## 19 Abstract

20 After 43 years of inactivity, the Calbuco volcano which is located in the southern part of Chile  
21 erupted on 22 April 2015. The space-time evolutions (distribution and transport) of its aerosol  
22 plume are investigated by combining satellite (CALIOP, IASI, OMPS), in situ aerosol counting  
23 (LOAC OPC) and LiDAR observations, and the MIMOSA advection model. The Calbuco  
24 aerosol plume reached the Indian Ocean one week after the eruption. Over the Reunion Island  
25 site (21°S; 55.5°E), the aerosol signal was unambiguously enhanced in comparison with  
26 “background” conditions with a volcanic aerosol layer extending from 18 km to 21 km during  
27 the May-July period. All the data reveal an increase by a factor of ~2 in the sAOD (stratospheric  
28 Aerosol Optical Depth) with respect to values observed before the eruption. The aerosol mass  
29 e-folding time is approximately 90 days which is rather close to the value (~80 days) reported

1 for the Sarychev eruption. Microphysical measurements obtained before, during and after the  
2 eruption reflecting the impact of the Calbuco eruption on the lower stratospheric aerosol content  
3 have been analyzed over the Reunion Island site. During the passage of the plume, the volcanic  
4 aerosol was characterized by an effective radius of  $0.16 \pm 0.02 \mu\text{m}$  with a unimodal size  
5 distribution for particles above  $0.2 \mu\text{m}$  diameter. Particle concentrations for sizes larger than  $1$   
6  $\mu\text{m}$  are too low to be properly detected by the LOAC OPC. The aerosol number concentration  
7 was  $\sim 20$  times higher that observed before and one year after the eruption. According to OMPS  
8 and LiDAR observations, a tendency toward conditions before the eruption has been observed  
9 by April 2016. The volcanic aerosol plume is advected eastward in the Southern Hemisphere  
10 and its latitudinal extent is clearly bounded by the subtropical barrier and the polar vortex. The  
11 transient behavior of the aerosol layers observed above Reunion Island between May and July  
12 2015 reflects an inhomogeneous spatio-temporal distribution of the plume which is controlled  
13 by the localization of these dynamical barriers.

## 14 1. Introduction

15 Stratospheric aerosols affect the chemical and radiation balance of the atmosphere (McCormick  
16 et al., 1995; Solomon, 1999; SPARC 2006). The importance of stratospheric aerosols on the  
17 chemistry is mostly due to its role in the ozone budget (Solomon et al., 1986; Bekki, 1997;  
18 Borrmann et al., 1997). Stratospheric aerosols provide sites for heterogeneous chemical  
19 reactions leading to stratospheric ozone depletion, significantly enhanced in periods of high  
20 aerosol loadings following major volcanic eruptions (Solomon, 1999 and references therein).  
21 In addition, periods of enhanced stratospheric aerosols loadings can lead to significant warming  
22 in the stratosphere and cooling in the troposphere (e.g. McCormick et al., 1995; Solomon et al.,  
23 2011; Arfeuille et al., 2013). As reported by Kremser et al. (2016), a better understanding of  
24 the processes governing the lifetime of stratospheric aerosols are needed to assess the impacts  
25 on climate and chemistry. Since the discovery of the permanent stratospheric aerosol layer,  
26 called Junge Layer, in 1961 (Junge, 1961), it has been established that stratospheric aerosols  
27 are mostly composed of sulfuric acid droplets with some more complex characteristics in the  
28 stratosphere where organic compounds and meteoritic dust can also contribute to its  
29 composition (Froyd et al., 2009; Mossop, 1965; Murphy et al., 1998). The main sources of  
30 stratospheric sulfur are Carbonyl Sulfide (OCS), Dimethyl Sulfide (DMS) and sulfur dioxide  
31 ( $\text{SO}_2$ ) (SPARC, 2006), the latter being significantly enhanced after volcanic eruptions (Carn et  
32 al., 2015). The injected  $\text{SO}_2$  into stratosphere is oxidized into  $\text{H}_2\text{SO}_4$ , which (after homogeneous  
33 nucleation and/or condensation onto existing aerosol particles) causes an increase in the content

1 of liquid sulfate aerosol (SPARC, 2006). Based on the control of the stratospheric aerosols  
2 burden over the last 25 years, Thomason et al. (2007) showed that volcanic effects dominate  
3 over natural and anthropogenic sources. Previous studies on stratospheric aerosols have  
4 significantly characterized its properties and variability during “background” (i.e. free of  
5 volcanic aerosols) and volcanic conditions (e.g., Stenchikov et al., 1998; Jäger and Deshler,  
6 2002; Bauman et al., 2003; Hermann et al.; 2003; Hofmann et al.; 2009).

7 The eruption of Pinatubo in 1991 is known to be the last major volcanic eruption injecting  
8 between 14 and 23 Tg of SO<sub>2</sub> significantly perturbed the global stratosphere for several years  
9 (Kinnison et al., 1994; McCormick et al., 1995; Stenchikov et al., 1998, 2002; Guo et al.,  
10 2004; Dhomse et al., 2014). As reported by Russell et al. (1996), in addition to the prodigious  
11 increase in the stratospheric aerosols loading, this event significantly affected numerous aspects  
12 of the atmospheric system including: i) a 2-year cooling of the global surface temperature of  
13 several tenths of degrees (Canty et al., 2013; Wunderlich and Mitchell, 2017); ii) a warming of  
14 the tropical stratosphere ranging from 1° to 4°C (Labitzke and McCormick et al., 1992; Young  
15 et al., 1994); (iii) a lifting of the tropical ozone layer by ~1.8 km (Pueschel et al., 1992; Grant  
16 et al., 1994). By the use of satellite and balloon-borne observations, various studies have shown  
17 that moderate volcanic eruptions (i.e., volcanic explosive index less or equal to 4) can  
18 significantly modulate stratospheric aerosols concentrations (Bourassa et al., 2010; Kravitz et  
19 al., 2010; Solomon et al., 2011; Vernier et al., 2011; Clarisse et al., 2012; Jégou et al., 2013).  
20 Based upon satellite observations, Vernier et al (2011) showed that the decadal increase in  
21 stratospheric aerosol loadings since 2002 can be attributed to a series of moderate volcanic  
22 eruptions. As reported by Kremser et al (2016), this decadal trend was also obtained from  
23 LiDAR (Hofmann et al., 2009; Trickl et al., 2013; Zuev et al., 2017) and ground-based sun-  
24 photometer observations (Ridley et al., 2014). **Three moderate volcanic eruptions occurred in  
25 the 2002-2012 period are ranked in the top 10 of the most influential events on the stratospheric  
26 aerosol burden including:** (1) The Kasatochi eruption (52.2° N; 175.5° W, Alaska) in 2008 which  
27 injected 1.5-2.5 Tg of SO<sub>2</sub> into the upper troposphere and lower stratosphere (UTLS) (Bourassa  
28 et al., 2010; Kravitz et al., 2010; Krotkov et al., 2010); (2) The Sarychev eruption in June 2009  
29 (48.1°N; 153.2°E, the Kuril Island) which released 0.9 Tg of SO<sub>2</sub> into the UTLS (Clarisse et al.,  
30 2012; Kravitz et al., 2011; Jégou et al., 2013); (3) The Nabro eruption (13.4°N; 41.7°E, Eritrea)  
31 in June 2011 which emitted 1.3 Tg of SO<sub>2</sub> into the UTLS (Bourassa et al., 2012; Sawamura et  
32 al.; 2012). In comparison, these recurrent moderate volcanic eruptions injected 10-20 times less  
33 SO<sub>2</sub> than the Pinatubo eruption (Solomon et al., 2011). These eruptions can also be used to

1 understand stratospheric dynamics as was done for the case of the Pinatubo eruption (Trepte et  
2 al., 1992).

