Response to Referee #1

In December 2016, the eastern part of China has suffered from the most severe haze pollution during the past decades. This study revealed the possible roles of atmospheric circulations on this haze pollution event in addition to the pollutant emissions, which is interesting and also important to increase understanding the impact of climate change on the increased haze pollutions in China. However, there are still some key points need to be clear in the future.

1. In this study, the authors have indicated that there are several atmospheric circulations including the East Asian jet, EA/WR pattern, PBL, wind speed etc. present significant correlations with the variations of December haze occurrences over North China. Most of these factors have been already revealed in the earlier papers, also including the works from the authors. However, the possible physical mechanisms for these factor influences have not been well addressed before, also in this paper. So, more discussions on this aspect are suggested in the next version.

Reply:

(1) More discussions about the physical mechanisms have been included in the revision version. Most of the earlier papers, including the works of the authors, focused on the variations of winter haze and associated atmospheric circulations. Differently, the issues addressed by this manuscript were the variation of December haze and the extreme events in 2016 which was not studied before. Actually, when we analyzed the sub-seasonal variation of haze occurrence, we found that the monthly characteristics were different. Thus, we tried to explore the reasons. This manuscript focused on December, and some other works about January and February haze were underway.

(2) Some comparisons with winter haze were included in Section 3, such as follows.

“To verify the relationship between the DHD$_{NH}$ and EA/WR pattern, the correlation coefficient was calculated; it was 0.66 from 1979 to 2016 after removing the linear trend and exceeded the 99% confidence level (Table 1). This positive correlation was stronger than that with winter haze days (i.e., 0.43), as analyzed by Yin et al. (2017).”

The main conclusions were that the associated circulations with December haze were similar, but more significant than those with winter haze. The underlying indication was that the correlated atmospheric circulations in late winter were possibly different with those associated with winter haze. Furthermore, the plausible external forcings were also discussed and the snow cover, as a new factor, was analyzed. The significantly correlated regions of SST (i.e. near the Gulf of Alaska and the subtropical eastern Pacific) were also different from that in winter (i.e. the subtropical western Pacific).
Revision, in section 3:

Physically, the positive phase of EA/WR pattern strengthened the anomalous anti-cyclone over NH area and Japan Sea from surface to the middle troposphere, resulting in confined vertical motion. The southerly anomalies made the cold air and surface wind speed weaker, but enhanced the humid flow. Under control of such atmospheric circulations and local meteorological conditions, the horizontal and vertical dispersion of atmospheric particulates was suppressed. Thus, the pollutants gathered within a narrow space and the haze occurred frequently. In addition, high humidity supported a beneficial environment for the hygroscopic growth of haze matters. In December 2016, the height of PBL was the lowest and the intensity of the anomalous anticyclone over the NH was the strongest (Table 1), indicating that the vertical dispersion condition of pollutants was the weakest during the past 38 years. The other key indices (i.e., the EA/WR index, surface wind speed and surface relative humidity) all were in top-six. Thus, the atmospheric circulations and local meteorological conditions were strongly benefit for haze occurrence and combined to result in the severest haze events in December 2016.

2. I think the “Abstract” should be reworded. Just present the correlations between the meteorological factors and haze occurrences is not enough, more discussions related their impacting processes a needed. Also, the key issues related why the haze pollution in December 2016 is the most severe in the past decades and why the event in 16–21 December 2016 is the most severe during December should be clear.

Reply:

(1) Following the advice, the “Abstract” was reworded to include the physical processed.

(2) In table 1, we added one row to evaluate the ranks of key indices in 2016. The atmospheric circulations and local meteorological conditions were strongly benefit for haze occurrence and combined to result in the severest haze events in December 2016. For the synoptic case in 16–21 December, the anthropogenic emissions were strongly confined. The limitation of pollutant emission was strongest in 2016, and this is the reason why we chose the synoptic case. Under such a background, the severest haze pollution still occurred, which emphasized the role of atmosphere. The anomalies of atmospheric circulation were similar to those throughout December, but they were more evident and much stronger than the mean status in December 2016 that resulted in the severest December haze.

