 

Figure 7: Presentation of \( X_i \) (black stars) obtained using the mixing model with assumed \( Y_i \) in the Rayleigh plot. The straight line shows tropical vertical isotopocule fractionation without transport/mixing effect. Curves show mixing between \( X_{i-1} \) and \( Y_i \) where mixing ratio \( Y_i/X_i \) is assumed to be 0.1.

Figure 8: Comparison of vertical profiles of mixing ratio (a) and \( \delta^{15}N_{\text{bulk}} \) (b) of \( N_2O \) between observations and simulation by the ACTM. Model simulations for equatorial profiles were conducted for two dates because the observations were conducted during a 5-day or 7-day period.

Figure 9: Comparison of results of ACTM simulation and stratospheric observation in Rayleigh plot. The square region shown by broken lines in panel (a) is enlarged in panel (b).

Figure 10: Vertical profiles of ratio of \( \varepsilon \) values for \( ^{15}N_{\text{bulk}} \) and \( ^{18}O \) (\( \psi \)) and the ratio of \( \varepsilon \) values for \( ^{15}N^a \) and \( ^{15}N^\beta \) (\( \eta \)) calculated in the manner similar to that of Kaiser et al. (2006). Grey bands show values obtained by laboratory broadband photolysis experiments (Kaiser et al., 2002; 2003) and photooxidation experiments (Kaiser et al., 2002; Toyoda et al., 2004) with widths representing their uncertainty. For photolysis, uncertainties associated with temperature (190–240 K) and wavelength (190–220 nm) dependency are shown with dark and light gray, respectively.
