20 **Abstract**

21 After 43 years of inactivity, the Calbuco volcano which is located in the southern part of Chile
22 erupted on 22 April 2015. The space-time evolutions (distribution and transport) of its aerosol
23 plume are investigated by combining satellite (CALIOP, IASI, OMPS), in situ aerosol
24 counting (LOAC OPC) and lidar observations, and the MIMOSA advection model. The
25 Calbuco aerosol plume reached the Indian Ocean 1 week after the eruption. Over the Reunion
26 Island site (21°S; 55.5°E), the aerosol signal was unambiguously enhanced in comparison
27 with “background” conditions with a volcanic aerosol layer extending from 18 km to 21 km
28 during the May-July period. All the data reveal an increase by a factor of ~2 in the SAOD
29 (Stratospheric Aerosol Optical Depth) with respect to values observed before the eruption.

1 The aerosol e-folding time is approximately 90 days. Microphysical measurements obtained
2 before, during and after the eruption reflecting the impact of the Calbuco eruption on the
3 lower stratospheric aerosol content have been analyzed over Reunion site. During the passage
4 of the plume, the volcanic aerosol was characterized by an effective radius of $0.16 \pm 0.02 \mu\text{m}$
5 with an unimodal lognormal size distribution and the aerosol number concentration appears
6 20 times higher than before and one year after the eruption. A tendency toward “background”
7 conditions has been observed about one year after the eruption, by April 2016. The volcanic
8 aerosol plume is advected eastward in the Southern Hemisphere and its latitudinal extent is
9 clearly bounded by the subtropical barrier and the polar vortex. The transient behavior of the
10 aerosol layers observed above Reunion Island between May and July 2015 reflects an
11 inhomogeneous geographical distribution of the plume which is controlled by the latitudinal
12 motion of these dynamical barriers.

13 1. Introduction

14 Stratospheric aerosol affect the chemical and radiation balance of the atmosphere
15 (McCormick et al., 1995; Solomon, 1999; SPARC 2006). The importance of stratospheric
16 aerosol on the chemistry is mainly due to their role on ozone budget (Solomon et al., 1986;
17 Bekki, 1997; Borrmann et al., 1997). Indeed, stratospheric aerosol provide sites for
18 heterogeneous chemical reactions leading to stratospheric ozone depletion, significantly
19 enhanced in periods of high aerosol loadings following major volcanic eruptions (Solomon,
20 1999 and references therein). In addition, periods of enhanced stratospheric aerosol loadings
21 can lead to significant warming in the stratosphere and cooling in the troposphere (e.g.
22 McCormick et al., 1995; Solomon et al., 2011; Arfeuille et al., 2013). As reported by Kremser
23 et al. (2016), a better understanding of the processes governing the lifetime of stratospheric
24 aerosol is needed to assess the impacts on climate and chemistry. Since the discovery of the
25 permanent stratospheric aerosol layer, called Junge Layer, in 1961 (Junge, 1961), it has been
26 established that stratospheric aerosol are mostly composed of sulfuric acid droplets with some
27 more complex characteristics in the lower stratosphere and upper stratosphere where organic
28 compounds and meteoritic dust can also contribute to its composition (Neely et al., 2011,
29 Froyd et al., 2009). The main sources of stratospheric sulfur are Carbonyl Sulfide (OCS),
30 Dimethyl Sulfide (DMS) and sulfur dioxide (SO_2) (SPARC, 2006), the latest being
31 significantly enhanced after volcanic eruptions (Carn et al., 2015). The injected SO_2 is then
32 oxidized into H_2SO_4 , which after homogeneous nucleation and/or condensation onto existing
33 aerosol, results in an increase in the content of liquid sulfate aerosol (SPARC, 2006).

1 Thomason et al. (2007) have shown that volcanic effects have dominated other natural and
2 anthropogenic sources on the control of the stratospheric aerosol burden over the last 25
3 years. Previous studies on stratospheric aerosol have mainly contributed to characterize their
4 properties and variability during “background” (i.e. free of volcanic aerosol) and volcanic
5 conditions (e.g., Stenchikov et al., 1998; Jäger and Deshler, 2002; Bauman et al., 2003;
6 Hermann et al.; 2003; Hofmann et al.; 2009).

7 The eruption of the Pinatubo in 1991 is known to be the last major volcanic eruption which
8 injected up to 20 Tg of SO₂ and perturbed significantly the global stratosphere for several
9 years (Kinninson et al., 1994; McCormick et al., 1995; Stenchikov et al., 1998, 2002; Dhomse
10 et al., 2014). As reported by Russell et al. (1996), in addition to the prodigious increase in the
11 stratospheric aerosol loading, this event has significantly affected numerous aspects of the
12 atmospheric system including: i) a 2-year cooling of the global surface temperature of several
13 tenths of degrees (Canty et al., 2013; Wunderlich and Mitchell, 2017) ii) a warming of the
14 tropical stratosphere (~3,5 K) near the aerosol peak (Labitze and McCormick et al., 1992) or
15 also a lifting of the tropical ozone layer by ~1.8 km (Pueschel et al., 1992; Grant et al., 1994).

