Abstract

Two-sized aerosol and rain sampling were carried out at a rural site located on the coast of the Eastern Mediterranean, Erdemli, Turkey (36° 33’ 54” N and 34° 15’ 18” E). A total of 674 aerosol samples in two size fraction (coarse = 337; fine = 337) and 23 rain samples were collected between March 2014 and April 2015. Samples were analyzed for NO₃⁻, NH₄⁺ and ancillary water-soluble ions by Ion Chromatography and water-soluble total nitrogen (WSTN) by applying a High Temperature Combustion Method. The mean aerosol WSON was 23.8 ± 16.3 nmol N m⁻³, reaching a maximum of 79 nmol N m⁻³, with about 66% being associated with coarse particles. The volume weighted mean (VWM) concentration of WSON in rain was 21.5 µmol N L⁻¹. The WSON contributed 37% and 29% to the WSTN in aerosol and rainwater, respectively. Aerosol WSON concentrations exhibited large temporal variations mainly due to meteorology and the origin of air mass flow. The highest mean aerosol WSON concentration was observed in the summer and was attributed to the absence of rain and re-suspension of cultivated soil in the region. The mean concentration of WSON during dust events (38.2±17.5 nmol N m⁻³) was 1.3 times higher than that of non-dust events (29.4±13.9 nmol N m⁻³). Source apportionment analysis demonstrated that WSON was originated from agricultural activities (43%), secondary aerosol (20%), nitrate (22%), crustal (10%) and sea-salt (5%). The dry and wet depositions of WSON were equivalent and amounted to 36% of the total atmospheric WTSN flux.

Keywords: Atmospheric water-soluble organic nitrogen, mineral dust, source apportionment, atmospheric deposition and marine productivity, Eastern Mediterranean
1. Introduction

Research assessing the atmospheric deposition of nitrogen (with a focus on inorganic N in rainwater i.e. ammonium and nitrate) can be traced back to the mid-1800s (Miller, 1905 and references therein) as it was accepted to be a vital plant nutrient. Miller (1905) mentioned about organic nitrogen in rain samples as well. To quote Miller: ‘With regard to the amount of organic nitrogen in the rainwater, the only available analyses relating to Rothamsted are those of Frankland who found from 0.03 to 0.66 per million in 69 samples’. Cornell et al., (1995) highlighted the importance of organic nitrogen in rain and snow accounting for almost half of the total atmospheric dissolved nitrogen deposition. Since then, research defining the quantitative importance of soluble organic nitrogen in the atmospheric transport of nitrogen has greatly expanded (Neff et al, 2002; Cornell et al., 2003; Mace et al., 2003a, b, c; Gilbert et al., 2005; Sorooshian et al., 2008; Violaki and Mihalopoulos, 2010; Violaki et al., 2010; Altieri et al., 2016).

WSON arises from a variety of sources including both natural and anthropogenic. Anthropogenic sources include agricultural activities (including fertilizer application, livestock and animal husbandry), cooking, high temperature fossil fuel combustion, vehicle exhaust, man-made biomass burning and industrial activities. In contrast natural sources of WSON include mineral dust, bacteria, algal blooms, degraded proteins, sea salt, organic debris, natural biomass burning (Neff et al, 2002; Cornell et al., 2003; Mace et al., 2003a, b, c; Gilbert et al., 2005; Sorooshian et al., 2008; Cape et al., 2011; Altieri et al., 2016). Atmospheric organic nitrogen can also be formed through chemical reactions. For example, reactions between volatile organic compounds, NOx and ammonium sulfate aerosols may lead to the formation of nitrogen-containing compounds (Surratt et al., 2008; Galloway et al., 2009; De Haan et al., 2011; Yu et al., 2011). Furthermore, atmospheric organic nitrogen plays an essential role in many global processes which may impact on the chemistry of the
atmosphere as well as climate and biogeochemical cycles. Similar to ammonium, some organic nitrogen species such as urea and amines have acid-neutralizing capacities (Ge et al., 2011). It has been shown that nitrogen containing organic compounds nucleate cloud droplets and may contribute considerably to the indirect aerosol effect (Twohy et al., 2005).

Phytoplankton and bacteria production in aquatic environments has been found to be stimulated by the addition of water-soluble organic nitrogen (Timperley et al., 1985; Peierls and Paerl, 1997; Seitzinger and Sanders, 1999). The laboratory experiments performed by Seitzinger and Sanders (1999) demonstrated production of coastal marine bacteria and phytoplankton which are stimulated by the addition of water-soluble organic nitrogen, 45-75% being bioavailable. From the mid 1800s to 2000, as a result of anthropogenic activities, reactive nitrogen and reactive anthropogenic organic nitrogen have increased by almost 3 and 5 fold, respectively, leading to a significantly modified global nitrogen cycle (Jickells et al., 2017). This in turn has impacted upon the marine nitrogen biogeochemical cycling (Galloway et al., 2002, 2008; Duce et al., 2008; Jickells et al., 2017).

