Finale Response

Kévin Lamy, Thierry Portafaix, Colette Brogniez, Sophie Godin-Beekman, Hassan Benchérif, Béatrice Morel, Andrea Pazmino, Jean Marc Metzger, Frédérique Auriol, Christine Deroo, Valentin Duflot, Philippe Goloub, Charles N. Long

October 30, 2017

The authors would like to thank the editor and the reviewers for their time and comments. We have addressed both referees comments in the discussion. The corresponding changes are detailed in the short comment 1 (in response to referee 1) and 2 (response to referee 2) in the discussion. From these changes and the latest co-authors review, a final version was written. The latest changes realised after the short comments 1 and 2 include:

- Corrections which are detailed in the short comment 1 and 2. (Response to referee 1 and 2)
- Additional syntax and grammar correction.
- Figures have been tweaked to be easier to read (line width or font size have been increased).
- References have been added (P2, L15 and P3, L19).
- Information about the threshold, the number of total and filtered measurements have been added (P3, L15).
- Figure 7: Only AOT at 340nm, SSA at 440nm and ngstrm exponent at 340-440nm have been kept.

The following items are included in this pdf:

- P1-5: Response to referee 1.
- P6-9: Response to referee 2.
- P10-46: Finale version of the manuscript.
1 General comment

The manuscript presents a comparison of spectrally measured UV-index under clear sky conditions with model calculations for a tropical site over the period 2009 to 2016. First a sensitivity study is reported, where the effect of different sources for local ozone column, of two different extraterrestrial spectra and of two different ozone cross sections on the calculated UV-index are discussed. These are not really new findings (as stated in 4.2.5, ln. 18), because very similar studies have been carried out already so far, but here they are specifically for the atmospheric conditions of a tropical station. Then in section 5 the model calculations are ‘validated’ against the observations.

In general I think this is an interesting approach, as measurements under such conditions are very rare, and they complete and improve our understanding of UV-levels at the Earth’s surface. Therefore I think the manuscript is worthwhile to be published.

We would like to thank the referee for his thorough review. The comments on the radiative amplification factor and the structure of the article have been very beneficial. We hope that the newer version has improved the paper.

2 Specific comments

The abstract could be shorter and more concise, there are some sentences appropriate for the introduction but not for the abstract.

The abstract is now shorter and was restructured to be clearer.

ad 2. Dataset: a bit more information could be given about the calibration of the spectroradiometer (traceability, frequency, . . .).

Specific information have been added.

ad 5.1 Radiative Amplification Factor (RAF):
- There are not 2 different definitions for the RAF. The linear relationship is simply the derivation of the power law. Therefore it is valid only for small variations of ozone and it becomes more and more erroneous for relative variations greater than 5%. The data presented in the manuscript are in the order of up to about 15%, but the systematic deviation between the linear relation and the correct power law is not obvious due to the scatter of the data points.

The referee is right about the relationship between the power law and the linear law. It has been taken into account, we used now only relative variations lower than 10%. We tried 5% at first but not enough data remained.
The RAF describes the sensitivity of UV to ozone variations, while all other influencing parameters should be constant. Therefore it does not make sense to calculate the RAF including the varying earth-sun-distance (ESD), because the RAF should be the same if ozone is 300 DU in January or July, whereas the UV is higher in January. This means, not the model calculation should include the varying ESD, but the measurements should be converted to a constant ESD. This is of specific importance, when the number of measurements is not constant over the months of the year, because then it will produce a systematic error. Similarly, also the aerosol amount should be constant in the model calculation, whereas in the measurements its variation will produce a significant scatter in the analysis. So the usage of model RTUV01 is not suited to determine the RAF, it only can be used to compare the measured results with modelling (but this is anyway better done by direct comparison of the UV-index derived from measurements and from modelling, as discussed in the following paragraphs).

The referee is correct. We also changed this part, now there is a new simulation RTUV07 which is similar to RTUV01 but with constant aerosols, total NO2 column, etc... Only total ozone column, SZA and ozone and temperature profil are not constant. It allowed to us to have an idea of the impact of ozone and temperature profil on the RAF. The observations were converted to a constant ESD by multiplying the UVI by \(1/\text{esfact}\).

- what data are used for the calculation of RAF with the ideal model case i-RTUV concerning extraterrestrial spectrum and ozone cross section in Tab. 3 there are in both cases two different options mentioned with 'or'.

Serdyuchenko et al. (2014) ozone cross section and Dobber et al. (2008) extraterrestrial spectrum is used in i-RTUV for the RAF calculation. Clarification have been added in the manuscript.

- the calculated RAF with the ideal model case i-RTUV for the power relation (1.2 at SZA=25°) is in very good agreement with the value of 1.25 from Herman [2010] at low SZA, so the statement in ln. 11 ('the higher RAF values found here . . .') is not valid. Furthermore, the argument that the 'lower value of ozone' (ln. 12) is responsible for any difference cannot be true, as the RAF is valid for the whole range of ozone values due to its definition.

The referee is right. The statement have been removed.

ad 5.2 Validation against observed clear-sky UVI: for a validation of different results of model calculations against measurements the significance of the comparison between model and observation should be stated. In this case, the uncertainty of the measurements is \(+/-5\%\) (I guess this holds for a coverage factor of 1). Therefore a mean relative difference between model and measurement in the range 0.4\% to 1.3\% (Table 4) cannot be significant. Only mean relative differences greater 4\% might be significant on a certain level.

We have added a statement about the significance of the comparison.

3 Technical corrections

The following errors have been corrected. Since the structure and have changed, corresponding pages and lines in the newer version are written below.

1. ad 1st page of introduction, ln. 20: not 'during winter' but 'during summer'

Corrected. P2,L22
ad 2nd page of introduction, ln.18: ‘tries’ instead of ‘tires’
Corrected. P3,L34

ad 3. Clear-sky filtering, ln. 35: ‘with 15 minute intervals’ instead of ‘with at 15 minute intervals’
Corrected. P7,L4

ad 4.1, ln. 27: ‘by Lacagnina’ instead of ‘by to Lacagnina’
Corrected. P8,L13

ad 4.1, ln. 30/31: unclear formulation
Removed in the newer version.

ad 4.2.1, ln. 17: ‘crossing the atmosphere is longer’ instead of ‘crossing the atmosphere travelled is longer’
Corrected. P9,L11

ad 4.2.1, ln. 18: ‘processes’ instead of ‘process’
Corrected. P9,L11

ad 4.2.4, ln. 32: ‘aerosol measurements’ instead of ‘aerosols measurements’
Removed in the newer version.

ad 1st page of 5.1, ln. 40: not a linear relation between UVI and TO3, but between delta(UVI)/UVI and delta(TO3)/TO3
Removed in the newer version.

ad 2nd page of 5.1, ln. 17: ‘RTUV01’ instead of ‘RTUV04’
Corrected.

ad 2nd page of 5.1, ln. 18: ‘to see how’ instead of ‘to seehow’
Corrected. P12,L15

ad 2nd page of 5.1, ln. 31: ‘RTUV01’ instead of ‘RTUV04’
Corrected.

ad 1st page of 5.2, ln. 11: this sentence is almost a repetition of ln. 5
Removed in the newer version.

ad 1st page of 5.2, ln. 13: ‘SAOZ’ instead of ‘SBUV’
Corrected. P13,L22

ad 1st page of 5.2, ln. 40-43: this paragraph is a duplication of ln. 1 and 2 and does not fit here
Removed in the newer version.
ad 1st page of 5.2, ln. 42: duplicate 'on on'
Corrected.

ad 2nd page of 5.2, ln. 11: 'which increased' instead of 'with increased'
Corrected. P14,L26

ad 1st page of 6, ln. 47: for which 'higher SZA' the given numbers are derived?
Corrected. P15,L26

ad 2nd page of 6, ln. 11: duplicate 'to to'
Corrected. P16,L10

Table 4, last line: 'Median of the RD' instead of 'Median of the Mean RD'
Corrected.