16 By the use of satellite and balloon-borne observations, studies have shown that moderate
17 volcanic eruptions (i.e., 10-20 times weaker than Pinatubo eruption in term of injected sulfur)
18 could significantly modulate stratospheric aerosol concentrations (Bourassa et al., 2010;
19 Kravitz et al., 2010; Solomon et al., 2011; Vernier et al., 2011; Clarisse et al., 2012; Jégou et
20 al., 2013). Based upon satellite observations, Vernier et al (2011) showed that the decadal
21 increase in stratospheric aerosol loadings since 2002 can be attributed to a series of moderate
22 volcanic eruption. As reported by Kremser et al (2016), this decadal trend was also obtained
23 from lidar (Hofmann et al., 2009) and ground-based sun-photometer observations (Ridley et
24 al., 2014). Three moderate volcanic eruptions are ranked in the top 10 of the most influential
25 events on the stratospheric aerosol burden including: (1) The Kasatochi eruption (52° N;
26 175°W, Alaska) in 2008 which injected 1.5-2.5 Tg of SO₂ into the upper troposphere and
27 lower stratosphere (UTLS) (Bourassa et al., 2010; Kravitz et al., 2010; Krotkov et al., 2010);
28 (2) The Sarychev eruption in June 2009 (48.1°N; 153.2°E, Kuril Island) which released 0.9 Tg
29 of SO₂ into the UTLS (Clarisse et al., 2012; Kravitz et al., 2011; Jégou et al., 2013); (3) The
30 Nabro eruption (13°N; 41°E, Eritrea) in June 2011 which emitted 1.3 Tg of SO₂ (Bourassa et
31 al., 2012; Sawamura et al; 2012). In comparison, these recurrent “minor” volcanic eruptions
32 injected 10-20 times less SO₂ than Mt Pinatubo, but contributed to counterbalance the global
33 warming observed between 2000 and 2010 (Solomon et al., 2011). These eruptions can also

1 be used to understand stratospheric **dynamic** as it was done **after Mt Pinatubo** (Trepte et al.,
2 1992).

3 Indeed, **following** a volcanic eruption, stratospheric aerosol can be used **as dynamical tracers**
4 (Bencherif et al., 2003; Fairlie et al., 2014). Based on satellite observations and a **lagrangian**
5 trajectory model, Fairlie et al. (2014) used the dispersion of the Nabro plume to study the
6 dynamics of the Asian Monsoon Anticyclone. Hitchman et al. (1994) and SPARC (2006)
7 suggested that the stratospheric aerosol distributions could be used to understand changes in
8 the Brewer-Dobson **Circulation**. Previous works have also revealed that stratospheric aerosol
9 can be used to study **meridional transport** from the tropical stratospheric reservoir (Trepte and
10 Hitchman, 1992; Randel et al., 1993; Chen et al., 1994; Grant et al., 1996, Vernier et al.,
11 2009). Based on satellite observations, Trepte and Hitchman (1992) **have shown** that **transport**
12 to mid-latitudes **is mainly favored** during **westerly** shear phases of **the QBO** than during the
13 easterly shear phases. More recently, by the use of satellite observations and climate models,
14 Hommel et al. (2015) revealed that the vertical and latitudinal extent of the stratospheric
15 aerosol layer (between 16 and 31 km) in the tropics is modulated by **QBO**.

16 This paper reports on the Calbuco plume observations over **Reunion Island** and its transport in
17 the southern tropics. The geometrical and optical properties of the Calbuco plume are inferred
18 from the ground-based observations at Reunion Island in the framework of the MORGANE
19 (Maïdo ObservatoRy Gas Aerosols NDACC Experiment) campaign. **The aim of this study is**
20 **to provide the dynamical framework controlling the time-space evolution of the volcanic**
21 **plume in the southern hemisphere**. The paper is organized as follows: Section 2 describes the
22 **observations** and the model used for the investigation of the volcanic aerosol transport. A
23 description of the long-range transport of the volcanic plume over the Indian Ocean is
24 provided in Section 3; Section 4 gives a dynamical analysis of this case study; and the
25 summary and **the** conclusions are given in Section 5.

26 **2. Instrumentation and model description**

27 **2.1 Observations**

28 **2.1.1 Ground-based lidar**

29 One part of the observations **used** in this study was performed during the MORGANE
30 campaign which took place at the Maïdo observatory on Reunion Island (**21°S; 55°E**) in May
31 2015. The MORGANE ground-based observational systems combine **Lidar** and balloon-borne
32 payloads to study the composition and **the** dynamics of the **Upper Troposphere-Lower**

1 Stratosphere (UTLS) in the southern hemisphere. Among the 4 lidar systems operated during
2 this campaign, we used the measurements from the stratospheric Differential Absorption
3 Lidar (DIAL) system built for the monitoring of the stratospheric ozone profile (Baray et al.,
4 2013). It is possible to retrieve also aerosol profiles in the 15-38 km altitude range from these
5 measurements. This instrument has been in operation at the Maïdo observatory since early
6 2013. The technical details and evaluation of its performance are given by Baray et al.,
7 (2013). A brief description of this DIAL system is given hereafter. It uses a tripled Nd:YAG
8 laser which provides a beam at 355 nm wavelength with a repetition rate of 30 Hz and a XeCl
9 excimer laser which emits a radiation at 308 nm at 40 Hz. The optical receiver is a telescope
10 composed of 4 parabolic mirrors where the backscattered signal is collected by 4 optical
11 fibers located at the focal points. The current configuration of the DIAL lidar system mainly
12 detects in the UV bands (308, 332, 355 and 387 nm). The lidar data set used in this study
13 consists of daily records of backscattering signal obtained from the Maïdo facility between 1
14 November 2014 and 30 November 2016 (106 profiles). It should be noted that no
15 measurements were recorded at Reunion from January to April 2016 because of technical
16 problems. The daily measurements are nocturnal and time-integrated over about 3 hours in
17 average.