Revision, in the Abstract and Section 3 & 4

……The atmospheric circulations must play critical roles in the sub-seasonal haze events. Actually, the positive phase of East Atlantic/West Russia pattern in the middle troposphere strengthened the anomalous anti-cyclone over NH area that confined
vertical motion below. The associated southerly anomalies made the cold air and surface wind speed weaker, but enhanced the humid flow. Thus, the horizontal and vertical dispersion of atmospheric particulates was suppressed and the pollutants gathered within a narrow space. In December 2016, these key indices were strongly beneficial for haze occurrence and combined to result in the severest haze pollution. The influences of preceding autumn sea surface temperature near the Gulf of Alaska and the subtropical eastern Pacific, October-November snow cover in western Siberia and associated physical processes on haze pollution were also discussed.

......In December 2016, the height of PBL was the lowest and the intensity of the anomalous anticyclone over the NH was the strongest (Table 1), indicating that the vertical dispersion condition of pollutants was the weakest during the past 38 years. The other key indices (i.e., the EA/WR index, surface wind speed and surface relative humidity) all were in top-six. Thus, the atmospheric circulations and local meteorological conditions were strongly benefit for haze occurrence and combined to result in the severest haze events in December 2016.

The anomalies of atmospheric circulation during 16–21 December were similar to those throughout December, but they were more evident and much stronger than the mean status in December 2016 that resulted in the severest December haze......

3. Actually, the meteorological conditions for the haze occurrences in December that revealed in this study present similar with that for the events in winter season. There is no new factor has been revealed in this study. The most important thing of this study is to address the reasons for the severest haze pollution in December 2016 and the event in 16-21 December. I think these key issues are not clear at the current MS.

Reply:

(1) The issues addressed by this manuscript were the variation of December haze and the extreme events in 2016 which was not studied in the earlier papers. Some comparisons with winter haze were included in Section 3. The main conclusions

4. what the definition of the “surface lift index”? how to calculate it?
Reply:

(1) Surface lifted index is the lifted index at 500-mb based on the surface parcel and was calculated as the difference between the temperature of the parcel when it was lifted to the upper level and the surrounding temperature. The surface lifted index is a measurement of the stability of an air mass at a given moment.

(2) The indicative function of surface lifted index was repeated with PBLH and anti-cyclone anomalies. To make the Figure 3(a) clearer, the surface lifted index was unused in the revision version.

Revision:

5. why not used NCEP/NCAR II? Or use ERA-Interim dataset across the study?

Reply:

Almost all of the datasets was downloaded from NCEP/NCAR across the study. However, the website of NCEP/NCAR did not support the height of PBL. Thus, only the PBLH was derived from ERA-Interim and the reason was explained the Section 2.

Revision, in section 2:

……For the representativeness of vertical dispersion, the 1°×1° height of PBL (not available on the website of NCEP/NCAR) was also used here, but derived from the ERA-Interim dataset (Dee et al. 2011). ……
6. which period is used for the correlation calculation in Table 1? In my first view, I think these correlations are just for the December 2016.

Reply:
The period was from 1979 to 2016.

Revision:

Table 1 The correlation coefficients between the DHD$_{28}$ and key indices from 1979 to 2016 and the ranks of key indices in 2016. The $\text{Corr Coe}^1$ and $\text{Corr Coe}^2$ indicate the correlation coefficients that were calculated after and before detrending. The AC was the anticyclone index that was defined as the mean Z500 over 105–125°E, 30–50°N. The local PBL, surface wind speed and relative humidity were calculated as the mean over the NH area. All the correlation coefficients were above the 99% confidence level. The rank was sorted from largest to smallest, when the $\text{Corr Coe}$ was positive. If the $\text{Corr Coe}$ was negative, the rank was calculated from smallest to largest.

Response to Referee #2

Air pollution is a complicated question, which is caused by both anthropogenic emissions and meteorological conditions. In this study, the authors investigated the possible mechanism for the several haze in December 2016 from the meteorological aspect. They concluded some atmospheric, oceanic, and snow cover factors which are related to the haze in eastern China. The results are interesting and important for us to understand the variability of haze over eastern China. I recommend the publication of the manuscript. However, the manuscript needs some revisions before it can be considered for publication, which can potentially contribute to enhance the value of the manuscript.