Figure 8: the figures 8a and 8b are by far too small to see the different data points
Corrected.

Figure 8: the legend says '8f', but this is not shown in the figure itself. May be '8e' would be appropriate (but not labelled). Anyway, this last part of Fig. 8 could be skipped.
Corrected.

Figure 11: in the Figure 'RTUV01' is mentioned, in the legend below the figure it says 'RTUV06'
Corrected.
Response to the Referee’s Comments

Kévin LAMY

September 17, 2017

I would like to thank the referee for his second review. We hope that the newer version has improved the paper.

1 General comment

There are still several syntactical, linguistic and editorial errors in the manuscript, especially in the abstract and paragraph 4.2.4. Thus, I suggest that the authors should try harder to improve it. In the following there are indicative recommendations for a number of corrections, but there are more that have to be done and additional work is necessary.

In the present study a standard SSA of 0.95 was used. Though, there are studies suggesting that the SSA in the UV may range between much lower values (e.g. 0.6) and values close to unity. Although for very low values of AOT (such as those that are usual at Reunion Island) changing the SSA would not induce important changes in the models output, I believe that it would be useful to quantify the possible errors/uncertainties due to the use of a standard SSA.

The differences between the simulated UVI for different ETS are surprisingly large. I believe that the dependence from ozone and SZA denotes very large differences between the UV-B wavelengths of the spectra from Dobber and Chance & Kurucz. Are there any other differences between these two spectra (e.g. different spectral resolution/analysis) which could induce such large differences in the simulated UVI?

Regarding the general comment, we tried to correct the remaining syntactical, linguistic and editorial errors. We greatly appreciate the effort the referee did to point them out in the specific comments.

We agree with the reviewer’s comment about SSA. It would be useful to quantify errors due to a constant SSA but we feel like it would be more suited for a future study dedicated on UVI modelling sensitivity to aerosols.

The referee is right, most of the difference between Dobber and Chance & Kurucz spectra are in the UV-B range. Nonetheless, as input for TUV model both spectra have a 0.01 nm resolution.

2 Specific comments

The following errors have been corrected.
2.1 Abstract

The text of the abstract should be rearranged so that its meaning is clearer. For example: The first two paragraphs of the introduction could be rearranged so that it is easier for the reader to follow them. The first paragraph should answer to the question: why studying SUR is important? while the second paragraph should answer to the question: why studying SUR over the tropics - and in particular in the Reunion Island - is important? After the first two paragraphs, there should be a general description of what has been done in this study, i.e. move the text of P2, L1-3 there. The discussion for the cloud filtering is also divided in two paragraphs (5 and 6). I suggest making this discussion in a single paragraph (i.e. move the relative information from the last paragraph since it is not one of the main findings of the study).

Following the reviewer suggestions the structure of the abstract has been reworked. It should be now easier to read.

1. P1,L4: Define SUR here instead of P2, L20
Corrected. P1, L1

2. P1, L18: Delete radiation
Corrected. P1, L15

3. P2, L4: SUR was instead of ultraviolet radiations were
Corrected. P2, L1

4. P2, L5: was based instead of based and while the second was based on applying
instead of the second applying
Corrected. P2, L2

5. P2,L10: ”were derived” instead of ”came”
Corrected. P2, L9

6. P2,L11: ”using” instead of ”with respect to”
Corrected.

2.2 Introduction

7. P2, L20: However, large instead of Large
Corrected. P2, L15

8. P2, L21: Delete As
Corrected. P2, L16

9. P2, L28: depends instead of depending
Corrected. P2, L24

10. P3, L8: Do you mean by absorbing and scattering processes in the atmosphere
instead of by the atmosphere and scattering processes?
Corrected. P3, L3
Corrected. P3, L18

12. P3, L23: What caused the reduction of 15.2%?
Corrected. P3, L18

13. P3, L24: usually reduce instead of can reduce
Corrected. P3, L19

14. P3, L27: role instead of part
Corrected. P3, L22

15. P3, L34: integral instead of integration
Corrected. P3, L29

16. P4, L11: projections instead of projection
Corrected. P4, L6

17. P4, L32: parameters instead of parameter
Corrected. P4, L27

2.3 Dataset

18. P5, L20: rephrase
Corrected. P5, L18

19. P5, L27-28: which one is the first paper and which one is the second paper?
Clarification has been added. P5, L25

We removed the information about the ASCO activity but kept Orphal et al. (2016) result in a more concise form. P5, L27

20. P6, L1-8: I think that this information is not related with the present work and I suggest removing it.
Corrected in the manuscript, the cloud observations are performed 10 km north of the measurements. P6, L4

2.4 Clear-sky filtering

22. For consistency I suggest using either clear-sky or clear sky throughout the entire manuscript.
Corrected. "Clear-sky" is now used throughout the entire manuscript.

23. P6, L19: observations instead of observation
Corrected. P6, L11

24. P7, L6: relative to instead of higher than
Corrected. P6, L27

25. P7, L8: At around instead of Around
Corrected. P6, L30

26. P7, L13: Delete with
Corrected. P7, L3
2.5 UV modeling

27. P7, L28: I suggest explaining in short why the used approximation is more accurate.
Corrected. P7, L19

28. P8, L11: performed instead of taken
Corrected. P8, L9

29. P10, L20-P11, L13: This paragraph is very badly written and confusing. I suggest rewriting it more carefully.
Corrected. P10, L21 - P5, L14

2.6 Model Validation

30. P11, L15: Declare that you compare the observations with the model output.
Corrected. P11, L14

31. P11, L17: I suppose that you mean the sensitivity of the model output on TO3. You should make it clear here.
Corrected. P11, L16

32. P12, L6: what means very clear sky?
Following on the first referee’s comment, the entire statement here was deleted.

33. Figure 8: In my opinion, the equations are not necessary in the legends of figures 8(a) 8(d) since there is an explanation of what is RAF P and RAF L. In the legend of figures 8(a) and 8(b), the value of RAF would be enough.
Corrected.

34. P12, L18: This range of SZAs is instead of These ranges of SZA are, measurements instead of measurement, the annual instead of annual, lower instead of low
Corrected. P12, L20

35. P12, L20: in figure instead of on figure. This is applicable to the entire manuscript.
Corrected.

36. P13, L14: Writing that the agreement between the measured and modeled UVIs is the best when the SBUV dataset is used as input would be more accurate than writing that the results RTUV03 is the best. The fact that the agreement is optimal does not necessarily mean that RTUV03 is the best.
Corrected. P13, L20

37. Figure 9: The title of the x-axis is below each sub-figure of fig. 9a, while at fig 9b it is only below the last sub-figure. For consistency I suggest removing the x-axis title from the five upper panels of fig 9a.
Corrected. P25
Ultraviolet Radiation modelling from ground based and satellite measurements at Reunion Island, Southern Tropics

Abstract.

Surface ultraviolet radiation (SUR) is not an increasing concern after the implementation of the Montreal Protocol and the recovery of the ozone layer (Morgenstern et al., 2008). However, large uncertainties remain in the prediction of the future changes of SUR (Bais et al., 2015). Several studies pointed out that UV-B impacts the biosphere (Erickson III et al., 2015), especially aquatic system, which plays a central part in biogeochemical cycle (Hader et al., 2007). It can affect phytoplankton productivity (Smith and Cullen, 1995). This influence can result in either positive or negative feedback on climate (Zepp et al., 2007).