The Mediterranean Sea is characterized by oligotrophic surface waters with Low Nutrient Low Chlorophyll (LNLC) regions. This has been attributed to mainly anti-estuarine (reverse thermohaline) circulation (Hamad et al., 2005). The Eastern Mediterranean (25) has higher molar N/P ratios than those observed in the Western Mediterranean (22) and the Redfield ratio (Krom et al., 2004; Yılmaz and Tuğrul, et al., 1998). Generally, the primary productivity in the Eastern Mediterranean is phosphorous limited (Krom et al., 1991; Krom et al., 2010; Powley et al., 2017). Depending on season, the limitation by nitrogen or co-limitation by nitrogen and phosphorus in the Eastern Mediterranean have been reported (Yücel, 2013; Yücel, 2017 and references therein). Based on molar N/P ratios in the atmospheric input (order of magnitude higher than that of Redfield, Markaki et al., 2003, 2010; Koçak et al., 2010) and riverine fluxes (at least 1.8 times larger than that of Redfield,
Ludwig et al., 2009; Koçak et al., 2010) it has been suggested that the Eastern Mediterranean receives excessive amounts of dissolved inorganic nitrogen and this unbalanced inputs may result in even more phosphorus deficiency (Ludwig et al., 2009; Koçak et al., 2010) whilst the atmospheric deposition of reactive nitrogen may cause accumulation of nitrogen in water column (Jickells et al., 2017). Very little research has focused on the importance of water-soluble organic nitrogen inputs to marine productivity in the Eastern Mediterranean (Mace et al., 2003a; Violaki and Mihalopoulos, 2010; Violaki et al., 2010). Hence, the unique contributions of the current study will be to (i) define the temporal variability of atmospheric water-soluble organic nitrogen, (ii) assign the origin of the water-soluble organic nitrogen, (iii) assess the influence of mineral dust on water-soluble organic nitrogen and (iv) enhance our knowledge of the quantitative dry and wet deposition for water-soluble organic nitrogen and its possible influence on marine productivity in the North Eastern Mediterranean.

These will be achieved by using the acquired data from the analyses for water soluble inorganic and organic nitrogen species of a series of size fractionated aerosol (coarse and fine) and rain samples collected from March 2014 to April 2015 from the northern coast (Erdemli, Turkey) of the Levantine Basin, Eastern Mediterranean.

2. Material and Methods

2.1. Sampling Site Description

Aerosol and rain sampling were carried out at a rural site located on the coast of the Eastern Mediterranean, Erdemli, Turkey (36° 33’ 54” N and 34° 15’ 18” E). The sampling tower (above sea level ~ 22 m, ~ 10 m away from the sea) is situated at the Institute of Marine Sciences, Middle East Technical University (IMS-METU). Its immediate vicinity is surrounded by cultivated land to the north and to the south of the Northern Levantine Basin. Although the site is not under the direct influence of any industrial activities (soda and
fertilizer), the city of Mersin with a population of around 800,000 is located 45 km to the east of the sampling site (Kubilay and Saydam, 1995; Koçak et al., 2012) and hence aerosol and rainwater samples may have been influenced by aforementioned regional anthropogenic activities when air mass transported from the east.

2.2. Sample Collection and Preparation

Aerosol: A Gent type stacked filter unit (SFU) was used to collect aerosol samples in two size fraction (coarse: $d = 10-2.5 \, \mu\text{m}$ and fine: $d < 2.5 \, \mu\text{m}$) (for more details see Hopke et al., 1997; Koçak et al., 2007). Briefly, the first section of the filter holder was loaded with an 8 $\mu$m pore size polycarbonate filter (Whatman Track Etched 111114, circle diameter: 47 mm), whilst the second section was loaded with a 0.4 $\mu$m pore size polycarbonate filter (Whatman Track Etched 111107, circle diameter: 47 mm). The cassette unit was then placed into the cylindrical cassette holder, which is designed to prevent the intrusion of particles larger than 10 $\mu$m when the sampler is operated at a flow rate of 16.0-16.5 L/min. Daily (24 hours) temporal sample resolution was carried out. Operational blank filters were processed in the same way as the collected samples with the exception that no air was passed through the filters. In order to minimize any possible contamination, the filter loading and unloading were achieved in a laminar airflow cabinet.

The aerosol sampling campaign commenced in March 2014 and ended in April 2015. During the sampling period, a total of 674 aerosol samples in two size fractions (coarse = 337; fine = 337) were obtained. The observational coverage of the aerosol sampling period was 80%. The observational coverage for winter, spring, summer and fall was respectively 60 %, 92 %, 81 % and 79 %. The seasonal observational coverage, after applying a precision value of 0.3 (for more details see section 2.4 and Eq.4), was found to be comparable for winter (49 %), spring (53 %), summer (51 %) and fall (52 %). The sampling was terminated from time to
time due to technical malfunction of the SFU and/or cleaning procedure of the sampling apparatus.

Rain: Rainwater samples were collected using an automatic Wet/Dry sampler (Model ARS 1000, MTX Italy). A total of 23 rain samples were collected during the sampling period. After each rain event, the rainwater samples were immediately transferred to the laboratory for filtration (0.4 µm Whatman, polycarbonate filters). Operational blanks for rain samples were taken by using 100 mL of Milli-Q water after cleaning the HDPE buckets with phosphate free detergent, HCl (10 %) and Milli-Q water (3 times).

Storage of Samples: Aerosol and rainwater samples were stored frozen (-20 °C) immediately after collection until analyses (not more than a month). Cape et al. (2001) have been shown that there were no significant losses for inorganic and organic nitrogen during the storage (freezing for 3 months) of rain samples with an added biocide.