Specified comments:

1. The abstract should be reworded to including more physical processes.

Reply:
Following the advice, the “Abstract” was reworded to include the physical processed.

Revision, in the Abstract

......The atmospheric circulations must play critical roles in the sub-seasonal haze events. Actually, the positive phase of East Atlantic/West Russia pattern in the middle troposphere strengthened the anomalous anti-cyclone over NH area that confined vertical motion below. The associated southerly anomalies made the cold air and surface wind speed weaker, but enhanced the humid flow. Thus, the horizontal and vertical dispersion of atmospheric particulates was suppressed and the pollutants gathered within a narrow space. In December 2016, these key indices were strongly beneficial for haze occurrence and combined to result in the severest haze pollution. The influences of preceding autumn sea surface temperature near the Gulf of Alaska and the subtropical eastern Pacific, October-November snow cover in western Siberia and associated physical processes on haze pollution were also discussed.

2. Datasets and method: what is the variable of “surface”? The NCEP/NCAR data are from 1948 onward, not from 1979.

Reply:
The variable on surface is wind.

The available period of NCEP/NCAR data was changed to “from 1948 to 2016”.

Revision, in section 2:
The geopotential height at 500 hPa (Z500), zonal wind at 200 hPa (U200), wind at 850 hPa, wind at surface, sea level pressure (SLP), surface air temperature (SAT), surface relative humidity and vertical wind (omega) were available on the website of
the National Centers for Environmental Prediction/National Center for Atmospheric
Research (NCEP/NCAR). These NCEP/NCAR reanalysis I datasets had a horizontal
resolution of 2.5°×2.5° from 1948 to 2016 (Kalnay et al. 1996).

3. For the reanalysis data, I recommend the authors use the NCEP/NCAR or
ERA-Interim for analysis. Using a dataset across the study can assure the match
guarantee the consistency among the variables.

Reply:
Almost all of the datasets was downloaded from NCEP/NCAR across the study.
However, the website of NCEP/NCAR did not support the height of PBL. Thus, only
the PBLH was derived from ERA-Interim and the reason was explained the Section 2.

Revision, in section 2:
……For the representativeness of vertical dispersion, the 1°×1° height of PBL (not
available on the website of NCEP/NCAR) was also used here, but derived from the
ERA-Interim dataset (Dee et al. 2011). ……

4. What time period for the correlations in Table 1?
Reply:
The period was from 1979 to 2016.

Revision:

Table 1 The correlation coefficients between the DHD_{25} and key indices from 1979 to 2016 and the ranks of key indices in
2016. The \textit{Corr} Coe\textsubscript{1} and \textit{Corr} Coe\textsubscript{2} indicate the correlation coefficients that were calculated after and before detrending. The
AC was the anticyclone index that was defined as the mean 2500 over 103°–125°E, 30°–50°E. The local PBL, surface wind
speed and relative humidity were calculated as the mean over the NH area. All the correlation coefficients were above the 99%
confidence level. The rank was sorted from largest to smallest, when the Corr Coe was positive. If the Corr Coe was negative,
the rank was calculated from smallest to largest. \textsuperscript{*}=

5. There is no (a) and (b) in Figure 3.
Reply:
The (a) and (b) was not clear in the submitted Figure 3 and they were revised now.

Revision:
6. Figure 6 is the averaged mean over 16-21 December 2016? How did the authors calculate the significant test in Figure 6? Similar question is also to Figure 7, 9, and 10.

Reply:
The data to plotted Figure 6, 7 and 9 was daily reanalysis and long-term-mean daily reanalysis. Thus, the significant test was calculated basing on the daily data to evaluate whether the atmospheric circulations in 16–21 December 2016 was significantly different from the climate mean status.

7. The authors should clearly show the definition for the EA/WR pattern, haze event, and surface lift index.

Reply:
(1) The definition of EA/WR pattern was clearly showed in the revised version.

(2) The definition and calculation process of haze event was revised and briefly introduced. The full calculation method was well introduced in the referred work of the authors, i.e. Yin et al. 2017. If we repeated the similar content here which is not necessary, the manuscript would become too long.