Global circulation model simulations predict an acceleration of the Brewer Dobson circulation over the next century (Butchart, 2014), which would lead to a decrease of ozone levels in the tropics and an enhancement at higher latitudes (Hegglin and Shepherd, 2009). Reunion Island is located in the tropics (21S, 55E), in a part of the world where the amount of ozone in the ozone column is naturally low. In addition, this island is mountainous and the marine atmosphere is often clean with low aerosol concentrations. Thus, measurements show much higher SUR than at other sites at the same latitude or at mid-latitudes. Ground-based measurements of SUR have been performed at Reunion Island by a BENTHAM DTMc300 spectroradiometer since 2009. This instrument is affiliated with the Network for the Detection of Atmospheric Composition Change (NDACC).

In order to quantify the future evolution of SUR in the tropics, it is necessary to validate a model against present observations. This study is designed to be a preliminary parametric and sensitivity study of SUR modelling in the tropics.

We developed a local parametrization using the Tropospheric Ultraviolet and Visible Model (TUV (Madronich, 1993)) and compared the output of TUV to multiple years of BENTHAM spectral measurements. This comparison started in early 2009 and continued to 2016.
Only clear-sky SUR were modelled, so we needed to sort-out the clear-sky measurements. We used two methods to detect cloudy conditions, the first was based on an observer’s hourly report of the sky cover, while the second was based on applying Long and Ackerman’s (2000) algorithm to broadband pyranometer data to obtain the cloud fraction and then discriminate clear-sky windows on SUR measurements. Long et al.’s (2006) algorithm, with the co-located pyranometer data, gave better results for clear-sky filtering than the observer’s report.

Multiple model inputs were tested to evaluate the model sensitivity to different parameters such as total ozone column, aerosol optical properties, extraterrestrial spectrum or ozone cross section. For total column ozone, we used ground-based measurements from the SAOZ spectrometer and satellite measurements from the OMI and SBUV instruments, while ozone profiles were derived from radio-soundings and the MLS ozone product. Aerosol optical properties came from a local aerosol climatology established using a CIMEL photometer. Since the mean difference between various inputs of total ozone column was small, the corresponding response on UVI modelling was also quite small, at about 1%. The Radiative Amplification Factor of Total Ozone Column on UVI was also compared for observations and model. Finally, we were able to estimate UVI at Reunion Island with, at best, a mean relative difference of about 0.5 %, compared to clear-sky observations.

1 Introduction

Ozone recovery prevented an important increase of SUR level (e.g Morgenstern et al. (2008), Dijk et al. (2013), Newman et al. (2009)...) . However, large uncertainties remain in the prediction of the future changes of SUR (Bais et al., 2015). Overexposure to this radiation is the main factor for the development of non-melanoma and melanoma skin cancers. Non-melanoma skin cancer is induced by chronic exposure and melanoma is induced by repeated burning and chronic exposure (Matsumura and Ananthaswamy, 2004). Holick et al. (1980) studied the beneficial effect of UV radiation on health through the synthesis of pre-vitamin D and numerous studies have assessed the balance between benefits and risks. McKenzie et al. (2009) looked at the relation between erythemal weighted UV (Mc Kinlay and Diffey, 1987) and vitamin-D weighted UV (MacLaughlin et al., 1982). This work showed that, during summer at mid-latitudes vitamin D can be produced in a few minutes while avoiding the skin damage that occurs after an hour of exposure, of course this depends on the skin area exposed. Behavioural studies have also been conducted in order to understand human activities in relation to UV intensity. Outdoor sports activities without sufficient solar protection have been shown to increase the risk of developing skin lesions in childhood (Mahé et al., 2011). Tourism in northern mid-latitude cities in summer can also present a non-negligible risk of skin cancer (Mahé et al., 2013). UV exposure and sun-protective practices during childhood were also investigated in New Zealand (Wright et al., 2007), and differences in children’s exposure were explained by their different activities. Sunburn risks among children and outdoor workers were evaluated in Reunion Island and South Africa. High values of cumulative daily ambient solar UV radiation were found for the three sites studied (Wright et al., 2013).

Total solar irradiance at the top of the atmosphere is, of course, the source of surface UV radiation. Its intensity varies directly with the sun radiative intensity. The sun has an 11 year solar cycle period (Willson and Hudson, 1991) which has a direct influence on total solar irradiance at the top of the atmosphere. Total solar irradiance at the top of the atmosphere is also
modulated by the variation in Earth’s orbital parameters, which should be taken into account in very long-term climate studies but can be neglected in multi-decadal studies such as ours.

SUR is attenuated by absorbing and scattering processes in the atmosphere from the top of the atmosphere to the surface. Investigating SUR variability from one year of ground-based measurements, McKenzie et al. (1991) showed that the dominant variation of SUR was linked to SZA, while attenuation by clouds could exceed 50% and a total ozone column reduction of 1% could induce an increase of SUR of $1.25 \pm 0.20\%$.

Due to the depletion of the ozone layer by human made halogenated substances and the important impact of ozone on climate change, a major observing programme was set up to monitor atmospheric ozone in the last decades. The latest assessment of the state of the ozone layer (WMO, 2014) reported the end of the stratospheric ozone decline since the end of the 1990s, with a stabilisation of ozone levels at about 2% below those observed in the early 1980s. However, global circulation model simulations predict an acceleration of the Brewer Dobson circulation over the next century (Butchart, 2014), which would lead to a decrease of ozone levels in the tropics and an enhancement at higher latitudes (Hegglin and Shepherd, 2009). Clouds and Aerosols are also being intensively investigated, given their role in the climate energy budget and the fact that their radiative forcing remains the main uncertainty for climate studies (Boucher et al., 2013). They also are the main uncertainty factors in the future projections of the solar UV irradiance (Bais et al., 2015). Global maps of UV-absorbing aerosols were derived by Herman et al. (1997). Later Krzyścin and Puchalski (1998) showed that a 10% decrease of aerosol optical thickness (AOT) at 550nm induced a $\sim 1.5\%$ increase in UV erythemal daily dose. More recently Kazadzis et al. (2009) investigated the aerosol forcing efficiency in the UVA region, between 325nm and 340nm and found a mean reduction of irradiance of 15.2 % per unit of AOT slant column at 340nm during autumn. Correa et al. (2013) looked at the influence of aerosol properties on projected changes in clear-sky erythemal UV doses through the 21st century. It has been shown that clouds usually reduce SUR variability (Bais et al., 1993), (Calbó et al., 2005) but broken clouds can also enhance it under specific conditions (Mayer et al., 1998).

Those three time-evolving parameters being an important source of variability of UV radiation, we need to better understand their effects on surface UV. Radiative transfer modelling plays a key role in deducing UV evolution over the next century, but it needs to take account of a fair projection of those parameters. Climate models associated with radiative transfer models or empirical methods have been used to assess SUR evolution over the next century. Bais et al. (2011) and McKenzie et al. (2011), respectively, found a 12% and 20% decrease of UVI at high latitude, a 3% to 5% decrease at mid-latitude and a 1% to 3% increase in the tropics. These projections depend strongly on the evolution of future climate, and Butler et al. (2016) presented the complexities associated with future ozone change and therefore surface UV change.