18 The method involves obtaining the extinction and backscatter coefficient from a Rayleigh Mie
19 lidar has been described first by Klett (1981). The methodology of Sasano (1985), used here,
20 is similar and has the advantage to give a numerical calculation of the extinction and
21 backscatter coefficient. Several parameters are needed: first, the temperature and the pressure
22 come from a radiosounding realized in the airport of Gilot at 11h (UTC). The profile is
23 completed by the Arletty model, based on European Centre for Medium Range Weather
24 Forecast (ECMWF) data. The second parameter is the ratio between the backscatter and the
25 extinction coefficient for aerosol, also call lidar coefficient. It depends of the kind of aerosol.
26 In the case of background stratospheric aerosol, the value found in the literature is near 60.
27 The third parameter is the altitude of reference defined as the altitude where there is no
28 aerosol. The altitude of reference is determined for each profile. On average, the altitude of
29 reference is located between 30 and 40 km.

30 2.1.2 Balloon-borne OPC.

31 In order to analyze the concentration and the size of the observed aerosol over the site, many
32 LOAC (Light Optical Aerosols Counter) systems were launched together with balloon-
33 ozonesondes. A detailed description of the LOAC is given by Renard et al. (2016). In brief,

1 LOAC is a lightweight Optical Particle Counter (OPC) of 1 kg which can fly under latex
2 weather balloons. Through the measurements of the light scattered by particles at two specific
3 angles (Lurton et al. 2014), it provides aerosol concentrations and particle size distributions
4 for 19 size classes ranging from 0.2 μm to 50 μm in diameter every ten seconds with a
5 vertical resolution of nearly 50 m depending on the ascent rate of the balloon. The number
6 concentration range is from 0.6 to a few thousands particles per cm^3 (Vignelles 2017).
7 Uncertainties on number concentration during the ascent under meteorological balloon are
8 mainly due to temperature variation effects on electronics (Renard et al. 2016, Vignelles
9 2017). Uncertainties on number concentrations for size bins than 1 μm is estimated to be of \pm
10 30 %. For larger size bins, uncertainties on number concentration is dominated by Poisson
11 law statistics estimated to be \pm 20 % and \pm 60 % at concentrations respectively lower than 10^1
12 ¹ and 10^2 part per cm^3 .

13 2.1.3 CALIOP

14 The Cloud-Aerosols Lidar with Orthogonal Polarization (CALIOP) on board The Cloud-
15 Aerosols Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) was used to study
16 the transport of the Calbuco plume. CALIPSO was launched in 2006 to a Sun-synchronous
17 polar orbit (Winkler et al., 2007) with a repeat cycle of 16 days. CALIPSO is composed of an
18 Infrared Imager Radiometer (IIR), a wide field visible camera and the CALIOP lidar.
19 CALIOP is a two-wavelength polarization-sensitive lidar (532 and 1064 nm) which measures
20 total attenuated backscatter vertical profiles with altitude-varying vertical (30-300 m) and
21 horizontal (300-5000 m) resolution (Winker et al., 2010). The data used in this study are the
22 total and perpendicular backscatter coefficient at 532 nm available from the CALIOP level 1B
23 V4.01 product. These data have been averaged every 1 degree in latitude for each orbit and
24 grouped into data files containing 16 days of measurements. From there, Scattering Ratio and
25 Depolarization Ratio coefficients at 532 nm have been calculated (Vernier et al., 2009).
26 Through the use of this algorithm, the full zonal mean between 20°S and 20°N are obtained by
27 averaging 7200 cells, leading to a precision of \pm 1.6 % (Vernier et al., 2009). The ability of
28 CALIOP to detect small volcanic plumes in the lower tropical stratosphere has been
29 highlighted in previous studies (Thomason et al., 2007; Vernier et al., 2009, 2011).

30 2.1.4 IASI

31 The Infrared Atmospheric Sounding Interferometer (IASI) observations were used to quantify
32 the amount of SO_2 emitted during the Calbuco eruption. IASI is a nadir looking thermal

1 infrared sounder on board the Meteorological Operational satellite (MetOp-A and MetOp-B)
2 launched in October 2006 with a polar orbit. Its global spatial coverage and its footprint of 12
3 km make IASI relevant for monitoring of the key atmospheric species, in particular for the
4 volcanic SO₂ (Clarisse et al., 2008, 2012; Clerbaux et al., 2009). The amount and altitude of
5 emitted SO₂ were obtained from the algorithms detailed in Clarisse et al. (2012) and Clarisse
6 et al. (2014) respectively. For each IASI observation, the height was estimated first, after
7 which the column was calculated using the height information as an input parameter. In this
8 study, only data from MetOp-A was used.