(3) To make the Figure 3(a) clearer, the surface lifted index was unused in the
**Revision version.** The indicative function of surface lifted index was repeated with PBLH and anti-cyclone anomalies. The definition of surface lifted index was also showed below.

Surface lifted index is the lifted index at 500-mb based on the surface parcel and was calculated as the difference between the temperature of the parcel when it was lifted to the upper level and the surrounding temperature. The surface lifted index is a measurement of the stability of an air mass at a given moment.

**Revision:**

(1) …..The EA/WR pattern consisted of four anomalous centers and the positive phase is associated with positive anomalous height over Europe and northern China, and negative anomalies over the central North Atlantic and north of the Caspian Sea. The EA/WR index was computed by the NOAA climate prediction center according to the Rotated Principal Component Analysis used by Barnston et al. (1987)…….

(2) …..The routine meteorological measurements included relative humidity, visibility and wind speed at surface that were collected eight times per day. The temperature profile was collected with a sounding balloon twice per day. The calculation procedure for the haze data was consistent with that of Yin et al. (2017), which was mainly based on the observed visibility and relative humidity…….

Abstract. In the east of China, recent haze pollution has been severe and damaging. In addition to anthropogenic emissions, atmospheric circulations and local meteorological conditions were conductive factors. The number of December haze days over North China and the Huanghuai area has increased sharply since 2010 and was greatest in 2016. During 2016, the most aggressive control measures for anthropogenic emissions were executed from 16–21 December, but the most severe haze pollution still occurred, covering approximately 25\% of the land area of China and lasting for 6 days. The atmospheric circulations must play critical roles in the sub-seasonal haze events. The associated atmospheric circulations that were verified by climatic correlation analysis were a weaker East Asia jet stream in the upper troposphere, a positive phase of the East Atlantic/West Russia pattern in the middle troposphere and conductive local weather conditions (lower PBL, small surface wind speed, and abundant moisture) near the surface. Actually, the positive phase of East Atlantic/West Russia pattern in the middle troposphere strengthened the anomalous anti-cyclone over NH area that confined vertical motion below. The associated southerly anomalies made the cold air and surface wind speed weaker, but enhanced the humid flow. Thus, the horizontal and vertical dispersion of atmospheric particulates was suppressed and the pollutants gathered within a narrow space. In December 2016, these key indices were strongly beneficial for haze occurrence and combined to result in the severest haze pollution. The influences of preceding autumn sea surface temperature near the Gulf of Alaska and the subtropical eastern Pacific, October-November snow cover in western Siberia and associated physical processes on haze pollution were also discussed.
1. Introduction

Because of its enormous adverse effects, haze pollution has become one of the most serious environmental problems in China, attracting considerable scientific and social attention. Increasing anthropogenic emissions have been contributing to severe haze pollution in China and mainly impacted on the long-term trend of haze days (Wang et al. 2013). However, interannual variations of haze days were affected by meteorological conditions (Wang et al. 2015; Yang et al. 2016; Wang and Chen. 2016). At present, aerosols have approached saturation in the atmosphere (Zhang et al. 2013). When the horizontal and vertical dispersion of atmospheric particulates is impeded, haze weather tends to occur (Yin et al. 2015a). Therefore, anomalous atmospheric circulations play a key role in the formation of heavy haze pollution in winter (December–February) (Chen and Wang 2015). From the hemispheric and regional perspective, the positive phase of the Arctic Oscillation (Yin et al. 2015b), the weak East Asia winter monsoon (Li et al. 2015; Yin et al. 2015b) and the positive phase of the East Atlantic/West Russia (EA/WR) teleconnection (Yin et al. 2017) contribute to the occurrence of winter haze by modulating local anticyclone anomalies over North China. As a key local circulation, this anomalous anticyclone resulted in descending motion (Wu et al. 2017) that contributed to a reduction in the height of the planetary boundary layer (PBL). Other conductive weather conditions include reduced surface wind speed and enhanced humidity in the lower atmosphere (Ding et al. 2014). Such weather conditions trap abundant atmospheric particles and moisture, leading to a high concentration of pollutants. Furthermore, the frequency and persistence of weather conditions conducive to the Beijing winter severe haze events were projected to increase substantially under climate change in the future (Cai et al. 2017).