3 Indeed, following a volcanic eruption, stratospheric aerosols can be used as a dynamical tracer  
4 (Bencherif et al., 2003; Fairlie et al., 2014). Based on satellite observations and a Lagrangian  
5 trajectory model, Fairlie et al. (2014) used the dispersion of the Nabro plume to study the  
6 dynamics of the Asian Monsoon Anticyclone. Hitchman et al. (1994) and SPARC (2006)  
7 suggested that the stratospheric aerosols distributions could be used to understand changes in  
8 the Brewer-Dobson Circulation. More recently, Ray et al. (2014) combined in situ balloon  
9 observations of SF<sub>6</sub>, CO<sub>2</sub> with a numerical model to show that major explosive volcanic  
10 eruptions can induce large-scale changes in the stratospheric circulation via radiative  
11 perturbations, improving our understanding of stratospheric transport variability. Aerosols  
12 heating in the lower stratosphere induces a westerly wind anomaly, and enhanced tropical  
13 upwelling (Ray et al., 2014; Pitari et al., 2016a). Using the University of L'Aquila climate-  
14 chemistry model (ULAQ-CCM), Pitari et al. (2016a) analyzed the volcanic aerosols  
15 perturbation from the eruption of Mt. Pinatubo on the transport of long-lived species, N<sub>2</sub>O and  
16 CH<sub>4</sub>. They showed that the observed decline of long-lived greenhouse gases one year after the  
17 eruption is quantitatively consistent with enhanced stratosphere-troposphere exchange, due to  
18 a change in the Brewer–Dobson circulation. They also revealed that the volcanic aerosols  
19 radiative perturbation to stratospheric dynamics may be found by looking at the stratospheric  
20 age-of-air. According to Pitari et al (2016a), enhanced tropical upwelling tends to decrease the  
21 tropical age of air and the latitudinal age gradient after major volcanic eruptions. Although most  
22 studies discuss major tropical eruptions and their induced dynamical effects, we cannot exclude  
23 the possibility that extratropical eruptions in the last 15 years may also have had a significant  
24 role in lower stratospheric trends of key dynamical quantities (Kremser et al., 2016).

25 Previous works have also revealed that stratospheric aerosols can be used to study meridional  
26 air mass transport from the tropical stratospheric reservoir (Trepte and Hitchman, 1992; Randel  
27 et al., 1993; Chen et al., 1994; Grant et al., 1996, Vernier et al., 2009). Based on satellite  
28 observations, Trepte and Hitchman (1992) have shown that transport from the tropics to mid-  
29 latitudes is favored during westerly shear phases of the quasi-biennial oscillation (QBO) rather  
30 than during the easterly shear phases. More recently, by the use of satellite observations and  
31 climate models, Hommel et al. (2015) revealed that the vertical and latitudinal extent of the  
32 stratospheric aerosol layer (between 16 and 31 km) in the tropics is modulated by the QBO.  
33 Pitari et al. (2016b) analyzed the radiative perturbations in the stratosphere induced by the last  
34 five major volcanic eruptions after 1960 (i.e, Agung, St Helens, El Chicon, Nevado del Ruiz

1 and Pinatubo) using a climate model which included an aerosols microphysics module for  
2 aerosols formation and growth. They found an increase in stratospheric temperature associated  
3 with a significant impact on the tropical upwelling. The impact on stratospheric upwelling is  
4 found to be larger when the volcanically perturbed stratospheric aerosols are confined to the  
5 tropics, as tends to be the case for eruptions which are followed for several months with easterly  
6 shear of the QBO. They showed that the Nevado del Ruiz and Pinatubo eruptions occurred  
7 during years with dominant QBO easterly shear, which led to the confinement of the aerosols  
8 near the equator, with less poleward transport. This tropical confinement produced a larger  
9 latitudinal gradient of the perturbation heating rate and a stronger impact on the tropical  
10 upwelling (Pitari et al., 2016b). It is worth noting that the life cycle of an aerosol is affected by  
11 sedimentation. The fact that sulphuric particles grow larger following major eruptions (e.g.  
12 Russell et al., 1996; Bauman et al., 2003) means they can sediment appreciably during transport  
13 within the stratosphere, causing the plume transport to diverge from the expected isentropic  
14 trajectory. Even in moderate eruptions, where sulphuric particle growth may not be significant,  
15 the accommodation of sulphur on to ultra-fine ash particles has the potential to also change the  
16 fate of a proportion of the volcanic plume.

17 This paper reports on the Calbuco plume observations over Reunion Island (20.5°S; 55.5°E) and  
18 its transport in the southern tropics. The geometrical and optical properties of the Calbuco  
19 plume are inferred from the ground-based observations at Reunion Island in the framework of  
20 the MORGANE (Maïdo ObservatoRy Gas Aerosols NDACC Experiment) campaign. The aim  
21 of this study is to provide a description of the dynamical context which has favored the spread  
22 of the Calbuco plume in the **Southern Hemisphere**. The paper is organized as follows: Section  
23 2 describes the observations and the model used for the investigation of the volcanic aerosol  
24 transport. A description of the long-range transport of the volcanic plume over the Indian Ocean  
25 is provided in Section 3; Section 4 gives a dynamical analysis of this case study; and the  
26 summary and the conclusions are given in Section 5.