The Ultraviolet Index (UVI) (WHO, 2002) is one of the most common parameters used to investigate the impact of SUR on human health. It is the weighted integral of the ultraviolet irradiance between 280 nm and 400 nm, with the weight depending on the human skin’s response to erythema determined by Mc Kinlay and Diffey (1987). UVI modelling was investigated thoroughly by Badosa et al. (2007), who tested multiple inputs and compared the results to observations at four different sites (Lauder (45.04° S), Boulder (40.01° N), Mauna Loa (19.53° N) and Melbourne (37.63° S)). They found mean relative differences in UVI between model and observations ranging from 10% to less than 0.1%.
Following these studies, the present work tries to improve the understanding of surface UV variability in the southern tropical region, a sensitive area where very few studies have been conducted. This article is intended to improve surface UV modelling by analyzing the model sensitivity to different inputs. Six years of ground surface UV measurements made with a BENTHAM DTMc300 spectroradiometer are analysed versus ozone, cloud, and aerosol data derived from ground and satellite measurements spanning the same time period. As discussed previously, climate model simulations predict a decrease of ozone levels in the tropics and their enhancement at higher latitudes. This study is designed to establish a fine parametrization of UVI modelling in the tropics in order to later couple radiative transfer modelling and a chemistry climate model to obtain precise UVI projections.

Reunion Island is a small tropical island located in the Indian Ocean at a latitude of 20.90° South and a longitude of 55.50° East. This island is very mountainous with a peak at 3070 m asl and a mean altitude of ∼ 600 m asl. Almost all of the ground measurements were made at Reunion Island University, which is situated in the north of the island at an altitude of 80.0 m and at less than 2 km from the coast. The atmosphere in the boundary layer is dominated by the ocean and is often clean with low aerosol concentration. The usual weather follows a typical pattern during the day, due to the trade winds: the sky is usually free of clouds at sunrise but, clouds start to appear during the day as the trade winds blow on to the mountain. There is a strong contrast between the east and west sides of the island, the accumulation of clouds leading to more precipitation on the east coast while the west coast is mostly dry.

Surface UV measurements show a very high UV index compared to other sites at the same latitude (Lee-Taylor et al., 2010). Aerosol optical thickness shows a mean value of ∼ 0.07 at 440 nm, with an occasional maximum at ∼ 0.3. These multiple conditions: mountainous, tropical island with low aerosol concentrations, makes Reunion Island an interesting site for studying surface UV radiation. Since the island presents a very high UVI, and the population lives at low to relatively high altitudes, the highest cities being located at about 1.5 km asl, surface UV radiation is an important health concern. Note that the time zone of the site is UTC+4:00.

In section 2, we will first present the different data and the radiative transfer model used in this study. As discussed previously, clouds are an important factor of UV variability and, since clouds are not well resolved in the radiative transfer model, we chose to work only on clear-sky UVI modelling here. The datasets used in this study will also be presented.

In section 3, we will address the filtering method used to select only UVI observations for clear-sky conditions with the use of broadband pyranometer global and diffuse solar irradiances and Long et al. (2006) algorithm. A brief comparison will be made with human observer’s report of cloud sky coverage.

In section 4, we will discuss the radiative transfer model sensitivity to various input parameters. Multiple modelling cases were run using different ozone and aerosol data at the time of the UV measurements, and also different input ozone cross sections and solar irradiance spectra at the top of the atmosphere. The impact on the UVI modelled will be analysed.

In section 5, the model will be validated against the clear-sky UVI observations at Reunion Island. We will investigate the model’s ability to reproduce diurnal and seasonal variation of UVI, and its ability to reproduce the effect of total ozone column (TO3) variation on UVI. Lastly we will discuss the results and draw some conclusions.
2 Datasets

The multiple types of measurements used in this study, as input for the radiative transfer model or as reference to validate the model output, are summarised in Table 1.

UVI measurements were performed with a BENTHAM DTMc300 spectroradiometer affiliated with NDACC. This spectroradiometer is composed of two monochromators and scans the wavelength range of 280-450 nm. According to Brogniez et al. (2016), Bentham DTMc300 UVI measurements have an expected uncertainty of about 5% and a coverage factor of 2. Recalibration is made every six months with a 150W lamp and a 1000W quartz tungsten halogen lamp traceable to National Institute of Standards and Technology. In this study, we used the standard erythemal action spectrum published by the International Commission on Illumination to calculate erythemal weighted UV (CIE Standard, 1998). Simulation experiments under clear-sky conditions were conducted over the time period covered by SUR measurements, i.e. from 2009 to 2015. The data used in this study for modelling are described below.

TO3 measurements:

- Ground based measurements from the SAOZ (Système d’Analyse par Observation Zenithal) (Pommereau and Goutail, 1988) UV-Visible spectrometer collocated with the Bentham.
- Satellite measurements from OMI (OMTO3 product) and SBUV (Bhartia and Wellemeyer, 2002).

Extraterrestrial solar spectra (ETS):

- Chance and Kurucz (2010)
- Dobber et al. (2008)

Ozone cross sections (O3XS) absorption:

Several datasets are available:

- Malicet et al. (1995) and Brion et al. (1998) (BDM) works which are currently used for SBUV instruments.
  - 345-450 nm at 195K from Brion et al. (1998).
- Bass and Paur (1985) (BP) are used currently for OMTO3.
- Gorshelev et al. (2014) and Serdyuchenko et al. (2014) obtained high spectral resolution ozone absorption cross sections (called SER hereafter) from a combination of Fourier transform and echelle spectrometers. Measurements, data analysis and comparisons are presented in the first paper (Gorshelev et al., 2014), and temperature dependence is investigated throughout the second paper (Serdyuchenko et al., 2014).
Orphal et al. (2016) published a recent report on the evaluation of different absorption cross sections of ozone. They found that BP data should no longer be used for retrieval of atmosphere ozone measurements. Either BDM or SER should be used in ground-based or satellite retrieval. These findings led us to choose BDM and SER O3XS in our current study. Ozone and temperature profiles came from radio-soundings, performed weekly at Reunion Island since 1993, and also from MLS satellite measurements (Froidevaux et al., 2008). Nitrogen dioxide measurements were obtained with the SAOZ spectrometer. Aerosol measurements were derived from CIMEL sunphotometer measurements between 2009 and 2016. Cloud observer reports were made at Reunion Island every hour at about 10 km north of the UVI measurements, while global and diffuse total irradiance were measured every minute at the same location as the UVI measurements.

3 Clear-Sky Filtering

Clouds are known to play an important role in surface UV variability (Bais et al. (1993), Calbó et al. (2005) and Mayer et al. (1998)). As mentioned previously, this study was limited to clear-sky UV observations and simulations. In order to filter out cloudy conditions, two different methods were used. The first, commonly used one was based on synoptic observer reports (SYNOP) made at a Météo-France weather station located about 10 km from the UV measurements site. The observer reports follow WMO guidelines for cloud observations (http://worldweather.wmo.int/oktas). Sky observations are made every hour and are quantified on a scale in oktas from 0 (clear-sky) to 8 (totally overcast sky). We kept only UV measurements made for a cloudiness ≤ 1 okta. Since the UV measurements are made every 15 minutes and sky observer reports are hourly, we interpolated these observations every 15 minutes. The effect of interpolation is taken into consideration and analysed below. The second method used Long and Ackerman (2000) and Long et al. (2006) algorithms. As input for this algorithm we used 1-min data of global and diffuse total irradiances measured at the same location as the UV measurements, with a SPN1 shaded pyranometer. These algorithms performed multiple tests on the global, diffuse and direct irradiance in order to identify periods of clear skies. They have been validated against whole sky imager, lidar data and observer reports (Long et al., 2006).

In order to compare the two methods, we tried multiple thresholds of the cloud fraction for the Cloud Observer Report (CF-SYNOP) and Cloud Fraction obtained with Long et al. (2006) algorithm, called CF-SWF hereafter. We considered that clear-sky conditions prevailed when the cloud fraction was less than or equal to the CF-SYNOP or CF-SWF thresholds. From these we obtained UVI filtered data, called respectively UV-SYNOP and UV-SWF hereafter.