On the sub-seasonal time scale, haze pollution in December is quite serious and has distinct characteristics, but it has not acquired adequate attention. As shown in Figure 1, there have been eight wide scale haze pollution events in China in 2016. During six of these events, the highest PM$_{2.5}$ concentration was observed in North China. During 2016, haze pollution was
most severe during 16–21 December with the highest PM$_{2.5}$ concentration of 1100 $\mu$g/m$^3$ in the whole of North China and the Huanghuai area (NH, located at 30–41°N, 110–120°E) where more than 300 million people live. The affected area was 2680 thousand km$^2$. Thereinto, the area affected by severe haze was 710 thousand km$^2$, which was close to the total area of the preceding 7 episodes in 2016. In addition, its duration was 6 days, which was approximately twice as long as the other haze episodes (Figure 1b). Furthermore, for the past 38 years, the number of December haze days (DHD) over the NH area (DHD$_{NH}$) was greatest in 2016 (Figure 1a). Since 2010, DHD$_{NH}$ has experienced a sharp increase and reached 21.5 in 2016, meaning that the air was polluted for approximately 70% of the days. Because air pollution is regulated and controlled by the Chinese Government, annual pollutant emissions varied slowly (Mathews and Tan, 2015), but this could not fully explain the sharp increase of DHD$_{NH}$ after 2010. In particular, although vehicle control and production restriction measures were timely, extensive and strictly implemented, haze pollution was still severe during 16–21 December. The effects of emissions reduction measures on air pollutants were efficient and proven during the 2015 World Championships and Parade (WCP) held in Beijing (Zhou et al 2017). Thus, understanding the role of atmospheric circulation on extreme haze pollution in December 2016 is vital, and this is analyzed in this paper.

The data and methods are described in section 2. In section 3, we analyzed the roles of global and regional atmospheric circulations on haze in December 2016. Then, a synoptic case (i.e., the severest haze pollution in 2016) was studied to understand the physical mechanisms in more detail in section 4. A discussion of our results and the main conclusions of the study are included in section 5.

2. Datasets and methods

The geopotential height at 500 hPa (Z500), zonal wind at 200 hPa (U200), wind at 850 hPa, wind at surface, sea level pressure (SLP), surface air temperature (SAT), surface lift index, surface relative humidity and vertical wind (omega) were available on the website of the National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR). These NCEP/NCAR reanalysis I datasets had a horizontal resolution of 2.5°×2.5° from 1948 to 2016 (Kalnay et al. 1996). For the representativeness of vertical dispersion, the 1°×1° height of PBL (not available on the website of NCEP/NCAR(4°×4°) was also used here, but derived from the ERA-Interim dataset (Dee et al. 2011). The monthly mean Extended Reconstructed SST datasets with a horizontal resolution of 2°×2° from 1979 to 2016 were obtained from the
National Oceanic and Atmospheric Administration (Smith et al. 2008). The monthly 1° by 1° snow cover data were supported by the Rutgers University (Robinson et al. 1993). The EA/WR pattern consisted of four anomalous centers and the positive phase is associated with positive anomalous height over Europe and northern China, and negative anomalies over the central North Atlantic and north of the Caspian Sea. The EA/WR index was computed by the NOAA climate prediction center according to the Rotated Principal Component Analysis used by Barnston et al. (1987). The routine meteorological measurements included relative humidity, visibility and wind speed at surface that were collected eight times per day. The temperature profile was collected with a sounding balloon twice per day. The calculation procedure for the haze data was consistent with that of Yin et al. (2017), which was mainly based on the observed visibility and relative humidity. Hourly PM$_{2.5}$ concentration data were downloaded from the website of the Ministry of Environmental Protection of China. Definitions of anomalies are described in the captions for each figure.