## 27 **2. Instrumentation and model description**

### 28 **2.1 Observations**

#### 29 **2.1.1 Ground-based LiDAR**

30 One part of the observations used in this study was performed during the MORGANE campaign  
31 which took place at the Maïdo observatory on Reunion Island in May 2015. The MORGANE  
32 ground-based observational systems combine LiDAR and balloon-borne payloads to study the

1 composition and the dynamics of the UTLS in the southern hemisphere. Among measurement  
2 data from four LiDAR systems operated during this campaign, we used data from the  
3 Differential Absorption Lidar (DIAL) system built for stratospheric ozone monitoring (Baray  
4 et al., 2013). It is also possible to retrieve aerosol profiles in the 15-38 km altitude range from  
5 these measurements. This instrument has been in operation at the Maïdo observatory since early  
6 2013. The technical details and evaluation of its performance are given by Baray et al., (2013).  
7 A brief description of this DIAL system follows. It uses a frequency-tripled Nd:YAG laser,  
8 which provides a beam at 355 nm wavelength, with a repetition rate of 30 Hz and a XeCl  
9 excimer laser which emits radiation at 308 nm at 40 Hz. The optical receiver is a telescope  
10 composed of 4 parabolic mirrors where the backscattered signal is collected by 4 optical fibers  
11 located at the focal points. The current configuration of the DIAL LiDAR system mainly detects  
12 signals in the UV regions of the spectrum (308, 332, 355 and 387 nm). The LiDAR data set  
13 used in this study consists of daily records of backscattering signal obtained from the Maïdo  
14 facility between 1 November 2014 and 30 November 2016 (106 profiles). It should be noted  
15 that no measurements were recorded at Reunion Island from January to April 2016 because of  
16 technical problems. The daily measurements are nighttime and time-integrated over about 3  
17 hours in average.

18 We used the methodology described by Sasano (1985) to obtain the extinction and backscatter  
19 coefficient from a Rayleigh-Mie LiDAR. This methodology is similar to the approach of Klett  
20 (1981) with the advantage of providing a numerical calculation of the extinction and backscatter  
21 coefficient. Temperature and pressure profiles are needed to retrieve optical properties from  
22 this approach. For this study temperature and pressure profiles obtained from a radiosondes  
23 launched from the airport of Gillot at 11h (UTC) are used. In order to obtain a complete  
24 temperature and pressure profiles range from **the ground to mesosphere**, we used the Arletty  
25 atmospheric model (Hauchecorne et al., 1998; Nair et al., 2012), based on European Centre for  
26 Medium Range Weather Forecast (ECMWF) data. The altitude of reference is determined for  
27 each profile. On average, the reference altitude is located between 30 and 40 km. Another  
28 parameters that we need to retrieve the optical properties is the ratio of backscatter and the  
29 extinction coefficient for aerosol, also called lidar ratio. For background stratospheric aerosol,  
30 the value found in the literature is near 60 (Trickl et al., 2013 ; Ridley et al., 2014; Sakai et al.,  
31 2016; Khaykin et al., 2017). This value is commonly used for volcanically quiescent conditions  
32 and periods of moderate eruptions (Sakai et al., 2016). The LiDAR ratio depends on the particle  
33 size distribution and the type of aerosol (Jäger and Deshler, 2002; Young and Vaughan, 2009).

1 Error in the LiDAR ratio could influence significantly the uncertainty on aerosols extinction  
2 and optical depth (Sakai et al., 2016; Khaykin et al., 2017). Moreover, it should be noted that  
3 new approaches to derive extinction from LiDAR, which also measure depolarization, have  
4 been developed and already applied to space-borne lidar such as CALIOP (Young and  
5 Vaughan, 2009).

### 6 **2.1.2 Balloon-borne OPC.**

7 In order to analyze the evolution of the concentration and the size of the observed aerosols over  
8 the Reunion Island site, many LOAC (Light Optical Aerosols Counter) systems were launched  
9 together with balloon-ozonesondes. A detailed description of the LOAC is given by Renard et  
10 al. (2016). In brief, LOAC is a lightweight Optical Particle Counter (OPC) of 1 kg which can  
11 fly under latex weather balloons. Through the measurements of the light scattered by particles  
12 at two specific angles (Lurton et al. 2014), the LOAC provides aerosols concentrations and  
13 particle size distributions for 19 size classes ranging from 0.2  $\mu\text{m}$  to 50  $\mu\text{m}$  in diameter every  
14 ten seconds with a vertical resolution of nearly 50 m depending on the ascent rate of the balloon.  
15 The number concentration range is from 0.6 to a few thousand particles per  $\text{cm}^3$  (Vignelles,  
16 2017). Uncertainties on number concentration during the ascent under meteorological balloon  
17 are mainly due to temperature variation effects on electronics (Renard et al., 2016, Vignelles,  
18 2017). Uncertainties on number concentrations for size bins smaller than 1  $\mu\text{m}$  is estimated to  
19 be  $\pm 30\%$ . For larger size bins, uncertainties on number concentration are governed by Poisson  
20 statistics and estimated to be  $\pm 20\%$  and  $\pm 60\%$  at particle concentrations lower than  $10^{-1}$  and  
21  $10^{-2} \text{ cm}^{-3}$ , respectively.

### 22 **2.1.3 CALIOP**

23 The Cloud-Aerosols Lidar with Orthogonal Polarization (CALIOP) on board The Cloud-  
24 Aerosols Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) was used to study the  
25 transport of the Calbuco plume. CALIPSO was launched to a Sun-synchronous polar orbit in  
26 2006 (Winkler et al., 2009) with a repeat cycle of 16 days. CALIPSO is composed of an Infrared  
27 Imager Radiometer (IIR), a wide field visible camera and the CALIOP LiDAR. CALIOP is a  
28 two-wavelength polarization-sensitive LiDAR (532 and 1064 nm) which measures total  
29 attenuated backscatter vertical profiles with altitude-varying vertical (30-300 m) and horizontal  
30 (300-5000 m) resolution (Winker et al., 2009). The data used in this study are the total and  
31 perpendicular backscatter coefficient at 532 nm, available from the CALIOP level 1B V4.01  
32 product. These data have been averaged every 1 degree in latitude for each orbit and grouped

1 into data files containing 16 days of measurements. From there, the scattering ratio and  
2 depolarization ratio at 532 nm have been calculated (Vernier et al., 2009). Through the use of  
3 this algorithm, the full zonal means of scattering ratio between 20°S and 20°N are obtained by  
4 averaging 7200 cells, leading to a precision of  $\pm 1.6\%$  (Vernier et al., 2009). The ability of  
5 CALIOP to detect small volcanic plumes in the lower tropical stratosphere has been highlighted  
6 in previous studies (Thomason et al., 2007; Vernier et al., 2009, 2011).

#### 7 **2.1.4 IASI**

8 The Infrared Atmospheric Sounding Interferometer (IASI) observations were used to quantify  
9 the amount of SO<sub>2</sub> emitted during the Calbuco eruption. IASI is a nadir view thermal infrared  
10 sounder on board the Meteorological Operational satellite (MetOp-A and MetOp-B). The IASI  
11 observations used in this study were realized from the MetOp-A platform which launched in  
12 October 2006. The IASI global spatial coverage and footprint of 12 km make it relevant for  
13 monitoring of the key atmospheric species, in particular for the volcanic SO<sub>2</sub> (Clarisse et al.,  
14 2008, 2012; Clerbaux et al., 2009). The amount and altitude of emitted SO<sub>2</sub> were obtained from  
15 the algorithms detailed in Clarisse et al. (2012) and Clarisse et al. (2014) respectively. For each  
16 IASI observation, the altitude was estimated first, after which the column was calculated using  
17 the altitude information as an input parameter.