9 2.1.5 OMPS

10 The Ozone Mapper and Profiler Suite (OMPS) Limb Profiler (LP) is also used in the present
11 study to analyze the optical properties of the volcanic plume over the Reunion site. OMPS
12 was launched on October 2011 on board the Suomi National Polar Partnership (NPP)
13 spacecraft. The data used in this study are the daily extinction profiles at 675 nm. A detailed
14 description of the aerosol extinction retrieval algorithm is given by Jaross et al. (2012) and
15 Rault and Loughman (2013). Briefly, the measured spectrum is used to infer information on
16 the size distributions and the radiances are normalized to their value at 35.5 km (weak
17 contribution of aerosol extinction). Then, the extinction coefficients are retrieved using the
18 Rodgers' maximum likelihood technique. We used 2 years (From November 2014 to
19 November 2016) of satellite overpasses above the lidar site, within a 5°x5° in latitude and
20 longitude grid. OMPS data have already used to be very effective at detecting and
21 characterizing major events, such as the Chelyabinsk bolide in February 2013 (Gorkavyi et
22 al., 2013).

23 2.2 MIMOSA model

24 The Modèle Isentropique de transport Mésoéchelle de l'Ozone Stratosphérique par Advection
25 (MIMOSA) model (Hauchecorne et al., 2002) is a Potential Vorticity (PV) advection model
26 running on isentropic surfaces. The advection scheme is semi-Lagrangian with a time step of
27 1 hour. The re-gridding onto the original orthonormal grid is performed every 6 hours. The
28 model resolution is 0.5°x0.5°. The advection is driven by ECMWF meteorological analyses at
29 a resolution of 0.5°x0.5°. In the case of the PV, its slow diabatic evolution is taken into
30 account by relaxing the model PV towards the PV calculated from the ECMWF fields with a
31 relaxation time of 10 days. Using this procedure, it is possible to run the model continuously
32 and follow the evolution of PV filaments during several months. The accuracy of the model

1 **has been** evaluated by Hauchecorne et al. (2002) and validated against airborne lidar ozone
2 measurements using **correlation** between PV and ozone, a quasi-conserved chemical tracer on
3 a week timescale within most of lower stratosphere (Heese et al., 2001).

4 **2.3 DyBAL code**

5 The Dynamical BARRIER Location (DyBAL) code is an original software developed at the
6 Laboratoire de l'Atmosphère et des Cyclones (LACy, France) to detect the subtropical barrier
7 position (Portafaix et al., 2003). The dynamical barriers are detected from the equivalent
8 length of the tracer **contour** and the gradient of isentropic Ertel's potential vorticity (PV) in
9 equivalent latitude **coordinate** as defined by Nakamura (1996). These two diagnostic tools are
10 used by **DyBAL** to identify weak mixing and transport barriers. The position of **the** dynamical
11 barrier is characterized by a local maximum of the PV gradient and a local minimum of the
12 equivalent length (Nakamura, 1996). The DyBAL code is applied to the PV map obtained
13 from the MIMOSA model runs. The ability of **DyBAL** to detect the position and **the**
14 deformation of the dynamical barriers **has been** highlighted in previous studies (Bencherif et
15 al., 2007; Morel et al., 2005; Portafaix et al., 2003).

16 **3. Long-range transport and evolution of the Calbuco volcanic** 17 **plume over the Indian Ocean**

18 **3.1 Formation and transport**

19 **3.1.1 SO₂ plume**

20 After 43 years of inactivity, **the Calbuco erupted** on 22 April 2015 and two intense explosive
21 events were recorded during the same week. Figure 1 shows the CALIOP cross-section of the
22 532nm total attenuated backscatter (**ATB**) for the overpass over South America on 24 April.
23 The **ATB signals ranging** from $1 \cdot 10^{-3}$ to $5 \cdot 10^{-3} \text{ km}^{-1} \text{ sr}^{-1}$ **correspond** to weak values of
24 brightness temperatures over the southern part of Brazil (34, 22°S; 53, 97°W) **can** be attributed
25 to volcanic material injected up to the lower stratosphere by the Calbuco eruption.

26 The evolution of the SO₂ total mass measured by **IAI** between 23 April 2015 and 31 May
27 2015 is reported in Figure 2. The SO₂ total mass is defined as the sum of SO₂ **mass** over the
28 atmospheric column **from midday to midnight over the southern hemisphere**. **As expected an**
29 **increase of the SO₂ amounts** was observed by IASI a few days following the Calbuco
30 eruption. One day after the eruption the SO₂ total mass was 10 times higher **than background**
31 **levels**. The SO₂ total mass **increased quickly** to its maximum value (0.41 Tg) on 25 April

1 2015 and slowly decreased to reach values close to the background values on 19 May 2015
2 (Figure 2). An e-folding times of ~11 days can be estimated which is in agreement with the
3 value reported for the Sarychev volcanic eruption (Jégou et al., 2013). The SO₂ total mass
4 increased again on 28 May 2015 to reach a secondary maximum (0.13 Tg) on 30 May 2015.
5 This new increase of the SO₂ total mass could be due to the Wolf eruption (Isabela Island,
6 Galapagos) which occurred on 25 May 2015 (Xu et al., 2016). The amount of SO₂ emitted
7 during the Calbuco eruption is about two times lower than the SO₂ mass emitted from the
8 Sarychev eruption in June 2009 (Jégou et al., 2013). It is also worth noting that the SO₂ mass
9 injected during this event is of the same order as quantified during the Grimsvötn eruption in
10 May 2011 (Clarisse et al., 2011). Given that the amount of SO₂ emitted in comparison to
11 previous volcanic eruptions, the Calbuco eruption can be considered as moderate in term of
12 produced aerosol loading. Figure 2 also depicts the maximum altitude of the SO₂ plume over
13 the period from 23 April 2015 to 31 May 2015. On average the maximum of SO₂ is located in
14 the lower stratosphere region around 17 km.