We investigated numerous days and found CF-SWF to be more responsive and consistent with the UVI measurements. An example of a typical day with varying cloud fractions is represented in Figure 1. UVI corresponding to all sky conditions (UV-ALL) are marked in black circles, the blue circles represent UV-SWF and the red ones UV-SYNOP. CF-SWF is also represented by the blue dashed line. A clear-sky day would produce a UVI diurnal cycle resembling a Gaussian shaped function centred on the solar noon, while moderate to high cloud fractions would generally reduce UVI. In some cases, broken cloud conditions may increase UVI by 20% relative to clear-sky conditions (Cede et al., 2002). Early in the day, at about 4:00 UTC, both UV-SYNOP and UV-SWF are absent, as no clear-sky conditions are detected: cloud fraction at that time is quite high and impacts the UVI slightly. At around 9:00 we clearly see the impact of a rising CF on UV-ALL which rapidly decreases. UV-SWF is
absent but CF-SYNOP still labels UV-ALL measurements (UV-SYNOP) as clear-sky while they are clearly not. This example, among many others, made us decide to use only UV-SWF for the UVI clear-sky measurements in all further work.

We then investigated the daily and monthly density of UVI measurements. In Figure 2a, average UVI data distribution through the day is represented for UV-ALL (green bars) and UV-SWF (blue bars), along with the mean CF-SWF (black dashed line). We can see that UV-ALL is equally distributed through the day, since UVI measurements are made every day at 15 minute intervals. In contrast, for clear-sky data UV-SWF, there are more measurements available during the morning than in the afternoon, which is anti-correlated with the mean climatological CF-SWF. As clouds tend to form during the day, clear-sky UV measurements are less frequent in the afternoon. In Figure 2b, representing UVI data distribution during the year, we see that UV-ALL are not equally distributed. There are less UV-ALL data for the first four months, especially during March and April, due to a few failures and technical maintenance of the BENTHAM spectroradiometer during the 6 years analysed here. We then see a seasonal variation of the availability of clear-sky UVI measurements. During the austral summer, there is an increasing mean cloud fraction and therefore fewer clear-sky measurements. Since the solar zenith angle and total ozone column also follow a diurnal and annual variability, respectively, the uneven clear-sky UVI distribution through the day or through the year will induce a statistical bias on the following comparisons. The threshold choose for the rest of the study is 1/8. There was 85412 measurements, after clear-sky filtering only 16390 remained.

4 UV Modelling

4.1 Radiative Transfer Model

For UVI modelling, we used the Tropospheric Ultraviolet Visible (TUV) radiative transfer model version 5.3 (Madronich, 1993). TUV is available with two different radiative transfer schemes. We used the pseudo-spherical 8th-stream discrete ordinates (psndo.f) (Stamnes et al., 1988) method to solve the radiative transfer equation. The computation time is higher than with the generalised 2-stream method (Toon et al., 1989) also available in TUV but psndo.f is more accurate (Petropavlovskikh and Brasseur, 1995). N-th-stream discrete ordinates schemes use analytical treatment before computation, the radiative transfer equation is decomposed into 2N differential equation. Then, with appropriate boundary conditions, the system is numerically solved for each layer of the atmosphere. No approximation is made on the vertical inhomogeneity of the atmosphere or on the phase function. Without computational time requirement, these schemes can have high level of accuracy. On the other hand 2-stream methods assume an irradiance independent of the azimuth angle and divide it into an upward and downward components. These approximations induce errors, specifically in the lower troposphere and on the diffuse part of the irradiance.

The following parameters were modified in the model in order to reproduce the UVI measurements and site-specific climatology.

- Extraterrestrial Spectrum (ETS)
- Solar Zenith Angle (SZA)
- Total Ozone Column Amount (TO3)
Due to the lack of reliable data, total column sulphur-dioxide (TSO2) was set to zero, which could induce a modelling error during a volcanic eruption. Between 2009 and 2015, there were a few volcanic eruptions of the Piton de la Fournaise, which is located on the opposite coast of Reunion Island to the site where the UVI measurements were performed. Unfortunately there is no TSO2 data available for this period. Following McPeters and Labow (2012), a monthly climatology of ozone and temperature profile was derived from ozone soundings and MLS satellite measurements. Single Scattering Albedo from the CIMEL sunphotometer was not usable as Dubovik et al. (2000) showed that SSA has a large uncertainty if the AOT is lower than 0.3, which was almost always the case here. As proposed by Lacagnina et al. (2015) and Takemura et al. (2002), a fixed SSA of 0.95 was set. The errors due to the use of a standard SSA were not investigated here and should be investigated in the future (Correa et al., 2013).

Following Koelemeijer et al. (2003), surface albedo was taken to be constant at 0.08. According to Koepke et al. (1998), the UVI modelling error is about 5 % if the sum of the different uncertainties in input is considered at about 5%.

4.2 Influence of input parameters

To study the impact of various inputs on surface UV calculations, we tested multiple inputs from a baseline configuration (Table 2). Then different cases, called RTUV for Reunion Tropospheric UltraViolet hereafter, were run, with only one parameter varying in each (Table 3).

4.2.1 Earth-Sun Distance and Extra-terrestrial Spectrum

In order to take into account the varying earth-sun distance (ESD, in Astronomical Unit), a time dependent coefficient (ESF) is used in TUV: \( ESF(t) = 1/ESD^2 \). The new extraterrestrial spectrum \( ET' \), which is the spectrum at the top of the atmosphere corrected for any instant of time \( it \) is then (1):

\[
ET' = ESF(it) \times ET
\]
For convenience, we will now refer to the corrected extraterrestrial spectrum simply as ET. The ESD correction is done when RTUV is used for time series studies but, in order to study the sensitivity to ET spectrum (or to the O3XS later in 4.2.2) we chose to run TUV in an idealized state (i-RTUV), with constant earth-sun distance, total ozone column varying from 250 DU to 350 DU, solar zenith angle varying from 0° to 60°, and mean values of aerosol representative of the entire study period (see Table 3).

Since we want to understand the sensitivity to ET spectrum, i-RTUV was run with Dobber et al. (2008) or with Chance and Kurucz (2010) ET spectrum. From there we took UVI output and defined the UVI relative difference (RD) between these two cases as:

$$RD\% = 200 \times \left( \frac{UVI_{dobber} - UVI_{chance}}{UVI_{dobber} + UVI_{chance}} \right)$$

RD on the surface UVI modelled between the two ET spectra for the SZA and TO3 studied is represented in Figure 4a for a monthly climatological OP and TP of January and in Figure 4b for October. The highest RD appears to occur for low SZA and low TO3, at about 5% for January and about 4% for October. Minima of RD are for high SZA and high TO3, at about 3% and 2% for January and October, respectively. At fixed TO3, when SZA increases, the path length travelled by the radiation crossing the atmosphere is longer and other processes, such as Rayleigh scattering, have more impact on the surface UVI modelled than different ET spectra do. At fixed SZA, when TO3 increases, the RD decreases, or when ozone molecular absorption increases the differences in the ET spectra are less important.

During the month of October, OP shifts from the annual mean (Figure 3). There is an increase in tropospheric ozone through the arrival of emissions due to biomass burning over the western part of the Indian Ocean zone Baldy et al. (1996). The absorption effectiveness of tropospheric ozone relative to stratospheric ozone depends on SZA (Brühl and Crutzen, 1989). This is why there is a small difference (about 1%) between January and October. This difference is only due to the shift in ozone and temperature profiles.