#### 18 **2.1.5 OMPS**

19 The Ozone Mapper and Profiler Suite (OMPS) Limb Profiler (LP) is also used in the present  
20 study to analyze the optical properties of the volcanic plume over the Reunion Island site.  
21 OMPS was launched in October 2011 on board the Suomi National Polar Partnership (NPP)  
22 spacecraft. The data used in this study are the daily extinction profiles at 675 nm. A detailed  
23 description of the aerosol extinction retrieval algorithm is given by Jaross et al. (2012) and  
24 Rault and Loughman (2013). Briefly, the aerosol extinction profiles are retrieved from the  
25 scattering solar radiation. The aerosols extinction are retrieved using spectral channels with  
26 weak gaseous absorption. Rodgers' maximum likelihood technique is used to retrieve the  
27 aerosol extinction profiles independently for each wavelength  $\lambda$  (Taha et al., 2011). We used 2  
28 years (From November 2014 to November 2016) of satellite overpasses above the LiDAR site,  
29 within a 5°x5° in latitude and longitude grid. OMPS data have already used to be very effective  
30 at detecting and characterizing major events, such as the Chelyabinsk bolide in February 2013  
31 (Gorkavyi et al., 2013).

#### 32 **2.2 MIMOSA model**

1 The Modèle Isentropique de transport Mésoéchelle de l'Ozone Stratosphérique par Advection  
2 (MIMOSA) model (Hauchecorne et al., 2002) is a Potential Vorticity (PV) advection model  
3 running on isentropic surfaces (surface of constant potential **temperature**). The advection  
4 scheme is semi-Lagrangian with a time step of 1 hour. The re-gridding onto the original  
5 orthonormal grid is performed every 6 hours. The model resolution is  $0.5^\circ \times 0.5^\circ$ . The advection  
6 is driven by ECMWF meteorological analyses at a resolution of  $0.5^\circ \times 0.5^\circ$ . In the case of the  
7 PV, its slow diabatic evolution is taken into account by relaxing the model PV towards the PV  
8 calculated from the ECMWF fields with a relaxation time of 10 days. Using this procedure, it  
9 is possible to run the model continuously and follow the evolution of PV filaments for several  
10 months. The accuracy of the model has been evaluated by Hauchecorne et al. (2002) and  
11 validated against airborne LiDAR ozone measurements using a correlation between PV and  
12 ozone, a quasi-conserved chemical tracer on timescales of a week or so within most of lower  
13 stratosphere (Heese et al., 2001; Jumelet et al., 2009). The MIMOSA model can also be used  
14 to determine the origin of air masses influencing a given site, similar to an isentropic Lagrangian  
15 trajectory model. The MIMOSA model is frequently used to detect the origin of air masses  
16 inducing laminae on ozone profiles (Hauchecorne et al., 2002; Godin et al., 2002; Portafaix et  
17 al., 2003).

## 18 **2.3 DyBAL code**

19 The Dynamical BARRIER Location (DyBAL) code is an original software developed at the  
20 Laboratoire de l'Atmosphère et des Cyclones (LACy, France) to detect barriers to mixing in  
21 the subtropical stratosphere (Portafaix et al., 2003). The dynamical barriers are detected from  
22 the equivalent length of the tracer contour and the gradient of isentropic Ertel's potential  
23 vorticity (PV) in equivalent latitude coordinate as defined by Nakamura (1996). These two  
24 diagnostic tools are used by DyBAL to identify weak mixing and transport barriers. The  
25 position of the dynamical barrier is characterized by a local maximum of the PV gradient and  
26 a local minimum of the equivalent length (Nakamura, 1996). The DyBAL code is applied to  
27 the PV map obtained from the MIMOSA model runs. The ability of DyBAL to detect the  
28 position and the deformation of the dynamical barriers has been highlighted in previous studies  
29 (Bencherif et al., 2007; Morel et al., 2005; Portafaix et al., 2003).

## 30 **3. Long-range transport and evolution of the Calbuco volcanic** 31 **plume over the Indian Ocean**

### 32 **3.1 Plume formation and transport**

### 3.1.1 SO<sub>2</sub> plume

1                   **3.1.1 SO<sub>2</sub> plume**

2   After 43 years of inactivity, Calbuco erupted on 22 April 2015 and two intense explosive events

3   were recorded during the same week. The evolution of the SO<sub>2</sub> total mass measured by IASI

4   between 23 April 2015 and 31 May 2015 is reported in Figure 1. The SO<sub>2</sub> total mass is defined

5   as the sum of SO<sub>2</sub> mass over the atmospheric column from midday to midnight over the

6   southern hemisphere. As expected an increase of the SO<sub>2</sub> amounts was observed by IASI a few

7   days following the Calbuco eruption. One day after the eruption the SO<sub>2</sub> total mass was 10

8   times higher than background levels. The SO<sub>2</sub> total mass increased quickly to its maximum

9   value (0.41 Tg) on 25 April 2015 and slowly decreased to reach values close to the background

10   values on 19 May 2015 (Fig. 1). The SO<sub>2</sub> e-folding time was estimated to be about 11 days that

11   is in agreement with the time value reported for the 2009 Sarychev volcanic eruption (Jégou et

12   al., 2013). The SO<sub>2</sub> total mass increased again on 28 May 2015 to reach a secondary maximum

13   (0.13 Tg) on 30 May 2015. This new increase of the SO<sub>2</sub> total mass could be due to the Wolf

14   eruption (Isabela Island, Galapagos) which occurred on 25 May 2015 (Xu et al., 2016). **The**

15   **maximum SO<sub>2</sub> total mass (0.41 Tg) emitted during the Calbuco eruption was about two times**

16   **lower than the maximum value (0.9 Tg) emitted from the Sarychev eruption (0.9 Tg) in June**

17   **2009 (Jégou et al., 2013).** It is also worth noting that the SO<sub>2</sub> mass injected during the Calbuco

18   eruption is of the same order as for the Grimsvötn eruption in May 2011 (Clarisse et al., 2011).

19   Figure 2 also depicts the maximum altitude of SO<sub>2</sub> over the period from 23 April 2015 to 31

20   May 2015. On average the maximum altitude of SO<sub>2</sub> is located in the lower stratosphere region

21   around 17 km.

22   The SO<sub>2</sub> measurements integrated from midday to midnight obtained from IASI are also used

23   to describe the transport of the volcanic plume over the southern hemisphere (Fig. 2). On 23

24   April 2015, a part of the Calbuco plume passed close to the Uruguay coast at an altitude of 17

25   km and then was transported by the general circulation. The plume reached Southern Africa

26   and East side of Madagascar on 1 May 2015 at altitude of 17-18 km and was organized

27   following a cyclonic rolling (Fig. 2b). **On 6 May, the plume was mainly located over the**

28   **Atlantic Ocean near the west coast of South Africa and partly over Namibia and South Africa.**

29   As expected, the SO<sub>2</sub> plume extent and amplitude began to diminish on 11 May 2015 by the

30   oxidation of SO<sub>2</sub> to gaseous sulphuric acid which **is further** converted into H<sub>2</sub>SO<sub>4</sub>-H<sub>2</sub>O liquid

31   aerosol. The plume was embedded in a thin 15-17 km altitude atmospheric layer, extending

32   from the Atlantic Ocean to the Indian Ocean passing over the Cape of Good Hope (Fig. 2d).