15 The SO₂ measurements integrated from midday to midnight obtained from IASI are also used
16 to describe the transport of the volcanic plume over the southern hemisphere (Figure 3). On
17 23 April 2015, part of the plume is present nearby Uruguay coast at 17 km and transported by
18 the general circulation. The plume reached Southern Africa and East side of Madagascar on 1
19 May 2015 at altitude of 17-18 km and was organized following a cyclonic rolling (Figure 3b).
20 On 6 May, the plume is mainly located over the Atlantic Ocean near the east coast of South
21 Africa and partly over Namibia and South Africa. The SO₂ plume extent and amplitude began
22 to diminish on 11 May 2015 as expected by the oxidation of SO₂ to gaseous sulphuric acid
23 which further condensed into H₂SO₄-H₂O liquid aerosol. The plume was embedded in a thin
24 layer between 15-17 km extending from the Atlantic Ocean to the Indian Ocean passing
25 through the Cape of Good Hope (Fig. 3d).

26 3.1.2 Spatial extent of the aerosol plume

27 The transport of the volcanic aerosol plume over the southern hemisphere can be followed by
28 CALIOP observations at 532 nm. Figure 4 presents the latitude-altitude cross sections of the
29 scattering ratio observed by CALIOP for 16-day selected periods in 2015. The scattering ratio
30 values observed during the 16-30 April period (before the eruption) in the Southern
31 hemisphere, particularly in the lower stratosphere, were in average at 1.05 (not shown).
32 Between one and three weeks after the eruption (1-16 May period), CALIOP observations
33 reveal that SR increased until 1.12 in the southern lower stratosphere. The amplitude of the

1 plume during the first weeks following the eruption was higher than the background aerosol
2 levels at mid-latitudes but was still below the scattering ratio values observed in the tropics.
3 This could be attributed to possible remnants of the Kelud (7.5°S; 112.2°E; erupted in
4 February 2014) volcanic aerosol superimposed to the equatorial background aerosol layer.
5 About one month after the eruption (16-31 May period) the Calbuco plume was much more
6 pronounced with scattering ratio values (ranging from 1.16 to 1.18) largely above background
7 levels and greater than aerosol amounts confined in the tropical reservoir. The plume
8 extended up to about 20 km in altitude and spread over a wide range of latitudes by nearly
9 reaching 60°S and showing a feature of intrusion into low latitudes, i.e. near 5°S. The rough
10 center of the plume was therefore slightly norther than the eruption. About one month later on
11 (16-30 June period), the plume top had moved upward by several hundred meters and was
12 thicker. The southern hemisphere between 10°S and polar latitudes was full of volcanic
13 aerosol with scattering ratio values much higher than elsewhere in the whole stratosphere.
14 About four months after the eruption (16-31 August period) the volcanic aerosol layer was
15 even thicker with scattering ratio remaining high.

16 In the upper stratospheric transport regime, i.e. in the 21-28 km altitude range, detrainment of
17 aerosol from the equatorial reservoir appears dependent upon the phase of **the quasi-biennial**
18 **oscillation (QBO)** and on the intensity of planetary wave activity (Trepte and Hitchman,
19 1992). When QBO easterlies descend in the tropics, planetary waves are blocked from
20 entering this region, thus limiting the extent to which these waves may have detrained aerosol
21 laterally from the tropical reservoir (Trepte et al., 1993). This corresponds to the situation in
22 Figure 4. However, during the westerly phase of the QBO particles tend to spread poleward
23 and mixing across the subtropics are expectedly favored, especially in winter (Trepte et al.,
24 1993). The meridional spread in aerosols amounts shown above 21 km in Figure 4c and 4d
25 may therefore be consistent with the phase reversal of the QBO from easterlies to westerlies
26 observed from mid-2015.

27 **3.2 Evolution of the aerosols plume over the Reunion site**

28 **3.2.1 Ground-based and satellite observations**

29 Figure 5 depicts the evolution of the stratospheric AOD (SAOD) at 532 nm calculated
30 between 17 and 30 km from the Reunion ground-based lidar and OMPS observations over
31 Reunion from November 2014 to November 2016. SAOD were calculated from lidar and
32 OMPS observations at 532 nm using angstrom exponent equal to 1.3 and 1.8 respectively

1 (Schuster et al., 2006; Jäger and Deshler 2002). As expected, an increase in the aerosol
2 loading was observed over the Reunion site a few weeks after the Calbuco eruption. OMPS
3 data show a doubling in the SAOD record in comparison with values observed at the end of
4 2014 and at the beginning of 2015 (Fig. 5). SAOD reached its maximum values (0.014 for
5 OMPS) at the beginning of June 2015, decreased afterward to 0.01 on August 2015 and went
6 back to pre-eruption values (0.004-0.006) in April 2016. The lidar record peaks at the same
7 period, but SAOD values are 1.2 times weaker than those observed by OMPS during the June-
8 December period. The lidar SAOD observations show less difference with values obtained
9 prior to the eruption (0.008). Discrepancies between OMPS and lidar were significantly
10 reduced in April 2016, i.e. with relative difference of 25% and 10% over the January-
11 December 2015 period and over the April-November 2016 period respectively. The reasons
12 for these discrepancies are unclear but effects due to different spatial samplings cannot be
13 excluded. From both datasets an aerosol e-folding of approximately 90 days can be derived,
14 which is rather close to the value (~80 days) reported for the Sarychev eruption (Jégou et al.,
15 2013).