In Figure 4c, the monthly mean of UVI RD between RTUV05 and RTUV01 is represented by a dashed blue line. These two RTUV cases have the same configuration except for the ET spectrum. The sign of the RD here is coherent with equation (2), i.e. RTUV05 (Chance ET) minus RTUV01 (Dobber ET). The monthly mean of RD between these cases oscillates between 2.7 and 3.4%, these values being of the same of order than as the i-RTUV cases. The oscillation observed here is anti-correlated with the maximum of SZA at solar noon at the site studied.

To conclude, UVI dependency on the ET spectra is higher at low SZA and low TO3 which are also the conditions where we find the maximum of UVI, i.e where the health risk is highest. While the RD is dependent on SZA and TO3 (at about 3.0%), OP and TP also constitute a factor of variability (about 1%). RD is modulated through the year with the variation of SZA. Finally, Chance’s spectrum impact on the surface UVI modelled will be an increase of about 3.0% with respect to Dobber’s.

### 4.2.2 Ozone Cross Sections

Following these studies we investigated the impact on simulated UV irradiance modelled with different absorption cross sections of ozone (O3XS). As mentioned previously we used BDM and SER and defined the relative difference between the two
modelling cases as:

\[ RD[\%] = 200 \times \frac{x_{BDM} - x_{SER}}{x_{BDM} + x_{SER}} \] (3)

Figure 5a represents the UVI RD using two different O3XS (equation 3) in an idealized run (i-RTUV) for October OP and TP climatologies. Here, RD ranges from 2.4% to 2.9%. We observe the same variability as for the ET sensitivity: highest values of RD correspond to low SZA and low TO3 and as either SZA or TO3 increases, UVI RD will decrease. Figure 5b shows the role of the varying Earth-Sun distance by using the corresponding RTUV cases (RTUV06 with BDM and RTUV01 with SER), which differ only by O3XS. There is also a yearly UVI RD oscillation anti-correlated with the maxima of SZA at solar noon. The mean RD is about 2.7% which is consistent with the i-RTUV case. The oscillation around the annual mean is smaller here than for the ET spectra (about 0.5%) but so is the mean RD.

To conclude on O3XS for this studied site, using SER O3XS instead of BDM O3XS increases the mean surface UVI by about 2.7%. This UVI RD is modulated by the SZA, TO3, OP and TP.

### 4.2.3 Total Ozone Column

Three different TO3 datasets, covering the period 2009 to 2016 in RTUV01 (SAOZ), RTUV02 (OMTO3) and RTUV03 (SBUV) were investigated. In contrast to the simulations in the idealized state, these simulations were conducted with varying earth-sun distance. The Relative Difference distributions for TO3 and UVI are represented in Figure 6 with one percent bins. Mean RD between TO3 datasets is smaller than 0.3% with a standard deviation of about 2%. The impact on the surface UVI modelled is slightly higher. There is a small mean relative difference of \( \approx 0.1 \pm 2.3\% \) between SBUV and OMTO3, \( 0.4 \pm 2.0\% \) between SAOZ and OMTO3 and \( -0.3 \pm 1.8\% \) between SAOZ and SBUV.

Since TO3 and surface UVI are anti-correlated, a positive RD in TO3 will lead to a negative RD on UVI and vice versa. This is expressed by the opposite sign of the mean RD between TO3 and UVI, and also by the RD distribution. If the distribution of RD of TO3 tends to shift towards positive values, the distribution of UVI RD will shift towards negative values.

### 4.2.4 Aerosol Climatology and Observations

Aerosol concentrations are usually very low in this region except during specific period of biomass burning or volcanic eruption. Here the objective is to evaluate the impact of the aerosol variability on UVI modelling.

Figure 7a, b and c represent respectively the monthly climatological values of AOT, SSA and Ångström exponent provided by a CIMEL instrument. Aerosol optical thicknesses are usually quite low. There is a peak centred around October. It coincides with the arrival of biomass burning emissions over the western part of the Indian Ocean zone (Baldy et al., 1996). In Figure 7b, the monthly climatologies of SSA (at 438 nm) derived from CIMEL measurements are represented. These values are very uncertain as mentionned previously. Ångström exponent is represented for 340-440nm. The Ångström exponent describes the spectral dependence of the AOT.

As aerosol input for UVI modelling, two datasets were used in this study, one being a monthly climatology derived from the CIMEL sunphotometer measurements from 2009 to 2016 and called hereafter Cimel Clim, and the other being the daily mean
derived from the same instrument and called hereafter Cimel Daily. RTUV01 was run with Cimel Daily and RTUV 04 with Cimel Clim (see Table 3). We define the AOT Anomaly as the difference between AOT daily mean and monthly climatology:

$$AOT_{ANOM} = AOT_{Cimel\, Daily} - AOT_{Cimel\, Clim}$$ (4)

Figure 7d represents the aerosol daily anomaly for the entire study period. We can observe few sharp peaks of 0.25 AOT anomaly and also several decreases to about 0.1 AOT anomaly. The maximum anomaly usually appears at the end of the year. Most of these anomalies are due to biomass burning emissions. Figure 7e shows UVI RD between RTUV04 and RTUV01. The succession of AOT anomalies has a direct impact on surface UVI; for the 0.25 increase in AOT, during the end of 2010, there is a ≈ 30% relative difference between the two surface UVI modelled. This is better observed on Fig.7f and g, which represent the monthly distribution of AOT anomalies and UVI relative difference split into 3 categories. Quantitatively more AOT anomalies (more than 0.15 AOT daily anomalies) are centred around October, which leads to higher values of UVI relative difference.

To conclude on aerosols, even though the mean relative differences in surface UVI for the two cases are very low for the entire studied period (-0.40%), there is still a punctual effect where surface UVI could be overestimated by ~30% when using aerosol climatology.

5 Model Validation

In this section, we compare observations made only in clear-sky conditions against the different RTUV modelling cases (Table 3).

5.1 Radiative Amplification Factor

To study the sensitivity of the modelling output on TO3, we need to understand the variability of UVI and ozone. The scaling function between UVI and ozone is commonly described as the Radiative Amplification Factor (RAF). Following Madronich (1993), we define the RAF as a power law:

$$\frac{UVI_{t_1}}{UVI_{t_2}} = \left( \frac{TO3_{t_1}}{TO3_{t_2}} \right)^{-RAF_p}$$ (5)

$$RAF_p = \frac{\ln \left( \frac{UVI_{t_1}}{UVI_{t_2}} \right)}{\ln \left( \frac{TO3_{t_2}}{TO3_{t_1}} \right)}$$ (6)

From there we can take every total ozone column measurement at a specific date t and the corresponding UVI and compute ratio.

If we derive the power law we can obtain a linear form of the RAF (Booth and Madronich, 1994):

$$RAF_L = -\frac{\Delta UVI}{UVI_{t_1}} / \frac{\Delta TO3}{TO3_{t_1}}$$ (7)
Since the derivative is local, only small percent change should be used, we choose here to select percent change smaller than 10%. We proceed by considering every total ozone column measurement at a specific date \( t \) and the corresponding UVI. We then compute the relative difference, for a specific SZA interval, between all pairs of UVI and TO3, such as at two dates \( t_1 \) and \( t_2 \):

\[
\frac{\Delta UVI}{UVI_{t_1}} = \frac{UVI_{t_1} - UVI_{t_2}}{UVI_{t_1}}
\]

(8)

\[
\frac{\Delta TO3}{TO3_{t_1}} = \frac{TO3_{t_1} - TO3_{t_2}}{TO3_{t_1}}
\]

(9)

In previous works, Booth and Madronich (1994) found a \( RAF_L \) of 1.1 from broadband measurements in Antarctica. More recently, from a theoretical point of view, Herman (2010) found a \( RAF_P \) of 1.25 at low SZA, decreasing to 1.1 at higher SZA. These values correspond to a mid-latitude profile. Bodhaine et al. (1997) analysed one year of UV measurements at Mauna Loa, Hawaii, and found \( RAF_P \) values between about 1.3 at a SZA of 15° and 0.6 at 85° SZA. At a SZA of 45°, while Bodhaine et al. (1997) found a \( RAF_P \) of 1.38 ± 0.2, McKenzie et al. (1991) found a \( RAF_P \) of 1.25 ± 0.20 at Lauder, New Zealand (45° S).