Sample Preparation: In order to determine the concentrations of water-soluble nitrogen species (WSTN, NO$_3^-$ and NH$_4^+$) and major water-soluble ions (Cl$^-$, SO$_4^{2-}$, Na$^+$, K$^+$, Mg$^{2+}$, Ca$^{2+}$) in an aerosol sample, one quarter of the filter was extracted for 60 minutes in 20 mL of ultra-pure water (18.2 Ωm) by mechanic shaking. About 100 µL chloroform (Merc 2444, 99.8 %) was added as a preservative to prevent biological activity after removing the filter (Bardouki et al., 2003, Koçak et al., 2007). Before measuring the water-soluble species, extracts were filtered with 0.4 µm pore size polycarbonate filters.
2.3. Chemical Analysis

Water Soluble Total Nitrogen: High Temperature catalytic oxidation (Torch Teledyne Tekmar TOC/TN) was applied to determine the WSTN concentrations in the aerosol and rainwater samples. The liquid aliquot of the sample is injected into the combustion furnace (750 °C) and the N in the sample was then converted to NO gas. The carrier gas (high purity dry air) sweeps the sample into nondispersive infrared detector. From here, the sample is carried to the nitrogen module. In this unit NO is mixed with O₃ since the chemiluminescent detection of NO is based on the reaction between NO and O₃. After the formation of excited nitrogen dioxide (NO₂⁺), the extra energy is given of as light when NO₂⁺ relaxes to its ground state. The light signal to an electronic signal for quantification is then measured by a chemiluminescence detector with a photomultiplier tube.

The standards were prepared from KNO₃ of high purity (> 99 %, Merck Extra Pure, CC551961). In order to evaluate accuracy of the WTSN measurements, nitrate, ammonium, urea and mixture of these species were detected by Torch Teledyne Tekmar instrument. Recovery for these substances was better than 92 %. In addition, the accuracy of the total nitrogen determination by the instrument was verified against intercalibration samples of QUASIMEME Program (Quality Assurance of Information for Marine Environmental Monitoring in European Laboratory Performance Studies). Correspondingly, recoveries for QNU277SW (IMS-METU = 4.67 µM, Mean = 5.17 µM), QNU278SW (IMS-METU = 10.41 µM, Mean = 11.30 µM) and QNU279SW (IMS-METU = 4.67 µM, Mean = 5.17 µM) 90 %, 92 % and 83 %. Blank values of WSTN for aerosol and rain samples were less than the limit of detection (3.6 nmol).
Water soluble Inorganic and Ancillary Species: In addition to NO$_3^-$ and NH$_4^+$, major water-soluble ions concentrations were measured by using a Dionex ICS-5000 Ion Chromatography instrument. Water-soluble anions (Cl$^-$, SO$_4^{2-}$, NO$_3^-$) were determined by applying AS11-HC separation column, KOH (30 mM) eluent and AERS-500 (4 mm) suppressor whilst water-soluble cations (Na$^+$, K$^+$, Mg$^{2+}$, Ca$^{2+}$) were detected electrochemically by using a CS12-A separation column, MSA (20 mM) eluent and CSRS-300 (4 mm) suppressor (Product Manual for Dionex IonPac AS11-HC-4m, IonPac CS12A Manual). The blank contributions for all water-soluble ions in aerosol samples were found to be less than 10 % and concentrations were corrected for blanks.

2.4. Calculations

WSON concentrations (see Eq. 1) were determined from the difference between the individual concentrations of WSTN and water-soluble inorganic nitrogen (WSIN) (see Eq. 2) since there is no direct analytical method to detect the concentration of water-soluble organic nitrogen. The precision for WSON was calculated via using the formula (see Eq. 3) suggested by Hansell (1993). The precision (75 nmol N m$^{-3}$) was found to be almost three times higher (see Eq. 4, R $\sim$ 0.3) than that of the arithmetic mean of WSON in aerosols whilst it (90 µmol N L$^{-1}$) was estimated to be approximately four times larger than that of volume weighted mean of WSON in rain. Such high values are not unusual. For example, if the data presented by Mace et al. (2003a) would be used, precisions would have been 5 and 8 times higher than those of the concentrations of WSON in aerosol and rain, respectively. Table 1 shows the number of negative WSON values and the positive WSON biases for coarse and fine modes. Correspondingly, about 5 (n=18) and 15 % (n=52) of the values were negative in coarse and fine particles. The substitution with zero yielded 2 and 14 % positive bias for coarse and fine mode whereas; the omission of zero resulted in 8 and 34 % positive bias in coarse and fine
WSON mean concentrations. Consequently, the presentation of the general characteristics of the data includes all negative concentrations (see Table 1) whilst the values presented in Table 1 will be used for calculating dry and wet deposition. It has been stated that the uncertainty in WSON concentrations results from the additions of errors such as oxidation efficiency of method, sampling material, storage of samples and usage of preservative (Cape et al., 2011). These authors have particularly pointed out that low precision for samples with low concentrations of WSON and high levels of WSIN (see Eq. 2). Although, the calculation of precision for WSON is very difficult owing to aforementioned errors, Hansell (1993) has proposed estimation of precision for WSON exclusively relaying on measured WSTN and WSIN concentrations. Consequently, in order to evaluate the variability in the aerosol WSON and apply PMF, however, different approach was adopted. To this end, arbitrary thresholds have been defined as the ratio between WSON mean concentration and the calculated precision (see Eq. 4). Thus, during assessing the variability in aerosol WSON and the application of PMF, WSON concentrations having R values larger than 0.3 will be considered since the arbitrary threshold simply reduces the uncertainty. A total of 216 aerosol samples were found to be higher than the value of 0.3.

\[
WSON = WSTN - WSIN \quad (1)
\]

\[
WSIN = NO_3^- + NH_4^+ \quad (2)
\]

\[
S_{WSON} = (s_{WSTN}^2 + s_{WSIN}^2)^{1/2} \quad (3)
\]

\[
R = \frac{WSON_{MEAN}}{S_{WSON}} \quad (4)
\]

The rain volume weighted average concentration (C_w) of nitrogen species can be calculated as follow:

\[
C_w = \frac{\sum_{i=1}^{n} C_i x Q_i}{\sum_{i=1}^{n} Q_i} \quad (5)
\]
The wet and dry atmospheric fluxes of nitrogen species were calculated according to the procedure explained in Herut et al. (1999, 2002). The wet atmospheric deposition fluxes \( (F_w) \) were calculated from the annual precipitation \( (P_{\text{annual}}) \) and the volume weighted mean concentration \( (C_w) \) of the substance of interest.