### 3.1.2 Spatial extent of the aerosol plume

1                   **3.1.2 Spatial extent of the aerosol plume**

2   The transport of the volcanic aerosols plume over the **Southern Hemisphere** can be followed by

3   CALIOP observations at 532 nm. Figure 3 shows the CALIOP cross-section of the 532nm total

4   attenuated backscatter (TAB) for the overpass over South America on 24 April. The TAB

5   signals ranging from  $1 \cdot 10^{-3}$  to  $5 \cdot 10^{-3} \text{ km}^{-1} \text{ sr}^{-1}$  corresponding to weak values of brightness

6   temperatures over the southern part of Brazil ( $34.22^{\circ}\text{S}$ ;  $53.97^{\circ}\text{W}$ ) can be attributed to volcanic

7   material injected up to the lower stratosphere by the Calbuco eruption. Figure 4 and 5 present

8   the latitude-altitude cross sections of the scattering ratio observed by CALIOP for 16-day

9   selected periods in 2015. The data displayed in Figure 4 and 5 correspond to the zonal mean

10   averages of CALIOP scattering ratio during 16-day periods. The data are calculated within  $1^{\circ}$

11   latitudinal zonal bands and have about 9% **error** (Vernier et al., 2009). The scattering ratio (SR)

12   values observed during the 16-30 April period (before the eruption) in the Southern hemisphere,

13   particularly in the lower stratosphere, were in average at 1.05 (not shown). Between one and

14   three weeks after the eruption (1-16 May period), CALIOP observations reveal that SR

15   increased up to 1.12 in the southern lower stratosphere (Fig. 4a). The amplitude of the plume

16   during the first weeks following the eruption was higher than the background aerosol levels at

17   mid-latitudes but was still below the scattering ratio values observed in the tropics. **The first**

18   **weeks following the eruption correspond to the period when the  $\text{SO}_2$  is still being converted**

19   **into  $\text{H}_2\text{SO}_4\text{-H}_2\text{O}$  liquid aerosols (Fig. 1).** The elevated backscatter in the tropics could be

20   attributed to possible remnants of the Kelud ( $7.5^{\circ}\text{S}$ ;  $112.2^{\circ}\text{E}$ ; erupted in February 2014)

21   volcanic aerosol superimposed to the equatorial background aerosol layer (Kristiansen et al.,

22   2015). About one month after the eruption (16-31 May period) the Calbuco plume was much

23   more pronounced with scattering ratio values (ranging from 1.16 to 1.18) largely above values

24   observed before the eruption from CALIOP and greater than aerosols amounts confined in the

25   tropical reservoir (Fig. 4b). The second half of May (16-31 May) corresponds to the period

26   **when  $\text{SO}_2$  has been oxidized to aerosol.** The plume extended up to about 20 km in altitude and

27   spread over a wide range of latitudes, nearly reaching  $60^{\circ}\text{S}$  and intruding into low latitudes near

28    $5^{\circ}\text{S}$ . About one month later (16-30 June), the plume top had moved upward by several hundred

29   meters and the layer was thicker (Fig. 5a). The **Southern Hemisphere** between  $10^{\circ}\text{S}$  and polar

30   latitudes was full of volcanic aerosols with scattering ratio values much higher than elsewhere

31   in the whole stratosphere. About four months after the eruption (16-31 August) the volcanic

32   aerosols layer was even thicker with scattering ratio remaining high (Fig. 5b). **Figure 5b** also

1 reveals a deepening of the volcanic aerosols layer and an enhancement of the equatorial  
2 backscatter in the Upper Troposphere.

3 In the 21-28 km altitude range, detrainment of aerosols from the equatorial reservoir depends  
4 upon the phase of the QBO and on the intensity of planetary wave activity (Trepte and  
5 Hitchman, 1992). Through the use of numerical model, Pitari et al (2016b) discussed on the  
6 impact of the QBO phase on the meridional transport of the aerosols plume to mid- and high  
7 latitudes. They revealed that the volcanic aerosols is confined to the tropics when the volcanic  
8 eruption occurred during the easterly shear of the QBO. When QBO easterlies descend in the  
9 tropics, propagation of planetary waves is inhibited from entering this region, thus limiting the  
10 extent to which these waves may detrain aerosol laterally from the tropical reservoir (Trepte et  
11 al., 1993). This corresponds to the situation in April-May, 2015 (Figure 4a, b). However, during  
12 the westerly phase of the QBO, mixing across the subtropics is favored, especially in winter  
13 (Trepte et al., 1993). The meridional spread in aerosols to southern midlatitudes shown above  
14 21 km in Figure 5a and 5b is consistent with the phase reversal of the QBO from easterlies to  
15 westerlies observed from mid-2015.

## 16 **3.2 Evolution of the aerosols plume over the Reunion site**

### 17 **3.2.1 Ground-based and satellite observations**

18 Figure 6 depicts the evolution of the stratospheric AOD (sAOD) at 532 nm calculated between  
19 17 and 30 km from the Reunion ground-based LiDAR and OMPS observations over Reunion  
20 Island from November 2014 to November 2016. The wavelength conversions to 532 nm were  
21 performed using the Angström exponents where detailed description of the methodology is  
22 given by Khaykin et al (2017). The Angström exponents for the 355-532 nm and 532-675 nm  
23 pairs were adopted from Jäger and Deshler (2002) and Khaykin et al (2017) set to -1.3 and -1.8  
24 respectively. sAOD were calculated from LiDAR and OMPS observations at 532 nm using  
25 Angstrom exponent mentioned previously. As expected, an increase in the aerosol loading was  
26 observed over the Reunion site a few weeks after the Calbuco eruption. OMPS data show a  
27 doubling in the sAOD record in comparison with values observed at the end of 2014 and at the  
28 beginning of 2015 (Fig. 6). sAOD reached its maximum values (0.014 for OMPS) at the  
29 beginning of June 2015, decreased afterward to 0.01 on August 2015 and went back to pre-  
30 eruption values (0.004-0.006) in April 2016. The LiDAR record peaks at the same period, but  
31 sAOD values are 1.2 times weaker than those observed by OMPS during the June-December  
32 period. The LiDAR sAOD observations show less difference with values obtained prior to the

1 eruption (0.008). Discrepancies between OMPS and LiDAR were significantly reduced by  
2 April 2016, (cf. relative differences of 25% over the January-December 2015 period and 10%  
3 over the April-November 2016 period). From both datasets an aerosols e-folding of  
4 approximately 90 days can be derived, which is rather close to the value ( $\sim 80$  days) reported  
5 for the Sarychev eruption (Jégou et al., 2013).