Here, both RAF (linear and power) are calculated for an ideal modelling case (i-RTUV) with SER O3XS and Dobber ET spectrum, for the observations (UV-SWF) and for a real-condition modelling case (RTUV07) where we fixed every parameter except TO3 and monthly ozone and temperature profiles. Observations are multiplied by the inverse of the ESF to bring them to constant ESD and be more similar with modelling at constant ESD. The first objective is to evaluate the RAF of TO3 on the UVI for the three cases, to see how they compare to each other, and to determine whether RTUV07 is close to the observations (UV-SWF) by being able to reproduce the RAF of TO3. The second objective is to compare the RAFs found here with those found previously in other studies at other sites.

In Figure 8a, \( \Delta UVI/UVI \) is plotted against \( \Delta TO3/TO3 \) for a SZA of 25° ± 0.1° for the three cases. The best fitting curve of each case is obtained from a least squares fitting method, from which \( RAF_L \) is also deduced (Booth and Madronich, 1994). This range of SZAs is chosen due to availability of measurements. Because of the annual variation of the SZA, lower values of SZA occur during the rainy season, the season when we filter out most of our data. UV-SWF is in blue, RTUV07 in red and i-RTUV in green. In Figure 8b, the same method is used in order to retrieve \( RAF_P \) (Madronich, 1993). Figures 8c and 8d represent \( RAF_L \) and \( RAF_P \), respectively, for the three cases versus SZA, with a two sigma dispersion bar. Figure 8e represents the number of cases and permutations used for the regression. Even if the number of permutations which are used for computation of the RAF is high, the number of cases compared between each other is quite low.

For i-RTUV, \( RAF_P \) (dashed green line) are at about 1.20 for a SZA of 25° decreasing to 1.11 for a SZA of 60° ,\( RAF_L \) (solid green line) decreases from 1.34 to 1.23. Between the same SZAs, while \( RAF_P \) derived from the clear-sky observations (UV-SWF, dashed blue line) decreases from 2.01 ± 0.11 to 1.73 ± 0.07, \( RAF_L \) (solid blue line) decreases from 1.23 ± 0.27 to 1.025 ± 0.09. From RTUV07, \( RAF_P \) (dashed red line) ranged between 1.40 ± 0.017 and 1.17 ± 0.07. At a SZA of 45°
from the observations, the $RAFP$ obtained was $1.65 \pm 0.12$, this value is higher than the one that found by Bodhaine et al. (1997), of $1.38 \pm 0.2$, for a similar site in the tropics.

RAF tends to decrease as SZA increases. When the SZA increases the path travelled through the atmosphere will be longer and other processes, such as Rayleigh scattering, will have a higher impact on the UVI. Since the absorption effectiveness of tropospheric ozone relative to stratospheric ozone depends on SZA (Brühl and Crutzen, 1989), the ozone distribution and the temperature profile have an impact on the RAF value. This is one of the reasons why both RAF deduced from i-RTUV cases present a smooth line. In i-RTUV, nothing changes except TO3 and SZA. While in UV-SWF, variations in aerosols, TNO2, ESD, OP and TP between t1 and t2 are naturally included. In RTUV07 only TO3, SZA, ozone and temperature profiles are not constant. The impact of OP and TP can be appreciated if we look at the difference between RTUV07 and i-RTUV.

$RAFL$ determined by observations (UV-SWF) is always lower than i-RTUV, by about 0.2 unit. However, $RAFP$ determined by observations (UV-SWF) is higher than the idealised case by about 0.6 unit at low SZA, between 25° and 35°. It is closer at higher SZA. The result from observations should be considered carefully, when two cases are compared the relative difference between every other parameters associated with theses cases (such as AOT, TNO2, OP, ...) are selected to be smaller than 10 %. Uncertainties are still important for the corresponding TO3, AOT, TNO2, OP, TP and clear-sky filtering associated with each UVI measurement. It is difficult to determine whether observations are better represented by a linear law or a power law as dispersion is high and number of cases is low (Fig 8e) in both cases.

5.2 Validation against Observed Clear-Sky UVI

In order to validate UVI modelling for the southern tropics, we compared the output of multiple model cases against UVI clear-sky measurements. Table 4 presents relative difference and standard deviation for the six Reunion Tropospheric UltraViolet (RTUV) model cases.

We define the Relative Difference between RTUV and UV-SWF as:

$$RD[\%] = 100 \times \frac{UVI_{RTUV} - UVI_{OBS}}{UVI_{OBS}}$$  \hspace{1cm} (10)

Closest agreement between measurements and model is found for the RTUV03 case. This corresponds to a configuration with daily aerosol measurements, Dobber ET spectrum, TO3 from SBUV and SER ozone cross sections. We compared measurements at SZA $\leq 60$ degrees. Of the three sets of ozone total column, the agreement between the measured and modeled UVIs is optimal when SBUV dataset is used as input (RTUV03), with a mean relative difference (MRD) of $0.43 \pm 5.60 \%$. It is 0.11% lower than RTUV02 (OMI) and 0.51% lower than the run with SAOZ measurements as input (RTUV01). Standard deviations (STD) are about the same for the 5 cases, around 5.7%. RTUV03 obtains the lowest median (MED) at 0.44 %. Nonetheless, some of those results are not significant because they are lower than the uncertainty of UVI measurements ($\pm 5 \%$).

For different extraterrestrial spectra in RTUV01 (Dobber et al., 2008) and RTUV05 (Chance and Kurucz, 2010), a 3.24 % difference is found between both MRD and MED. The difference is consistent with the one found in Section 4.2.1.
The influence of the choice of ozone cross sections on UVI modelled can be analysed with RTUV01 (SER) and RTUV06 (BDM). The first is 3.44% lower than the second. The difference between the two is higher here than the difference found previously (section 4.2.2) in an idealised run, where only one profile of temperature and one of ozone were used for the sensitivity test. BDM O3XS ((Brion et al., 1998) and (Malicet et al., 1995)) were calibrated for four temperatures, 295 K, 243 K, 228 K and 218 K, while SER was run with temperatures ranging from 193 K to 293 K with a 10K step. Since UVI is sensitive to the ozone and temperature profiles, different O3XS can induce higher differences in surface UVI than we calculated previously during the sensitive test. This needs to be further investigated, notably the impact of O3XS and ozone and temperature profiles on the surface UVI.