\[
F_w = C_w \times P_{\text{annual}} \quad (6)
\]

The dry deposition \( (F_d) \) is calculated as the product of the atmospheric mean nutrient concentrations \( (C_d) \) and their settling velocities \( (V_d) \), where \( F_d \) is given in units of \( \mu \text{mol m}^{-2} \text{ yr}^{-1} \), \( C_d \) in units of \( \mu \text{mol m}^{-3} \) and \( V_d \) in units of \( \text{m yr}^{-1} \).

\[
F_d = C_d \times V_d \quad (7)
\]

The settling velocities \( (V_d, \text{see Eq. 8}) \) for each water-soluble nitrogen species were calculated by using an approach adopted by Spokes et al. (2001). \( C_c \) and \( C_f \) refer to as the relative contribution of coarse and fine modes and 2.0 and 0.1 cm s\(^{-1}\) are deposition velocities proposed by Duce et al. (1991) for coarse and fine particles, respectively.

\[
V_d = C_c \times 2.0 + C_f \times 0.1 \quad (8)
\]

### 2.5. Air Masses Back Trajectories and Airflow Classification

Three day back trajectories of air masses at the four altitude (1000, 2000, 3000 and 4000 meter) levels arriving at Erdemli station were computed by using the HYSPLIT Dispersion Model (HybridSingle Particle Lagrangian Integrated Trajectory; Draxler and Rolph, 2003). Three day back trajectories reaching at the altitude of 1000 m were classified into six sectors: (i) Middle East, (ii) North Africa, (iii) Turkey, (iv) Eastern Europe, (v) Western Europe and (vi) Mediterranean Sea in order to assess the influence of airflow on WSON concentration in PM\(_{10}\) (for more details see Koçak et al., 2012).
2.6. Positive Matrix Factorization (PMF) for Source Apportionment of WSON

The receptor modeling tool *Positive Matrix Factorization* (U.S. Environmental Protection Agency PMF version 5.0, hereinafter referred to as ‘PMF’) was utilized to identify the sources of WSON in PM$_{10}$ at Erdemli. PMF has been proven to be a robust tool in characterizing the sources of aerosol (Paatero and Tapper, 1994; Huang et al., 1999; Lee et al., 1999; Viana et al., 2008; Koçak et al., 2009, for more details see Appendix A). EPA PMF 5.0 software mainly consists of Model Run and Rotational tools (see EPA/600/R-14/108; USEPA, 2014). Before application of the software, the user must supply two input files namely, concentration and uncertainly. The former contains concentrations of the aerosol species whilst the latter has corresponding uncertainty for each variable. Uncertainty was set to 5 % for each species with the exception of WSON (15 %) since WSON exclusively donated high uncertainty (for more details see Appendix A). The base run of PMF was achieved by setting the number of runs and random starting points (in other word seeds) to 250 and 50, respectively. Base Model Displacement (DISP), Bootstrap (BS) and Bootstrap Displacement (BS-DISP) methods were sequentially used after base run. The DISP accesses the rotational ambiguity. DISP error estimates showed that there were no factor swaps and significant decrease in Q during DISP, being 0 and 0.00, respectively. Therefore, DISP results did not reveal rotational ambiguity, implying the solutions to be robust. Except in one case, results from BS and BS-DISP (n=50) did not indicate any asymmetry and rotational ambiguity for 5 factors. To evaluate the rotational ambiguity, different Fpeak values were applied, considering changes in dQ to be less than 5 %. Furthermore, G-shape plots of Fpeak solutions were examined to determine convergence toward the axis or lower/zero contribution. Thus, Fpeak value of -0.7 was used and five factors were identified by using PMF 5.0. BS of Fpeak at -0.7 did not reveal any swaps for five factors. The slope of the
estimated WSON against measured WSON was 10 % less than unity with correlation coefficient and intercept of 0.87 and 1.5 (nmol N m\(^{-3}\)), respectively.

3. Results and Discussion

3.1. General Characteristics of the Data

In this section the general characteristics of the Water-Soluble Organic Nitrogen (WSON), Nitrate (NO\(_3^-\)), Ammonium (NH\(_4^+\)) and Water-Soluble Total Nitrogen (WSTN) in aerosol and rain will be discussed.

**Aerosol:** The statistical summary for WSON, NO\(_3^-\), NH\(_4^+\) and WSTN in PM\(_{10}\) aerosol samples obtained from Erdemli between March 2014 and April 2015 is presented in Table 2. Median values for WSON, NO\(_3^-\), NH\(_4^+\) and WSTN were respectively 10 %, 20 %, 40 % and 10 % lower than those of arithmetic means. Among the nitrogen species, WSON exhibited the highest arithmetic mean, followed by ammonium and nitrate concentrations respectively. The maximum concentration of WSON was estimated to be 79 nmol N m\(^{-3}\) with a mean value and standard deviation of 23.8 ± 16.3 nmol N m\(^{-3}\). The observed arithmetic was comparable to those reported by Mace et al. (2003a) for the same site. Approximately 66 % of the WSON was associated with coarse particles, the remaining fraction (34 %) was present within the fine mode. A number of studies have reported the relative size distribution of WSON for the Eastern Mediterranean marine aerosol (Finokalia, Violaki and Mihalopoulos, 2010) and those observed at remote marine sites (Hawaii, Cornell et al., 2001; Tasmania, Mace et al., 2003b). The aerosol WSON at Finokalia (68 %) and Hawaii were primarily found in the fine mode whilst WSON in the south Pacific marine aerosol (Tasmania) was mainly associated with the coarse fraction. It is likely that the WSON at Erdemli (a) is relatively less impacted by
anthropogenic sources and/or (b) is more influenced by mineral dust transport and re-
suspension of cultivated soil compared to that observed at Finokalia.