16 Figure 6a illustrates the weekly-averaged extinction profiles at 532 nm derived from lidar
17 measurements over Reunion. This figure reveals a sharp increase of the extinction between 18
18 and 19 km in May 2015 and reaching its maximum value (greater than $4 \cdot 10^{-3} \text{ km}^{-1}$) in June.
19 The vertical extent of the plume had increased significantly over the May-July period with a
20 volcanic aerosol layer spanning from 18 to 21 km. At the beginning of June, the plume was
21 structured in two layers with the first one centered at 18.5 km and the second one at 20 km
22 (Fig.6a). We note also a quick decrease in the local extinction around mid-May. The
23 variability observed in the weekly-averaged extinction profiles and in the vertical extent of the
24 aerosol signal over the May-July period reflects the presence of transient aerosol layers above
25 Reunion and indicates that the plume is not homogeneously distributed at this stage. The
26 altitude of the volcanic aerosol plume and the extinction values decreased from mid-August
27 onwards. The plume is hence centered around 18 km on September. Overall, the temporal
28 evolution of the weekly-averaged extinction presents similar general features as the lidar
29 observations, with maximum values in June and a subsequent gradual decrease of the aerosol
30 signal. Nevertheless, in OMPS data the plume is smeared out over a wider vertical range than
31 in the lidar record (Fig. 6b). The vertical and horizontal structures of the plume are not
32 reproduced in OMPS data. In particular, the decrease in the plume altitude in mid-August is
33 not observed by OMPS. This can be due to dilution (along the space borne instrument lines of

1 sights) of the aerosol signal and vertical resolution issues. The evolution of the scattering ratio
2 at 532 nm obtained from the lidar and CALIOP space-borne observations during the April-
3 December 2015 period over the Reunion site are presented on Figure 7. The scattering ratios
4 from CALIOP have been averaged within $\pm 5^\circ$ in latitude and $\pm 50^\circ$ in longitude around
5 Reunion Island (Fig. 7b). CALIOP observations confirm also the presence of the volcanic
6 aerosol plume over the Reunion site at the beginning of May 2015 with maximum scattering
7 ratio values (greater than 1.9) on mid-May 2015. Overall, the aerosol variability is smoother
8 in CALIOP observations than in the lidar record, which shows more fluctuations in the
9 altitude of the volcanic plume. Conversely to the lidar and OMPS observations, CALIOP data
10 do not point out an increase of the vertical extent of the plume and maximum scattering ratio
11 values at the beginning of June 2015. According to CALIOP, the scattering ratio begin to
12 decrease at mid-June followed by a slight decrease of the altitude of the plume since the end
13 of July (Fig 7b). From July onwards, the CALIOP aerosol scattering ratio decreases gradually
14 with similar values as observed by the lidar.

15 **3.2.2 In-situ observations**

16 Four LOAC OPCs were launched over the Reunion site from November 2014 to November
17 2016. SAOD were calculated at 532 nm following Mie Theory. LOAC observations reveal
18 also an increase by a factor of 2 in the SAOD on 19 May 2015 ($1.35 \cdot 10^{-2}$). Then SAOD
19 decrease to $8.4 \cdot 10^{-3}$ on 19 August 2015 followed by a return to pre-eruption levels on
20 November 2016 (Fig. 5). Though the SAOD overall evolution derived from LOAC compares
21 fairly well to OMPS and lidar observations accounting for error bars (Fig. 5), the
22 discrepancies in terms of SAOD amplitude mainly observed in May could be due to the
23 different measurement techniques using different spatial and temporal coverages. The
24 integration time of the LOAC instrument and the ascent velocity of the balloon limit the
25 vertical resolution on the profile. The in situ data are averaged over 1 minute which tends to
26 spread out the structure attributed to the volcanic aerosol plume and can explain the difference
27 with the daily-integrated lidar observations.

28 Figure 8 illustrates the volume concentration ($dN/d\ln(D)$) and number concentration
29 ($DV/d\ln(D)$) obtained from the LOAC OPC observations over the Reunion site on 19 May
30 2015 at 1746 UTC. The best fit obtained from LOAC OPC observations reveals an unimodal
31 lognormal size distribution (Fig. 8). We note that the shape of the size distribution obtained
32 during the Calbuco event is similar to the results obtained by Kravitz et al. (2011) for the
33 Sarychev eruption. As suggested by Kravitz et al. (2011) for the Sarychev event, we can also

1 assume that the Calbuco eruption did not eject enough material to create a bimodal structure
2 over Reunion Island. The effective radius derived from the LOAC OPC on 19 May is 0.17
3 ± 0.02 μm reflecting that the particles observed several weeks after the Calbuco eruption are
4 quite small. Interestingly, Jégou et al. (2013) have reported that the effective radius obtained
5 during the Sarychev event ranged from 0.15 to 0.20 μm more than one month after the
6 eruption, in agreement with the results of O'Neill et al. (2012). Therefore both eruptions are
7 comparable in terms of size distribution shape and effective radius. Conversely to the Calbuco
8 and Sarychev moderate eruptions, bimodal size distributions were observed for the Pinatubo
9 aerosols on the first weeks after the eruption, the second mode possibly consisting of volcanic
10 ash (e.g. Russell et al., 1996). Russell et al. (1996) have reported that in the month following
11 the Pinatubo eruption the effective radius did not differ greatly from pre-eruption values (i.e.
12 0.17 ± 0.07 μm in their study) possibly because a large number of particles with sizes both
13 smaller and larger than 0.17 μm were injected.