### 3. Associated atmospheric circulations in December 2016

Figure 2 shows the distribution of atmospheric circulation anomalies in December 2016. In the upper troposphere, the East Asia jet stream (EAJS) was weaker and northward relative to the mean status, indicating that meridional cold air activity in East Asia was restricted (Chen et al. 2015). As a result, the land surface of East China was warmer (Figure 2b). On the mid-level, there were positive anomalies of Z500 over Europe and North China and negative centers over the Central-North Atlantic and to the north of the Caspian Sea (Figure 2a). This Rossby wave train resembled the positive phase of the EA/WR pattern. To verify the relationship between the DHD$_{NH}$ and EA/WR pattern, the correlation coefficient was calculated; it was 0.66 from 1979 to 2016 after removing the linear trend and exceeded the 99% confidence level (Table 1). This positive correlation was stronger than that with winter haze days (i.e., 0.43), as analyzed by Yin et al. (2017). Specific to the positive Z500 anomalies over 105–125°E, 30–50°E (i.e., the easternmost center of EA/WR pattern), the correlation coefficient was 0.62 (Table 1). Thus, the anomalous anticyclone over the NH area in December 2016 could efficiently weaken the vertical motion, resulting in shallower PBL and weaker surface lift motion (Figure 3a). Furthermore, possible conductive local weather conditions that included shallow PBL (impacting vertical dispersion), small surface wind speed (impacting horizontal dispersion) and high relative humidity (impacting moisture absorption), whose correlation coefficients with DHD$_{NH}$ were −0.59, −0.63 and 0.49 from 1979 to 2016, all passed the 99% confidence test (Table 1). Near the surface, the SLP gradient between Eurasia and West Pacific decreased (Figure 2b) and induced southerly over the east of China. Warm
and humid airflow from the south caused the surface wind speed to be slower and the surface relative humidity to be higher (Figure 3b). **Physically, the positive phase of EA/WR pattern strengthened the anomalous anti-cyclone over NH area and Japan Sea from surface to the middle troposphere, resulting in confined vertical motion. The southerly anomalies made the cold air and surface wind speed weaker, but enhanced the humid flow.** Under control of such atmospheric circulations and local meteorological conditions, the horizontal and vertical dispersion of atmospheric particulates was suppressed, **Thus, the pollutants gathered within a narrow space** and the haze occurred frequently. In addition, high humidity supported a beneficial environment for the hygroscopic growth of haze matters. **In December 2016, the height of PBL was the lowest and the intensity of the anomalous anticyclone over the NH was the strongest (Table 1), indicating that the vertical dispersion condition of pollutants was the weakest during the past 38 years. The other key indices (i.e., the EA/WR index, surface wind speed and surface relative humidity) all were in top-six. Thus, the atmospheric circulations and local meteorological conditions were strongly benefit for haze occurrence and combined to result in the severest haze events in December 2016.**

4. A synoptic case study

On 15 December of 2016, the Ministry of Environmental Protection of China warned that severe haze pollution would occur over the NH area in the coming week. After that, nearly 30 cities were issued an air pollution red (the highest level) warning, and another 20 cities were issued an orange (the second level) warning (figure omitted). There was a haze-prone zone located from southwest to northeast, i.e., from the north of Henan Province to Beijing. In this haze-prone zone, vehicle control and production restriction measures were both strictly implemented. In the surrounding cities, the industrial production was also restricted (Figure 4a). These regulatory measures were distributed according to the measured PM$_{2.5}$ concentration, illustrating good scientific-based decision-making and management. Anthropogenic emissions were also more stringently limited at this time than for other haze weather processes that had occurred during the same year, but the most severe haze pollution still occurred. The highest PM$_{2.5}$ concentration (i.e., 1100 μg/m$^3$) was observed in Shijiazhuang, the provincial capital of Hebei Province (Figure 4b). The measured maximum hourly PM$_{2.5}$ concentrations over the NH area were almost above 500 μg/m$^3$, which was beyond the level of severe air pollution for China. Furthermore, there were three groups of stations with PM$_{2.5}$ concentrations greater than 700 μg/m$^3$, and these were in the central Shaanxi Province, the North of Henan Province and south of Hebei Province, and the central Shandong Province. In addition, the coverage for this haze pollution process was quite large. Spreading to the south, PM$_{2.5}$ concentrations larger than 300 μg/m$^3$ could be observed
in most sites in Jiangsu Province. Around the north edge of the haze area, high PM$_{2.5}$ concentrations occurred in Liaoning Province and Inner Mongolian.