NO$_3^-$ and NH$_4^+$ aerosol concentrations ranged between 0.2-88.4 and 0.5-164.4 nmol N m$^{-3}$ with mean values (standard deviations) of 17.9 (±15.7) and 23.3 (±24.4) nmol N m$^{-3}$. As expected, NO$_3^-$ was mainly associated with coarse particles, accounting for 87 % of the observed mean value while NH$_4^+$ was dominant in the by fine mode, contributing 96 % to the detected mean concentration. Similar results have been reported for Eastern Mediterranean marine aerosol (Bardouki et al, 2003; Koçak et al., 2007). The predominance of NO$_3^-$ in the coarse mode might be due to gaseous nitric acid or other nitrogen oxides reacting with alkaline sea salts and mineral dust particles. In contrast, the occurrence of NH$_4^+$ in the fine fraction is mainly as a result of the reaction between gaseous alkaline ammonia and acidic sulfuric acid (Mihalopoulos et al., 2007).

WSTN concentrations in aerosols varied between 9.7 and 176.5 nmol N m$^{-3}$ with an arithmetic mean value of 63.5± 32.0 nmol N m$^{-3}$, respectively. The mean WSTN concentration being almost equally influenced by coarse (51 %) and fine particles (49 %). Table 2 demonstrates the relative contributions of WSON, NO$_3^-$ and NH$_4^+$ to the WSTN in PM$_{10}$. As can be deduced from the table, the WSTN concentration was equally influenced by WSON and NH$_4^+$, each species contributing 37% and 35 %, respectively. In contrast the contribution of NO$_3^-$ to WSTN was found to be 28 %.

**Rain:** Volume-weighted-mean (VWM) concentrations of WSON, NO$_3^-$, NH$_4^+$ and WSTN in rainwater are presented in Table 2, along with the minimum and maximum concentrations as well as the relative contributions of WSON, NO$_3^-$ and NH$_4^+$ to WSTN. As can be deduced from table, VWM concentrations of each species were comparable, NH$_4^+$ exhibited the highest concentration with a value of 28.7 μmol N L$^{-1}$. The VWM concentration of WSON and NO$_3^-$
were 21.5 and 23.3 μmol N L⁻¹, respectively. Considering their relative contributions to WSTN, WSON and NO₃⁻ account 29 and 32 % of the WSTN whilst NH₄⁺ represented 39 % of the observed WSTN concentration in rainwater.

3.2. Comparison of WSON in Aerosol and Rain with data from the Literature

The concentrations of WSON in marine aerosols and rain samples collected from different sites located around the Mediterranean, Atlantic and Pacific regions are illustrated in Table 3. Comparing the current WSON values with those reported in the literature is challenging due to (i) different applied sampling periods, sampling and measurement techniques and (ii) the high uncertainty associated with the estimation of WSON. Furthermore, within the literature there is a lack of information defining the uncertainty of WSON though there is a substantial statistical knowledge. Keene et al. (2002) in particular, have highlighted the tendency in the literature to neglect negative values or substitute such values with zero instead when calculating the WSON from the difference between WSTN and WSIN. As these authors have highlighted the omission or substitution of such values inevitably would result in a positive bias in the WSON concentrations.

In general, the lowest concentrations in aerosols were found in those derived from remote or pristine marine environments. The WSON concentrations in the atmosphere over the Indian (Amsterdam Island: 1.0 nmol N m⁻³, Violaki et al., 2015), Atlantic (Barbados: 1.3 nmol N m⁻³, Zamora et al., 2011) and Pacific Ocean (Hawaii, Oahu: 4.1 nmol N m⁻³, Cornell et al., 2001, Tasmania: 5.3 nmol N m⁻³, Mace et al., 2003b) were at least 4 times less than those observed for Eastern Mediterranean (Erdemli: 23.8 nmol N m⁻³, this study; Finokalia: 17.1 nmol N m⁻³, Violaki and Mihalopoulos, 2010). These lower values might be attributed to (i) the absence of the strong anthropogenic sources in the vicinity of the sampling sites, (ii) the dilution of the WSON originating from long range transport via both dry and wet
deposition and/or (iii) small contributions from non-land based local emissions such as sea salt and algal blooms. The highest WSON concentrations emerged particularly over China (Ho et al., 2015) concentration of WSON measured in PM$_{2.5}$ and Taiwan (Chen et al., 2010) with values above 70 nmol N m$^{-3}$. As stated in Chen et al. (2010) WSON concentrations at these sampling sites were markedly influenced by anthropogenic activities such as fossil fuel combustion and man induced biomass burning. Concentrations over the Amazon (Mace et al., 2003c) in the dry season (61 nmol N m$^{-3}$) have also been noted. Such high values were ascribed to natural fires (Mace et al., 2003c). The mean WSON concentration at Erdemli (23.8 nmol N m$^{-3}$) was comparable to that reported previously for the same site (29 nmol N m$^{-3}$, Mace et al., 2003a). In contrast, the present WSON concentration was almost 1.5 times higher than that observed at Finokalia (Violaki and Mihalopoulos, 2010).

The reported WSON values for rain also exhibited the lowest concentrations in those derived from remote or pristine marine environments, such as Hawaii (2.8 μmol N L$^{-1}$, Cornell et al., 2001). The highest WSON concentrations were observed in China (North China Plain: 103 μmol N L$^{-1}$, Zhang et al., 2008) and Norwich, UK (33 μmol N L$^{-1}$, Cornell et al., 1998), respectively. These high values were again attributed to the anthropogenic sources.