14 The integrated number of particles obtained over 19 size classes from 0.2 to 2 μm in diameter
15 is presented in Figure 9. A local aerosol concentration enhancement is detected in the lower
16 stratosphere (16.8 - 19 km) over Reunion on 19 May 2015 at 1746 UTC. A maximum
17 concentration of about 150 particles per cm^3 (total number of particles: 730 ± 130 particles
18 ($\pm 1\sigma$)) is observed by the aerosol counter for particle sizes larger than 0.2 μm . This aerosol
19 number concentration appears 20 times higher than the one observed by the LOAC flight on
20 26 November 2014 at 1442 UTC. Few in situ observations are available in the tropical region
21 to provide a reference state of the background aerosol content. Based on COPAS
22 measurements (Condensation Particle counter System, Weigel et al., 2009) on board the M-
23 55 Geophysica aircraft, Borrmann et al. (2010) found that the aerosol number concentration,
24 in average, over the lower stratosphere, is ranging from 40 to 100 particles per cm^3 for sizes
25 greater than 10 nm in the tropical/subtropical region during the background period. Although
26 the LOAC size lower bound is limited to 200 nm excluding the detection of the smallest
27 particles, the observed concentrations on 19 May 2015 are above the levels recorded by the
28 aircraft pointing out the impact of the Calbuco eruption on the lower stratospheric aerosol
29 content. Three months later, another LOAC OPC was launched over the Reunion site but the
30 in situ profile partially shows the volcanic aerosol layer because of a telemetry loss. The
31 aerosol number concentration obtained on 19 August 2015 at 1300 UTC over Reunion may
32 reveal a tendency to return to concentration values observed before the eruption (Fig. 9), with
33 a number concentration of 40 particles per cm^3 in the lower stratosphere. This tendency is

1 confirmed with the LOAC flight conducted on 2 November 2016 at 2030 UTC with a total
2 number concentration close to 20 particles per cm^3 in the lower stratosphere (Fig. 9).

3 The residence time of the aerosol particles in the stratosphere depends on the balance between
4 the growth processes and the removal processes which are likely to be controlled by the
5 dynamical context. In the following section, we will discuss the influence of the dynamical
6 activity on the variability of the volcanic aerosol over the southern hemisphere.

7 **4. Dynamical modulation of the aerosol plume**

8 **4.1 Long-range isentropic transport**

9 In order to analyze the isentropic transport, the high resolution MIMOSA model has been
10 used to produce a continuous evolution of PV fields for the period from 1 April 2015 to 31
11 August 2015. Four advected PV maps, derived for the 400 K isentropic level from the
12 MIMOSA model, together with dynamical barrier locations derived from the DyBaL code are
13 superimposed in Figures 10 and 11. The localization of the volcanic aerosol plume obtained
14 from OMPS observations at $400 \text{ K} \pm 5 \text{ K}$ isentropic level is also superimposed (Fig. 10 and
15 11). On 24 April 2015, a significant wave activity is observed, leading to a fairly mixed surf
16 zone in the 20°S - 60°S latitude band (not shown). The Calbuco plume is situated inside the
17 surf zone and the plume was mixed equatorward. On 27 April 2015, the subtropical and mid-
18 latitude barriers are detected following the Nakamura's formalism (described in Section 2.3)
19 around 15°S and -40°S in latitude respectively, still limiting the geographical extent of the
20 plume (Fig. 10a). Figure 10a shows clearly that the plume cannot move beyond the south of
21 Brazil because of the presence of the subtropical barrier. On 01 May 2015, the air masses
22 were confined between the two dynamical barriers located in average at 25°S and 40°S in
23 latitude respectively. The air masses were advected eastward between South Africa and
24 Madagascar following the wave shape of the barrier, in consistency with the OMPS
25 observations near South Africa (Fig. 10b). The subtropical barrier previously located in
26 average at 25°S moved northward crossing South Africa. The air masses containing aerosol
27 previously situated in the south side of Madagascar were transported northward and eastward
28 following the displacement of the barrier and reached the Reunion site.

29 On 19 May 2015, we note the presence of the subtropical and mid-latitude barriers around
30 28°S and 43°S respectively. (Fig. 11a). As expected, the volcanic aerosol plume was confined
31 between the two dynamical barriers and embedded eastward. At this stage, the presence of the
32 subtropical barrier and the polar vortex seems to drive significantly the Calbuco plume

1 inducing its transport eastward. Between end of May and beginning of June, the subtropical
2 barrier has dissipated while the polar vortex was around $\sim 40^{\circ}\text{S}$ (see Fig. 11b). The OMPS
3 observations reveal that the most part of the plume was located over the southern African and
4 the Indian Ocean region in June (Fig. 11b). On the following months of July and August, the
5 polar vortex is clearly identified at 60°S which is a classical pattern for the austral winter.

6 **4.2 Removal processes**

7 As shown above, in the lower stratosphere distributions of the aerosol are modulated (or
8 mostly driven) by isentropic transport. However, particle removal processes should be
9 considered. Based on a semi-Lagrangian transport model, Chen et al. (1994) showed that
10 isentropic mass exchange between tropical and extratropical latitudes in the stratosphere can
11 act as a significant removal process of stratospheric aerosols. Depending on the strength of the
12 Brewer-Dobson circulation, stratospheric materials such as aerosols can be rapidly transported
13 from the tropics to high latitudes (Dhomse et al., 2006, 2014).