6 Figure 7a illustrates the weekly-averaged extinction profiles at 532 nm derived from LiDAR  
7 measurements over Reunion Island. This figure reveals a sharp increase of the extinction  
8 between 18 and 19 km in May 2015 and reaching its maximum value (greater than  $4 \times 10^{-3} \text{ km}^{-1}$ )  
9 in June. The vertical extent of the plume had increased significantly over the May-July period  
10 with a volcanic aerosols layer spanning from 18 to 21 km. At the beginning of June, the plume  
11 was structured in two layers with the first one centered at 18.5 km and the second one at 20 km  
12 (Fig.7a). We note also a brief decrease in the local extinction, ranging from  $1.5$  to  $3 \text{ km}^{-1}$ , around  
13 mid-May. The variability observed in the weekly-averaged extinction profiles and in the  
14 vertical extent of the aerosols signal over the May-July period reflects the presence of transient  
15 aerosol layers above Reunion Island and indicates that the plume is not homogeneously  
16 distributed at this stage. The altitude of the volcanic aerosols plume and the extinction values  
17 decreased from mid-August onwards. The plume is hence centered around 18 km in September,  
18 and extinction values in September are around two times less than those observed in June. This  
19 decrease of the extinction values is accompanied by a decrease of the altitude of the plume and  
20 could be due to the sedimentation processes (Fig. 7a). Hamil et al (1997) revealed that  
21 sedimentation can play a significant role in loss of stratospheric aerosols to the troposphere.  
22 Overall, the temporal evolution of the weekly-averaged extinction presents similar general  
23 features as the LiDAR observations, with maximum values in June and a subsequent gradual  
24 decrease of the aerosol signal. Nevertheless, in the OMPS data the plume is smeared out over  
25 a wider vertical range than in the lidar record (Fig. 7b). The vertical and horizontal structures  
26 of the plume are not reproduced in the OMPS data. In particular, the decrease in the plume  
27 altitude in mid-August is not observed by OMPS. More generally, extinction values observed  
28 by OMPS in the 15-17 km altitude range are higher than those observed by the LiDAR. The  
29 evolution of the scattering ratio at 532 nm obtained from the LiDAR and CALIOP space-borne  
30 observations during the April-December 2015 period over the Reunion Island site are presented  
31 on Figure 8. The scattering ratios from CALIOP have been averaged within  $\pm 5^\circ$  in latitude and  
32  $\pm 50^\circ$  in longitude (extending from Africa to Australia) around Reunion Island (Fig. 8b).  
33 CALIOP observations confirm the presence of the volcanic aerosols plume over the Reunion

1 Island site at the beginning of May 2015 with maximum scattering ratio values (greater than  
2 1.9) on mid-May 2015. Overall, the aerosols variability is smoother in CALIOP observations  
3 than in the LiDAR record, which shows more fluctuations in the altitude of the volcanic plume.  
4 In contrast to the LiDAR and OMPS observations, CALIOP data do not show an increase in  
5 the vertical extent of the plume and maximum scattering ratio values at the beginning of June  
6 2015. According to CALIOP, the scattering ratio begins to decrease in mid-June followed by a  
7 slight decrease of the altitude of the plume from the end of July (Fig 8b). From July onwards,  
8 the CALIOP aerosol scattering ratios decrease gradually with similar values as observed by the  
9 LiDAR. The decrease of the aerosols scattering ratio is associated with a descent in the altitude  
10 of the plume, which could be due to sedimentation, and is consistent with the observations from  
11 OMPS.

12 The reasons for these discrepancies between ground-based and satellite observations may be  
13 multiple but effects due to different spatial samplings cannot be excluded. The difference in  
14 vertical resolution between ground-based LiDAR and satellites (OMPS, CALIOP) which could  
15 be one possible cause at the origin of discrepancies. The discrepancies between the satellites  
16 and ground-based LiDAR could be significant when the difference of vertical resolution is high  
17 between these devices. **We note that the vertical resolution of OMPS is 10 times lower than the**  
18 **ground-based LiDAR with 1.5 km and 0.15 km respectively (Jaross et al., 2012).** Thus, the  
19 structures of the plume look smoother than those obtained from the ground-based LiDAR. In  
20 the case of CALIOP where the vertical resolution is better (~ 3 times less to the ground-based  
21 LiDAR), the differences in the structure of the plume are less. Moreover, the discrepancies  
22 existing between results presented in this study could be also due to horizontal resolution or  
23 different measurement techniques. Unlike satellite experiments that allow global observations,  
24 a ground-based LiDAR system is able to derive aerosols characteristics at a specific location.  
25 OMPS views the Earth's limb looking backward along the orbit track of approximately 125 km  
26 with a horizontal resolution of 50 km. It is difficult for OMPS to detect with accuracy small  
27 amount of aerosol at a local point with these weak vertical and horizontal resolutions. It is for  
28 this reason that the structure of the plume observed since July is not in agreement with the  
29 ground-based LiDAR. As we will discuss more details in Section 4, the dynamical context can  
30 induce an inhomogeneity of the plume. As a consequence, this inhomogeneity of the plume  
31 could lead to incorrect identification of the volcanic aerosols by the satellites.

### 32 **3.2.2 In-situ observations**

1 Four LOAC OPCs were launched over the Reunion Island site on 26 November 2014, 19 May  
2 2015, 19 August 2015, and 2 November 2016 respectively. sAOD 532 nm were calculated  
3 following Mie Theory from fits to the observed size distributions at each level. LOAC  
4 observations also reveal an increase by a factor of 2 in the sAOD on 19 May 2015 ( $1.35 \times 10^{-2}$ ).  
5 sAOD decreases to  $8.4 \times 10^{-3}$  on 19 August 2015 followed by a return to pre-eruption levels  
6 by November 2016 (Fig. 6). The overall evolution of sAOD derived from LOAC compares  
7 fairly well to OMPS and to lidar observations, accounting for error bars (Fig. 6). The 10-second  
8 sampling rate of the LOAC instrument and the ascent velocity of the balloon determine the  
9 vertical resolution. The difference observed between the daily LiDAR and the in-situ data may  
10 be due to the 1-minute averaging of the in-situ data, which tends to smooth structure attributed  
11 to the volcanic aerosols.

12 Figure 9 illustrates the number ( $dN/d\ln(D)$ ) and volume ( $dV/d\ln(D)$ ) concentrations obtained  
13 from the LOAC OPC observations over the Reunion Island site on 19 May 2015 at 1746 UTC.  
14 LOAC OPC observations reveal a size distribution with decreasing concentrations for particle  
15 sizes larger than  $0.2 \mu\text{m}$  (Fig. 9). The value of  $0.2 \mu\text{m}$  represents the lower bound of the LOAC  
16 size range, so the data may miss possible secondary modes for smaller particles (Wilson et al.,  
17 2008). Particle concentrations for sizes larger than  $1 \mu\text{m}$  are too low to be properly detected by  
18 the LOAC OPC and undoubtedly indicate a coarse mode. However there is no clear evidence  
19 for a bimodal distribution, as observed during the first weeks after the eruption of Mt. Pinatubo,  
20 an intense second mode possibly consisting of volcanic ash (e.g. Russell et al., 1996). The shape  
21 of the size distribution obtained during the Calbuco event is similar to that obtained by Kravitz  
22 et al. (2011) for the Sarychev eruption. As suggested by Kravitz et al. (2011), we can also  
23 assume that the Calbuco eruption did not eject enough material to create a bimodal structure  
24 over Reunion Island.