### 3.3. Temporal Variability of Water-Soluble Nitrogen Species in Aerosol Erdemli

Fig.1 illustrates daily variation of the water-soluble nitrogen species in aerosol samples together with the daily rainfall from March 2014 to April 2015. The same figure also presents the concentrations in rainwater samples collected between October 2014 and April 2015. It is clear that WSON concentrations exhibited large variations from one day to another day. The daily variability in the concentration of WSON may be an order of magnitude. Such variability has also been reported in the Atlantic (Zamora et al., 2011), Pacific (Chen et al., 2010) and Eastern Mediterranean marine aerosols (Violaki and Mihalopoulos, 2010).
studies demonstrated that the daily change in the concentrations of WSON arises from a combination of (a) meteorological parameters (such as rain, temperature and wind speed/direction), (b) chemical reactions, (c) history of air masses back trajectories and (d) source emission strength.

In general, lower concentrations of WSON were found to be associated with rainy days. To serve as an illustration, one of the lowest WSON concentrations was observed on 19th of October 2014, after two consecutive days of rainfall, with a value of 6 nmol N m$^{-3}$. In contrast, one of the highest observed WSON concentrations (66.1 nmol N m$^{-3}$) was detected on 2nd of March 2014 when the air mass back trajectories were associated with south/south westerly airflow (for more details see section 3.4). Another high concentration of WSON was observed on 5th of July 2014, with a value of 66 nmol N m$^{-3}$. 94% of the WSON was present in the coarse mode, however, during this event there was no intense dust intrusion either from the Sahara or from the Middle Eastern deserts. Corresponding OMI-AI index and nssCa$^{2+}$ (33 nmol m$^{-3}$) also supports this observation (see Fig.2). Lower layer air mass back trajectories (1000 and 2000 m) demonstrated that Erdemli was under the influence of north/north westerly airflow from Turkey after passing over Turkey’s largest cultivated plain, Konya. Thus, this high value might be attributed to re-suspension of the soil affected by intense agricultural activities. On 20th of January 2015 the WSON concentration was 60 nmol N m$^{-3}$, 72% being present in the fine mode. For this event, the NH$_4^+$ concentration was 20 nmol N m$^{-3}$, two times higher than the observed arithmetic mean in winter. Corresponding trajectories, AOD (Aerosol Optical Depth) and AC (Angstrom Component) images are presented in Fig.3. Airflow at 1 km showed air mass flow arriving at the sampling site from Turkey. AOD values over the sampling site and coastline of Northeastern Mediterranean ranged from 0.2 to 0.5 whilst AC values demonstrated that the region was dominated by fine particles. Based on above indicators, it may be concluded that anthropogenic sources were dominant.
A summary of the statistical analyses of the seasonal dataset of aerosol associated WSON, NO$_3^-$ and NH$_4^+$ are shown in Table 4. The Mann-Whitney U test indicated that there was a statistically significant difference among seasons, such that Summer > Spring ≈ Winter > Fall. The arithmetic mean value of WSON in the summer was found to be 1.3 and 2.0 times greater than observed for Spring/Winter and Fall, respectively. Percent WSON contributions of coarse mode for winter (50 %), spring (50 %) and fall (55 %) were comparable. However, WSON was chiefly associated with coarse particles in summer, amounting to 83 %. This high value in summer might be due to the absence of rainfall (see Fig.1) and enhanced re-suspension of cultivated soil in the region. In summer, the mean concentration of NH$_4^+$ was almost 2.4 times larger than all other seasons. The mean water-soluble NO$_3^-$ in summer was 1.4 higher than that of spring. High NH$_4^+$ and NO$_3^-$ concentrations in summer might be attributed again to the absence of rainfall and increase in incoming radiation. Similar results have been reported for the Eastern Mediterranean (Bardouki et al., 2003).

3.4. Influence of Mineral Dust Episodes on WSON aerosol concentrations

As it is well documented, the Eastern Mediterranean Sea is heavily impacted by mineral dust episodes originating from Sahara and the Middle East deserts (Kubilay and Saydam, 1995; Kubilay et al., 2000, Koçak et al., 2004a, b and 2012).

For the current study between March 2014 and April 2015, water-soluble non-sea salt calcium concentrations higher than 50 nmol m$^{-3}$ (2000 ng m$^{-3}$, as a threshold value) were defined as mineral “dust events”. These events were additionally confirmed using air mass back trajectories and OMI-AI. However, it is worth mentioning that for samples containing concentrations of nssCa$^{2+}$ less than 50 nmol m$^{-3}$, mineral dust transport from Sahara and the Middle East deserts to sampling site may not be excluded, peculiarly in winter. Yet, the
For example, one of the highest WSON concentrations (66.1 nmol N m\(^{-3}\)) was observed on 2\(^{nd}\) of March 2014 when the air mass back trajectories was associated with south/south westerly airflow. During this event, nssCa\(^{2+}\) and NO\(_3^-\) showed a dramatic increase in their concentrations compared to those observed during the previous day, reaching up to 429 and 60 nmol m\(^{-3}\), respectively. OMI (Ozone Mapping Instrument) Aerosol Index (AI) and three-day backward trajectory (1, 2, 3 and 4 km altitudes) air masses arriving at the Erdemli sampling site on 2\(^{nd}\) of March 2014 is shown in Fig.4. As can be seen from the figure, all air masses (except at 1 km altitude) originated from North Africa whereas the back trajectory for 1 km altitude exhibited airflow from the Middle East. Hence, suggesting that the sampling site was under the influence of mineral dust transport originating from desert regions located at the Middle East and North Africa. In support, the OMI-AI diagram clearly indicates a large dust plume over the Eastern Mediterranean between coordinates 20-45 °N and 15-40 °E. The Aerosol Index was found to be very high over the Northeastern Mediterranean, ranging from 2.0 to 4.5. During this dust episode, 85% of the WSON was associated with the coarse fraction, which further supports mineral dust being a main source of water-soluble organic nitrogen.