14 Dhomse et al. (2014) using the CCM model (UM-UKCA) have revealed the influence of STE
15 events on the budget of the stratospheric aerosols. In particular, they showed that
16 overestimation of the strength of a STE event could lead to fast removal of aerosols from
17 stratosphere into the middle and high latitude. Moreover, Hamill et al. (1997) reported that
18 STE through the isentropic surfaces due to Rossby wave activity can be considered as a
19 significant dynamical process for removal of stratospheric aerosol. Sixteen years of ozone
20 measurements (1992–2006) at Reunion have been processed to detect stratospheric signatures
21 on each single ozone profile by Clain et al. (2010). They shown that the STE occurred
22 frequently all the year at Reunion and strongly linked to dynamical processes occurred near to
23 tropopause such as tropopause fold. Given the potential of a STE event to impact the
24 stratospheric aerosol loading, we cannot exclude its contribution (even though small) on the
25 stratospheric aerosols loading at Reunion.

26 The modulation of the plume over Reunion could be also caused by particle removal
27 processes such sedimentation which is considered as the primary loss mechanism of
28 stratospheric aerosol or by dilution of the stratospheric plume (Hamill et al, 1997; Rasch et
29 al., 2008). Nevertheless, the sedimentation of aerosol is an effective removal mechanism for
30 the few particles that somehow survive long enough in the stratosphere to grow to larger sizes
31 (Hamill et al., 1997). We note also that larger particles fall faster, which causes a vertical
32 gradient in the particle size distribution (Mann et al., 2015). However, highlighting

1 sedimentation processes from Figures 6 and 7 is somewhat complicated by the transient
2 feature of the volcanic aerosols with variable plume altitudes especially from the lidar local
3 data.

4 **5. Summary and conclusion**

5 The long-range isentropic transport of the volcanic aerosol produced following the Calbuco
6 eruption was examined. The analysis focuses on the dynamical context which led to the
7 spread of the aerosol plume over Indian Ocean between April 2015 and November 2016. The
8 transport of the volcanic aerosols to the Indian Ocean was investigated by combining satellite
9 (CALIOP, IASI, OMPS), and ground-based experiments: Optical Particle Counter (LOAC)
10 and lidar, in addition to numerical tools: the DyBal code and the high resolution MIMOSA
11 model.

12 From the IASI observations, the amounts of SO₂ injected into the atmosphere during the
13 Calbuco eruption have been quantified. SO₂ amounts emitted by the Calbuco eruption were
14 about two times lower than for the Sarychev moderate eruption in the northern hemisphere in
15 June 2009, but we report the same e-folding time for both eruptions, i.e. ~11 days (Jégou et
16 al., 2013; Kravitz et al., 2011). It is found from CALIOP observations that the Calbuco
17 aerosol layer was observable up to lower stratosphere, between 18 and 21 km, and spreaded
18 exclusively over the Southern Hemisphere. Moreover, OMPS observations reveal that the
19 Calbuco plume reached the Indian Ocean **two weeks after the eruption**. It is shown from
20 ground-based observations deployed at Reunion Island that SAOD increased by a factor of ~2
21 by the beginning of May 2015 and decreased afterward and returned to pre-eruption values by
22 November 2016. The aerosol e-folding time is estimated to be ~90 days, i.e. close to the ~80
23 days reported for the Sarychev eruption (Jégou et al., 2013). Though the various datasets
24 rather agree in terms of aerosol signal intensity we report significant differences for the plume
25 height and its variability possibly as a result of different observations geometries, resolutions
26 and spatial scales inherent to each instrument.

27 In situ measurements by the LOAC OPC have pointed out the impact of the Calbuco eruption
28 on the lower stratospheric aerosol content over the Reunion site. Aerosol number
29 concentrations were 20 times higher than values observed before and one year after the
30 eruption. On May 2015, the volcanic aerosol was characterized by an effective radius of 0.16
31 ±0.02 μm and an unimodal lognormal size distribution. These microphysical characteristics

1 are in agreement with previous studies focussing on the Sarychev eruption (Kravitz et al.,
2 2011; Jégou et al., 2013).

3 Through the use of the MIMOSA model and the DyBAL code, it was clearly identified that
4 the transport of the volcanic aerosols was eastward mainly in form of planetary-scale tongues.
5 In particular, the combination of MIMOSA and DyBal simulations revealed that the transport
6 of the volcanic aerosol plume eastward was controlled and confined between the subtropical
7 barrier and polar vortex. The two dynamical barriers acted as a channel within which most of
8 zonal transport took place, including transport of Calbuco plume. Our results support the
9 assumption that the processes explaining the structure of the plume over the southern
10 hemisphere had mainly a dynamical origin. Thus, the fluctuation of the localization of the
11 dynamical barrier induced transient aerosol layers above Reunion and an inhomogeneous
12 distribution of the plume between May and July 2015. The present study supports also the
13 assumption that the modulation of a volcanic plume may result from the contribution of both
14 dynamical and microphysical processes. Fully understanding the contribution of the
15 microphysical processes on the evolution of the volcanic plume over the southern hemisphere
16 requires further investigation. This will be examined in a forthcoming study.