25 The effective radius derived from the LOAC OPC on 19 May is  $0.17 \pm 0.02 \mu\text{m}$  indicating that  
26 the particles observed several weeks after the Calbuco eruption are quite small. Interestingly,  
27 Jégou et al. (2013) reported that the effective radius obtained during the Sarychev event ranged  
28 from  $0.15$  to  $0.20 \mu\text{m}$  more than one month after the eruption, in agreement with the results of  
29 O'Neill et al. (2012). Therefore, both eruptions are comparable in terms of size distribution  
30 shape and effective radius. Russell et al. (1996) reported that in the month following the  
31 Pinatubo eruption the mean effective radius did not differ greatly from pre-eruption values (i.e.  
32  $0.17 \pm 0.07 \mu\text{m}$  in their study), possibly because a large number of particles with sizes both  
33 smaller and larger than  $0.17 \mu\text{m}$  were injected (the latter consisting most likely of volcanic ash).

1 The integrated number of particles obtained over the full 19 size classes from 0.2 to 50  $\mu\text{m}$  in  
2 diameter is presented in Figure 10. A local aerosols concentration enhancement is detected in  
3 the lower stratosphere (16.8-19 km) over Reunion Island on 19 May 2015 at 1746 UTC. A  
4 maximum concentration of about 150  $\text{particles.cm}^{-3}$  (total number of particles:  $730 \pm 130$   
5 particles ( $\pm 1\sigma$ )) is observed by the aerosols counter for particle sizes larger than 0.2  $\mu\text{m}$ . Few  
6 in situ observations are available in the tropical region such as Reunion Island to provide a  
7 reference state of the background aerosols content. In comparison to LOAC flight on 26  
8 November 2014 at 1442 UTC (five months before the eruption), the aerosols number  
9 concentration observed on 19 May 2015 is  $\sim 20$  times higher. Three months later, another LOAC  
10 OPC was launched over the Reunion Island site but the in situ profile only partially shows the  
11 volcanic aerosols layer because of a telemetry loss. The aerosols number concentration obtained  
12 on 19 August 2015 at 1300 UTC over Reunion Island may reveal a tendency to return to  
13 concentration values observed before the eruption (Fig. 10), with a number concentration of 40  
14 particles per  $\text{cm}^3$  in the lower stratosphere. This tendency is confirmed with the LOAC flight  
15 conducted on 2 November 2016 at 2030 UTC with a total number concentration close to 20  
16  $\text{particles.cm}^{-3}$  in the lower stratosphere (Fig. 10).

17 The residence time of the aerosols particles in the stratosphere depends on the balance between  
18 the growth processes and the removal processes which are likely to be controlled by the  
19 dynamical context. In the following section, we will discuss the influence of the dynamical  
20 activity on the variability of the volcanic aerosols over the Southern Hemisphere.

## 21 4. Dynamical modulation of the aerosol plume

### 22 4.1 Long-range transport

23 In order to analyze the isentropic transport, the high resolution MIMOSA model has been used  
24 to produce a continuous evolution of PV fields for the period from 1 April 2015 to 31 August  
25 2015. Four advected PV maps, derived for the 400 K isentropic level from the MIMOSA model,  
26 together with dynamical barrier locations derived from the DyBaL code are superimposed in  
27 Figures 11 and 12. The localization of the volcanic aerosols plume obtained from OMPS  
28 observations at  $400 \text{ K} \pm 5 \text{ K}$  isentropic level is also superimposed (Fig. 11 and 12). On 24 April  
29 2015, a significant wave activity is observed, leading to a fairly mixed surf zone in the  $20^\circ\text{S}$ -  
30  $60^\circ\text{S}$  latitude band (not shown). The Calbuco plume is situated inside the surf zone and the  
31 plume was mixed equatorward. On 27 April 2015, the subtropical and mid-latitude barrier are  
32 detected following the Nakamura's formalism (described in Section 2.3) around  $15^\circ\text{S}$  (red line,

1 Fig. 11) and 40°S (blue line) in latitude respectively, limiting the geographical extent of the  
2 plume (Fig. 11a). Figure 11a shows clearly that the air masses containing aerosols cannot move  
3 beyond the south of Brazil because of the presence of the subtropical barrier. On 01 May 2015,  
4 the air masses were confined between the two dynamical barriers located in average at 25°S  
5 (red line, Fig. 11b) and 40°S (blue line, Fig.11b) in latitude respectively. The air masses were  
6 advected eastward between South Africa and Madagascar following the wave shape of the  
7 barrier, consistent with the OMPS observations near South Africa (Fig. 11b). The subtropical  
8 barrier previously located at 25°S (red line, Fig.11b) moved northward crossing South Africa.  
9 The air masses containing aerosol previously situated in the south side of Madagascar were  
10 transported northward and eastward following the displacement of the barrier and reached the  
11 Reunion Island site.

12 On 19 May 2015 (Fig. 12a), the volcanic aerosol plume was confined between the two  
13 dynamical barriers and advected eastward. At this stage, the presence of the subtropical barrier  
14 and the polar vortex seems to constrain the Calbuco plume inducing its transport eastward.  
15 Between end of May and beginning of June, the subtropical barrier has dissipated while the  
16 edge of the polar vortex was around ~40°S (blue line, Fig. 12b). The OMPS observations reveal  
17 that the most part of the plume was located over the southern African and the Indian Ocean  
18 region in June (Fig. 12b). On the following months of July and August, the polar vortex is  
19 clearly identified at 60°S (blue line, Fig. 12b) which is a classical pattern for the austral winter.

20 This present study discuss only on the transport of the volcanic aerosols plume at 400 K  
21 isentropic level (isentropic level where the Calbuco plume is detected at Reunion). **Figure 4 and**  
22 **5 reveal that the meridional transport of the plume occurred between 12 and 20 km. In**  
23 **particular, Figure 5b reveals also the possibility to the Calbuco aerosols plume to penetrate the**  
24 **polar vortex at the end of August 2015. This assumption seems to be consistent to the works**  
25 **reported by Ivy et al. (2017) and Solomon et al. (2016).** Based on SD-WACCM (Specified  
26 Dynamics-Whole Atmosphere Community Climate Model) model and balloon observations at  
27 Syowa (69°S; 34.58°E), Solomon et al. (2016) discussed on the impact of the Calbuco plume  
28 on the deepest Antarctic ozone depletion observed in October 2015. They reveal that the  
29 integrated additional Antarctic ozone column losses averaged over the polar cap are between 5  
30 and 13 DU following the Calbuco eruption. Through the use of FR-WACCM (free-running  
31 Whole Atmosphere Community Climate Model), Ivy et al. (2017) shown that the forced  
32 response to the eruption of Calbuco was an increase in the size of the ozone hole by  $4.5 \cdot 10^6$   
33  $\text{km}^2$ .