Arithmetic mean concentrations together with corresponding standard deviations of WSON, NO\(_3^-\), NH\(_4^+\) and nssCa\(^{2+}\) for dust and non-dust events are presented in Fig.5. As can be deduced from diagram (except for NH\(_4^+\)), WSON, NO\(_3^-\) and nssCa\(^{2+}\) indicated distinct difference between dust and non-dust events. Indeed, the application of the non-parametric Mann Whitney U test indicated statistically significant differences between dust and non-dust events for WSON (p <0.03), NO\(_3^-\) (p < 0.00002) and nssCa\(^{2+}\) (p < 0.000001) whereas no statistically significant difference were observed for NH\(_4^+\),(p=0.56). The crustally derived
nssCa\textsuperscript{2+} and anthropically derived NO\textsubscript{3} for dust events had arithmetic mean of 95.8 nmol m\textsuperscript{-3} and 26.1 nmol N m\textsuperscript{-3} which were almost four and two times higher than those of observed for non-dust events, respectively. Such an increase in concentrations during dust events for these species has been previously reported in the Eastern Mediterranean (Koçak et al., 2004b). Similarly, the arithmetic mean of WSON (38.2 nmol m\textsuperscript{-3}) during dust events was 1.3 times higher compared to the value observed during non-dust events (29.4 nmol m\textsuperscript{-3}). Percent contributions of coarse WSON for dust and non-dust events were almost identical, being 58 % and 60 %, respectively. A similar enrichment of WSON during dust events has been reported for Erdemli (Mace et al., 2003a; Yellow Sea (Shi et al., 210) and Finokalia (Violaki and Mihalopoulos, 2010). In addition, Griffin et al. (2007) have demonstrated a significant difference between dust and non-dust events for bacterial and fungal colony forming units at Erdemli, the former being much greater. Thus, it might be speculated that this enhancement during dust events can be due to (a) mineral dust borne microorganisms, (b) interaction (e.g. adsorption, acid-base reaction) and/or between mineral dust and organic nitrogen compounds.

3.5. Impact of Airflow on WSON

Arithmetic mean concentrations together with corresponding standard deviations for water-soluble nitrogen species and nssCa\textsuperscript{2+} in aerosol samples according to categorized air mass sectors (at 1 km) are presented in Table 5. WSON concentrations for Middle East, North Africa and Turkey were comparable and arithmetic mean values were respectively 33, 36 and 32 nmol m\textsuperscript{-3}. Correspondingly, mean WSON concentrations for Eastern Europe, Western Europe and Mediterranean Sea were 26, 26 and 22 nmol m\textsuperscript{-3}, being at least 1.2 times lower than those observed for Middle East, North Africa and Turkey (Mann-Whitney U test, p < 0.05). Coarse mode contributions of WSON for air flow from Middle East (61 %), North
Africa (58 %) and Turkey (63 %) ranged from 58 to 63 %. However, lower coarse mode contributions were observed when air flow originated from Eastern Europe (49 %), Western Europe (48 %) and Mediterranean Sea (27 %). The highest NO$_3^-$ concentrations were associated with airflow from North Africa and Turkey with a value of 18 and 15 nmol N m$^{-3}$, respectively, and there was a statistically significant difference compared to the remaining air mass sectors (p > 0.05). The mean concentrations of NO$_3^-$ for air masses derived from North Africa and Turkey was at least 1.3 times larger than those calculated for the Middle East, Eastern Europe, Western Europe and Mediterranean Sea air sectors (p > 0.05). NH$_4^+$ had the highest concentration under the influence of airflow derived from Turkey. For this airflow, detected concentration was 1.5-2.4 times greater than those calculated for other air masses sectors. The Mann-Whitney test showed that there was a statistically significant difference in the nssCa$^{2+}$ concentrations. Arithmetic mean concentrations of nssCa$^{2+}$ in the Middle East and North Africa were approximately 2 times higher compared to the remaining air masses. As expected, these two airflows were primarily influenced by crustal material due to sporadic dust events originating from deserts located in North Africa and the Middle East.

3.6. Source Apportionment for WSON in Aerosol

A number of studies have discussed the possible sources of WSON in aerosol material by applying either simple correlation analyses (Mace et al., 2003a; Violaki and Mihapoulos, 2010; Ho et al., 2015) or multivariate factor analyses (Chen and Chen, 2010), including PMF (Chen et al., 2010). Usage of correlation analyses is useful when the number in sample-populations are limited however; large datasets are required in order to carry out PMF and FA. Direct and indirect emissions of WSON from the sea surface have been demonstrated (Miyakazi et al., 2011; Altieri et al., 2016). Previous studies in the Eastern Mediterranean have observed WSON to be associated with mineral dust (Mace et al., 2003a; Violaki and
Mihalopoulos, 2010). As stated by Mace et al. (2003a), WSON might either have originated from mineral dust or carried by dust events owing to adsorption of gaseous organic nitrogen compounds onto pre-existing particles. In addition, Violaki and Mihalopoulos (2010) have shown fossil fuel and biomass burning as sources of WSON to the Eastern Mediterranean atmosphere.