A linear regression representation and mean relative difference versus SZA are given in Figure 9 for all RTUV cases. On all subplots of Figure 9a, data corresponding to a daily mean AOT higher than the monthly mean AOT are represented in red. All conditions are in blue. RTUV01 and RTUV04 use different aerosol inputs, RTUV01 was modelled with an aerosol daily mean and RTUV04 used a monthly climatology. The MRD of RTUV01 is lower than that of RTUV04, whereas the opposite is true for the MED. Unlike the mean, the median is insensitive to outliers. In section 4.2.4 it was noted that, even if MRD is very low, there are also singular peaks that can reach up to 30% MRD. These are the outliers that are taken into account in RTUV04. Close examination of Figure 9a reveals consistent outliers under the fitted curves for RTUV01, 02, 03, 05 and 06, which correspond to an underestimation of the UVI (due to overestimation of AOT). For RTUV04, which is the case with monthly climatological values of AOT, there are of course only blue crosses. Bottom outliers on every other RTUV case can be explained by the use of an AOT daily mean. Since the CIMEL sunphotometer only takes measurements when the sun is directly visible, and we have previously shown a strong presence of clouds, using an AOT monthly climatology can sometimes be better than the daily mean.

The optimised input configuration is RTUV03. The corresponding statistical values are consistent with those found in other studies. Badosa et al. (2007) found a MRD lower than 10% concerning observations with a similar instrument and filtering techniques at Lauder (45.04° S), Boulder(40.01° N), Mauna Loa(19.53° N) and Melbourne(37.63° S). Mauna Loa can be compared with Reunion Island as both sites are in the tropics with similar weather conditions, MRD between Badosa et al. (2007) model cases and observations ranged from -1.8 % to 3.6 %. In the present study comparable values of MRD were found (ranging from 0.43 % to 4.38 %, which is well within the modelling uncertainty of 5 %). The filtering method at Mauna Loa was probably stronger due to the use of Sky Imager.

Diurnal cycles of RD between RTUV01 and UV-SWF are represented in Figure 10 for all the year and for two seasons, austral winter (June, July and August) and austral summer (December, January and February). Since the SAOZ instrument is colocated with the BENTHAM spectrometer we choose to use RTUV01 for the comparison even if RTUV03 gave better results. RD tends to increase during the day for all year and both seasons due to the formation of clouds. Standard deviation is higher in the afternoon during summer, due to the strong presence of clouds in this period (see Figure 2). Since there are fewer clear-sky measurements for this period, the comparison is statistically weaker here, which increased the dispersion. In winter, there is more data available, and less filtering (see Figure 2), so standard deviations are smaller.
In Figure 11 the diurnal cycle of the UVI seasonal mean and maximum are represented. Consistent results are obtained. Mean non-filtered UVI are always lower than mean clear-sky values. As mentioned before, the model tends to overestimate clear-sky UVI. Both filtered data (UVI-SWF and UVI-SYNOP) are in agreement, UVI-SYNOP diverges from UVI-SWF during the afternoon for the austral summer but, as stated before, SYNOP observer reports are less accurate than SWF cloud fractions. This is probably due to the distance between SYNOP observer reports, which are about 10 km from SWF, and UVI measurements, and the sampling difference: 1h for SYNOP, 1 min for SWF and 15 min for UV measurements. It would be very interesting to add an all-sky camera on the same site for more accurate indications of cloudiness. Austral summer is usually a very cloudy season in this southern tropical region. A maximum of UVI appears for unfiltered data (green dashed line) with strong values, usually up to 18, around 8:00 UTC (local noon time). This is probably due to UV enhancement by cloud fractional sky cover. This phenomenon has been described before, for example by Calbó et al. (2005) and Jégou et al. (2011) and its quantification in the southern tropics will be the subject of a future study.

6 Conclusions

The physics of radiative transfer is a well understood but the modelling of surface UV radiation is still a challenge since multiple parameters need to be taken into account. For clouds, we can simply filter observations and work in clear-sky conditions.

We investigated the sensitivity of clear-sky UV radiation modelling to various input parameters. The impact of different extraterrestrial spectra or ozone cross sections has not been investigated previously. For the extraterrestrial spectrum, we found a relative difference between 2.7% and 3.5% depending on the total ozone column and solar zenith angle. For the ozone cross sections, the relative difference ranged from 2.4 to 2.9%, also with a dependency on total ozone column and solar zenith angle. The impact was higher for low solar zenith angle and low total ozone column during the diurnal and seasonal maximum of UVI, i.e. when the burning efficiency of the radiation on human skin is higher. This difference was found to be dependent on the ozone and temperature profile.

For total ozone column and aerosols, the results were close to those of other studies carried out at different latitudes (Badosa et al., 2007). Badosa et al. (2007) also investigated the impact of ozone total column and aerosol optical thickness for four different sites: Lauder, New Zealand (45.04° S, 169.68° E), Boulder, Colorado (40.01° N, 105.25° W), Mauna Loa, Hawaii (19.53° N, 155.58° W) and Melbourne, Australia (37.69° S, 144.95° E). They found that different sources of input for total ozone column (SBUV or TOMS satellite measurements or Dobson ground measurements) had an impact of ~2% to 5% on the surface UVI modelled. Here we found monthly mean differences between -2.5% and 7.5% (Figure 4). The mean difference of UVI sensitivity to the total ozone column was smaller than 0.4% between any two datasets. UVI RTUV01 (SAOZ) was higher than RTUV02 (OMTO3). OMTO3 was on average the lowest total ozone column, which led to the highest modelled values of UVI. Brogniez et al. (2016) found that OMI-UVI products were higher than local measurements of UVI in Reunion Island with a mean relative bias of about 2% and and median relative bias of 4%. OMI-UVI products are based on the OMTO3 product, but also take other OMI products (aerosols, surface albedo) into account (Krotkov et al., 2002). Here, using OMTO3 as the only input parameter to retrieve UVI did not produce a strong positive bias. Following the same study for aerosol (Badosa
et al., 2007), it was found that AOT was very low at Mauna Loa, with values centred around 0.08, and the ratio between UVI modelled with and without aerosol was always between 0.96 and 1.02. Here, we found small mean differences between UVI modelled using daily measurements and monthly climatological values of AOT (about -0.40%) but strong peaks in AOT could be missed and would yield UVI overestimations of ~30%. Aerosol monthly climatology could be used for climatic studies of surface UVI but should be avoided for short-term predictions and preventive action for the population concerned, especially during the biomass burning season.

We also investigated the relationship between total ozone column and UVI variations through the Radiative Amplification Factor (from a linear and a power law). At a SZA of 25° for the observations (UVI-SWF), model (RTUV07) and idealized model (i-RTUV), a $RAF_L$ of respectively 1.23, 1.34 and 1.34 was found. At a higher SZA, 60° a lower $RAF_L$ was found: respectively 1.02, 1.16 and 1.23. $RAF_P$ was higher than in other studies ((Booth and Madronich, 1994) (Herman, 2010)) but these were done at higher latitudes. Here we found a $RAF_P$ of 1.65 ± 0.12 for UVI-SWF at a SZA of 45 °. Bodhaine et al. (1997) found 1.38 ± 0.2 for a similar site in the tropics. In general RAF tends to decrease as SZA increases. The significant dispersions on the observations make it impossible to conclude on the linear or power relation between Total Ozone Column and UVI.

As previously noted RAF tends to decrease as SZA increases, presumably because of various effects such as the influence of ozone, temperature profiles and Rayleigh scattering, which would reduce the impact of TO3 on UVI.

Clear-sky UVI in the southern tropics was modelled with a MRD of 0.43 ± 5.83 % up to 4.38 ± 5.78 % when comparing to ground-based measurements, which is within the modelling uncertainty of 5%. MED values ranged from 0.44 % to 4.51 %.

Monthly climatology of filtered and unfiltered clear-sky conditions revealed few maximum values of UVI during all sky conditions, this phenomenon is due to multiple reflections on cloud edges in case of broken cloud cover.

Future study will be needed to take this into account. TUV is a one-dimensional model but, to considerer backscattering we need to have at least two-dimensional radiative transfer modelling. Following these results, the next step will be a projection of UV changes in the southern tropics.