## 4.2 Removal processes

As discussed above, in the lower stratosphere distributions of the aerosols are modulated (or mostly driven) by isentropic transport. However, particle removal processes should be considered. As reported by Kremser et al (2016), aerosol in the vicinity of the tropopause can be transported into the troposphere by variety of mechanisms. Hamill et al. (1997) reported that stratosphere-troposphere exchange (STE) on isentropic surfaces due to Rossby wave activity can be considered a significant dynamical process for removal of stratospheric aerosols. Depending on the strength of the Brewer-Dobson circulation, stratospheric materials such as aerosols can be rapidly transported from the tropics to high latitudes (Dhomse et al., 2006, 2014). Based on semi-Lagrangian and analyzed winds from ECMWF, Chen et al. (1995) investigated the extratropical STE on isentropic surfaces that intersect the tropopause. Above 340 K they found that STE exhibits a strong annual cycle where very little STE takes place in the winter hemisphere, but significant STE occurs in the summer hemisphere, particularly in the northern summer. The weak STE in the winter hemisphere is mainly due to the barrier effect of the strong PV gradient at the tropopause (Chen et al., 1995). Through the use of 10 years of LiDAR observations at Pasadena (34°N, 118°W; California), Menzies and Tratt. (1995) found a clear link between the aerosol optical properties in UT-LS and the active extratropical STE processes occurring the winter and early spring. The calculated stratospheric mass extrusion rate is consistent with a 45-day lifetime of lower stratospheric aerosols during this part of the year, which implies that extratropical STE is a significant sink for stratospheric aerosols (Menzies and Tratt, 1995). Given the potential of a STE event to impact the stratospheric aerosols loading, we cannot exclude its contribution (even though small) on the stratospheric aerosols loading at Reunion Island.

Dhomse et al. (2014) using the CCM model (UM-UKCA) discussed the influence of STE events on the budget of the stratospheric aerosols. In particular, they suggested that a general overestimation of STE in global composition climate models could lead to overestimated removal of aerosols from stratosphere into the troposphere. Through the use of ULAQ-CCM model, Pitari et al (2016b) shown that the efficiency of STE depends on large-scale transport following the down-welling branch of the Brewer-Dobson circulation together with gravitational settling. The long-range transport of a volcanic plume is less likely to be isentropic, due to sedimentation of ash or other large particles (with any accommodated sulphur) within the plume. The modulation of the plume over Reunion Island could be caused by particle removal processes such sedimentation (considered as the primary loss mechanism

1 of stratospheric aerosol) or by dilution of the stratospheric plume (Hamill et al, 1997; Rasch et  
2 al., 2008). Sedimentation is an effective removal mechanism for particles that survive long  
3 enough in the stratosphere to grow to larger sizes (Hamill et al., 1997).

4 We note the potential role of removal processes on the initial dispersion of volcanic aerosols,  
5 in particular co-emitted ultrafine ash particles, but do not explore this effect here. Highlighting  
6 removal processes from Figures 7 and 8 is somewhat complicated by the transience in plume  
7 altitudes especially in the LiDAR local data. The potential role of removal processes on the  
8 evolution of the plume requires further investigation and will form the basis for a forthcoming  
9 study.

## 10 **5. Summary and conclusion**

11 The long-range transport of the volcanic aerosol produced following the Calbuco eruption has  
12 been examined. The analysis focuses on the dynamical context which led to the spread of the  
13 aerosol plume over Indian Ocean between April 2015 and November 2016. The transport of the  
14 volcanic aerosols to the Indian Ocean was investigated by combining satellite (CALIOP, IASI,  
15 OMPS), and ground-based experiments: Optical Particle Counter (LOAC) and LiDAR, in  
16 addition to numerical tools: the DyBal code and the high-resolution MIMOSA model.

17 The amount of SO<sub>2</sub> injected into the atmosphere during the Calbuco eruption has been  
18 quantified using IASI observations. SO<sub>2</sub> mass emitted by the Calbuco eruption was about two  
19 times lower than for the moderate Northern Hemisphere eruption of Sarychev in June 2009, but  
20 had a similar SO<sub>2</sub> e-folding time (Jégou et al., 2013; Kravitz et al., 2011). It is found from  
21 CALIOP observations that the Calbuco aerosol layer was observable in the lower stratosphere,  
22 between 18 and 21 km, and spread exclusively in the **Southern Hemisphere**. OMPS  
23 observations reveal that the Calbuco plume reached the Indian Ocean two weeks after the  
24 eruption. It is shown from ground-based observations deployed at Reunion Island that SAOD  
25 increased by a factor of ~2 by the beginning of May 2015 and decreased afterward, returning  
26 to pre-eruption values by November 2016. The aerosols e-folding time is estimated to be ~90  
27 days, close to the ~80 days reported for the Sarychev eruption (Jégou et al., 2013). Though the  
28 various datasets agree in terms of aerosols signal intensity, we report significant differences for  
29 the plume height and its variability, possibly as a result of different observations geometries,  
30 resolutions and spatial scales inherent to each instrument.

31 In situ measurements by the LOAC OPC have pointed out the impact of the Calbuco eruption  
32 on the lower stratospheric aerosol content over the Reunion Island site. Aerosols number

1 concentrations were 20 times higher than values observed before and one year after the  
2 eruption. On May 2015, the volcanic aerosol was characterized by an effective radius of 0.16  
3  $\pm 0.02$   $\mu\text{m}$  and a unimodal lognormal size distribution above 250 nm diameter. These  
4 microphysical characteristics are in agreement with previous studies focusing on the Sarychev  
5 eruption (Kravitz et al., 2011; Jégou et al., 2013).

6 Through the use of the MIMOSA model and the DyBAL code, it was clearly identified that the  
7 eastward transport of the volcanic aerosols occurred mainly in form of planetary-scale tongues.  
8 In particular, the combination of MIMOSA and DyBal simulations revealed that the transport  
9 of the volcanic aerosol plume eastward was confined between subtropical barrier and mid-  
10 latitude (polar vortex) dynamical barriers, within which most of the zonal transport took place.  
11 Our results support the assumption that the processes explaining the structure of the plume over  
12 the southern hemisphere had mainly a dynamical origin. Thus, the fluctuation of the subtropical  
13 barrier induced transient aerosol layers above Reunion Island and an inhomogeneous  
14 distribution of the plume between May and July 2015. The present study also supports the  
15 hypothesis that the modulation of a volcanic plume results from a contribution of both  
16 dynamical and microphysical processes. Fully understanding the contribution of the  
17 microphysical processes to the evolution of the volcanic plume over the southern hemisphere  
18 requires further investigation. This will be examined in a forthcoming study.