Low visibility is another representation of haze that is widely used in meteorology. Area-averaged visibility was lower than 10 km, and haze pollution was gradually aggravated from 16-21 December (Figure 5). During 16–18 December, the diurnal variation of visibility was obvious, i.e., visibility decreased at night and increased a little in the morning. Then, visibility decreased persistently and to a minimum value on 21 December. The correlation coefficient between visibility and surface wind speed (surface relative humidity) was 0.4 (−0.69), passing the 99.99% confidence test. The continuous small surface wind speed (<2 m/s) restrained the horizontal dispersion of aerosols, and high humidity in the environment promoted hygroscopic growth that dramatically reduced visibility. The intensity of the temperature inversion remained positive for 132 hours and reached 9°C on 20 December, so atmospheric particles were limited to a shallow PBL and accumulated easily. The meteorological conditions also showed obvious diurnal variation during the early stage of this haze process. Relative humidity was continuously above 80% after 20 December, resulting in persistent decreasing and minimum value of visibility.

The anomalies of atmospheric circulation during 16–21 December were similar to those throughout December, but they were more evident and much stronger than the mean status in December 2016 that resulted in the severest December haze. The EAJS was weaker than the mean status and moved northward, resulting in weak cold air activity and a warmer surface (Figure 6). In the middle troposphere, the EA/WR pattern could be clearly recognized, and the anomalous anticyclone over North China and Japan was very strong. Under their influence, there was a descending motion from 30°N to 55°N (Figure 7), and the height of PBL was approximately 400 m lower than the mean status of December (Figure 8). Furthermore, the anomalous height was almost negative all month. In addition to vertical accumulation, there was northward and horizontal transportation of atmospheric particles from the surface to 950 hPa (Figure 7). Near the surface, the SLP of the mid-high latitude was distributed as the positive phase of the AO pattern and the cold air of Polar Regions was toward the Aleutian Islands, so the cold air was difficult to move southward to the NH area. The gradient of SLP (SAT) between Eurasia and the west Pacific receded. The stimulated southerly over the east China coastal area not only weakened the surface wind speed but also led to high humidity over the NH area. In summary, during 16–21 December, atmospheric circulations resulted in highly conductive local weather conditions to severe haze pollution over the NH area.
5. Discussion and Conclusions

The most forceful controlling measures of anthropogenic emissions in 2016 were executed during 16–21 December, but the severest haze pollution still occurred, covering approximately 25% of the land area of China and lasting for 6 days. The highest PM$_{2.5}$ concentration observed was 1100 μg/m$^3$. Thus, it was hypothesized that atmospheric circulation must play a critical role. Our results verified that a weaker and northward EAJS led to weak cold air activity. In the middle troposphere, the positive phase of the EA/WR pattern was evident, and it stimulated a descending motion from 30°N to 55°N and lower PBL over the NH area. Near the surface, the positive phase of the AO pattern confined the cold air to move southward. The anomalous southerly not only weakened the surface wind speed but also led to high humidity over the NH area. The atmospheric circulations were very conductive to severe haze pollution over the NH area. During all of December, the number of DHD$_{NH}$ increased sharply from 2010 and was greatest in 2016. The associated atmospheric circulations that were verified by climatic correlation analysis were similar. In other words, there was a weaker EAJS in the upper troposphere, a positive phase of EA/WR pattern in the middle troposphere and conductive local weather conditions (lower PBL, small surface wind speed, and abundant moisture).

The preceding autumn SST in the Pacific significantly influenced the winter haze days in North China (Yin et al. 2016) and could partly explain the severe haze pollution during the winter of 2014 (Yin et al. 2017). For December, the significantly correlated SST with DHD$_{NH}$ was located near the Gulf of Alaska and the subtropical eastern Pacific (Figure 10a). The preceding autumn SST of these two areas was averaged as an index (SST$_{EP}$), and the correlation coefficients with December Z500 were calculated and are shown in Figure 10b. The EA/WR pattern, especially the anomalous anticyclone over NH and Japan, was obvious. The correlation coefficient between SST$_{EP}$ and EA/WR index (DHD$_{NH}$) was 0.48 (0.55) after detrending; thus, we speculated that the SST$_{EP}$ influenced DHD$_{NH}$ by modulating the EA/WR pattern. The positive SST anomalies near the Gulf of Alaska and the subtropical eastern Pacific could impact the wave activity flux (WAF) and (Figure 10b) and stimulated a Rossby wave-like pattern propagating from eastern Pacific, through North America and Atlantic and to East Asia. The atmospheric action centers over North Atlantic and Eurasia overlapped with that of EA/WR teleconnection pattern. Therefore, the positive phase of the EA/WR pattern could be stimulated or enhanced by positive SST$_{EP}$ and then lead to weak ventilation conditions that were beneficial for the occurrence of haze. In 2016, the positive SST$_{EP}$ in autumn were consistent with the positive correlation fields, leading to more DHD$_{NH}$. Furthermore, the DHD$_{NH}$ varied with an obvious
decreasing trend from 2006 to 2010, and with a dramatic increasing trend after 2010. The variation of the EA/WR and SSTEP index exhibited similar features. During the most recent 10 years, the EA/WR pattern was distributed as its strongest negative phase in 2010 and strongest positive phase in 2016, which was consistent with the variation of DHD_NH (Figure 11). The variation of the EA/WR pattern could largely explain the trend break of DHD_NH. As shown by Gao and Chen (2017), October SST anomalies near the Gulf of Alaska and the subtropical eastern Pacific contributed to the haze pollution over North China in October 2016. Impacts of the SSTEP on ventilation conditions were robust and could continue into December. Furthermore, the relationships with autumn SST in Atlantic were also examined to be weaker and significant only in small regions (figure omitted).

The Eurasian snowpack and atmospheric circulation dominant modes were stably coupled from autumn to the subsequent spring (Sun 2017), so the role of the preceding October–November (ON) snow cover were also examined (Figure 12). The snow cover over western Siberia (SnowWS) was significantly correlated with DHD_NH (EA/WR) (Figure 12a), i.e., the correlation coefficient was 0.52 (0.45) after detrending (Table 1). More snow was correlated with a higher albedo, resulting in a colder land surface. When there was higher SnowWS, negative Z500 anomalies over western Siberia and positive anomalies over eastern China, i.e., the two active centers of the EA/WR pattern in the east, were significantly stimulated. The WAF associated with positive SnowWS anomalies was evidently induced near western Siberia and efficiently propagated westwards, and stimulated an obvious anti-cyclone over Baikal Lake and NH area (Figure 12b). The SnowWS varied similarly with DHD_NH and achieved its maximum (minimum) in 2016 (2010). As revealed by Wang et al (2015) and Yin et al (2017), the preceding autumn Arctic sea ice has a close relationship with the winter haze days in the east of China. The climatic relationship between the Arctic sea ice and DHD_NH and the anomalies in December were also examined and found to be not significant (figure omitted). This may be due to the relationship being different in the early and late winter, which requires more research in the future. The detailed mechanisms between the external forcings and haze pollution should be studied physically and dynamically in future work. Furthermore, although anthropogenic emissions were limited during haze pollution events, there were still aerosols being discharged in the atmosphere by the dense population and industry before and during 16–21 December. There is little doubt that the high concentration of PM2.5 was the fundamental cause for haze pollution, and the associated atmospheric anomalies played key roles in the severe haze pollution events. The previous accumulation of atmospheric particles also contributed to the occurrence of haze pollution events. As revealed in this study, it was difficult to modify the simultaneous atmospheric circulations, which significantly contributed to the haze. Therefore,
the controlling measures of anthropogenic emissions should be implemented in advance to reduce the stock of aerosols in the atmosphere.

**Table 1** Correlation coefficients between the DHD$_{NH}$ and key indices from 1979 to 2016 and the ranks of key indices in 2016.

The Corr Coe$^1$ and Corr Coe$^2$ indicated that correlation coefficients were calculated after and before detrending. The AC was the anticyclone index that was defined as the mean Z500 over 105–125°E, 30–50°E. The local PBL, surface wind speed and relative humidity were calculated as the mean over the NH area. All the correlation coefficients were above the 99% confidence level. The rank was sorted from largest to smallest, when the Corr Coe was positive. If the Corr Coe was negative, the rank was calculated from smallest to largest.