Fig.6 describes the potential sources of WSON by applying PMF 5.0. The predominant two factors were chiefly found to be related with WSTN. The first factor had a high-loading for NH$_4^+$ with a value of 0.81 and a moderate loading of SO$_4^{2-}$ (0.45). As expected, the factor contribution plot (not shown) indicated summer maximum, demonstrating accumulation of these particles due to the absence of rain and enhanced gas-to-particle formation under the prevailing conditions (high temperature and solar radiation). The equivalent ratio of NH$_4^+$ and SO$_4^{2-}$ for this factor was 0.79, indicating (NH$_4$)HSO$_4$ formation (Koçak et al., 2007). 60 % of the air mass trajectories was found to be originated from Turkey when the first highest 20 % of the factor loading were considered. Consequently, this factor might principally be ascribed to regional sources such as urban agglomerations (Ankara, İzmir, and İstanbul) and industrial activities (particularly Marmara Region). The second factor explained 77 % of the NO$_3^-$ variation and described 17 and 10 % of the SO$_4^{2-}$ and NH$_4^+$, variation, respectively. This group was also associated with cations such as Na$^+$ (11 %), K$^+$ (7 %), Mg$^{2+}$ (22 %) and Ca$^{2+}$ (29 %), implying reactions mainly between acidic nitrate and alkaline species. It has been shown that emissions of Cl$^-$ and NO$_3^-$ resulting from motor vehicles (Lim at al., 2010). Taking into account the absence of Cl$^-$, this factor may be attributed to combustion. The first and second factors accounted for 20 and 22 % of the variability in WSON, respectively. It might, therefore be argued that the variability of WSON in the first group resulted from the reaction between volatile organic N and ammonium sulfate aerosols whilst the variability of WSON explained by the second factor was as a result of the
reaction between volatile organic compounds and NO\textsubscript{x} and/or neutralization of acidic nitrate by alkaline nitrogen-containing compounds such as urea and amine. The third factor was heavily influenced by Cl\textsuperscript{−} (0.8) and Na\textsuperscript{+} (0.70) while moderately impacted by Mg\textsuperscript{2+} and K\textsuperscript{+}. This factor is likely due to sea salt formation. The forth factor was predominantly impacted by Ca\textsuperscript{2+} and hence may be attributed to crustal material. Crustal sources explained 10% of the WSON variability. The final defined factor had a moderate loading of WSON (EV = 0.43, explained 43%) while it was affiliated with Na\textsuperscript{+} (0.15), K\textsuperscript{+} (0.22) and Mg\textsuperscript{2+} (0.24). The factor contribution diagram denoted highest values in summer (not shown) and hence it can be attributed to re-suspension of the soil particularly affected by intense agricultural activities.

### 3.7. Atmospheric Depositions of N-Species and Implications Regarding Marine Production

The atmospheric dry (n = 337; 21.3 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}) and wet (n = 23; 36.7 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}) deposition fluxes of WSON, NO\textsubscript{3}\textsuperscript{−} and NH\textsubscript{4}\textsuperscript{+} and WSTN from March 2014 and April 2015 are demonstrated in Table 6. The atmospheric deposition of water-soluble total nitrogen (57.8 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}) was chiefly originated from wet deposition (36.7 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}), amounting to 63% of the total atmospheric deposition. This difference might be attributed to the water-soluble ammonium, for instance, the atmospheric depositions of NH\textsubscript{4}\textsuperscript{+} (15.6 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}) was dominated by wet deposition, contributing 92% of the total ammonium atmospheric flux. Whereas, the atmospheric flux of WSON and NO\textsubscript{3}\textsuperscript{−} were more or less equally influenced by both deposition modes. Corresponding WSON (9.8 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}) and NO\textsubscript{3}\textsuperscript{−} (10.0 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}) contributions to dry deposition were found to be 46% and 48% respectively. In contrast, NH\textsubscript{4}\textsuperscript{+} (1.3 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}) was only estimated to contribute 6% of the total deposition. Wet deposition of nitrogen was impacted by WSON (10.8 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}), NO\textsubscript{3}\textsuperscript{−} (11.7 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}), and NH\textsubscript{4}\textsuperscript{+} (14.3 mmol N m\textsuperscript{-2} yr\textsuperscript{-1}) in the increasing
order 29% < 32% < 39%. On average, WSON accounted for 36% of the total atmospheric deposition of WSTN. The atmospheric deposition of the dissolved inorganic nitrogen (DIN = 37.3 mmol N m⁻² yr⁻¹) was found to decrease about 45% compared to the value reported by Koçak et al. (2010, DIN = 70 mmol N m⁻² yr⁻¹). The reason of this decrease is out the scope of this article; nonetheless, there is a need to understand how DIN flux changed from the beginning of 2000s to 2015.

4. Summary

In the current study, water-soluble organic nitrogen in aerosol and rain samples obtained over the Eastern Mediterranean has been investigated. From this investigation the following summary may be made:

1) Of the nitrogen species, aerosol WSON (23.8 ± 16.3 nmol N m⁻³) exhibited the highest arithmetic mean, followed by ammonium (23.3 ± 14.4 nmol N m⁻³) and then nitrate (17.9 ± 15.7 nmol N m⁻³). Aerosol WSON was mainly associated with coarse particles (66%). The WSTN was equally influenced by WSON and NH₄⁺, each contributing 37 and 35%, respectively, whereas the contribution to WSTN of NO₃⁻ was 28%. In rainwater, the VWM concentrations of water-soluble nitrogen species were comparable. WSON and NO₃⁻ accounted for 29 and 32% of the WSTN whilst NH₄⁺ elucidated 39% of the WSTN.

2) Aerosol WSON concentrations exhibited large variations from one day to another day. Generally, lower concentrations were observed during rainy days. Higher concentrations of aerosol WSON were associated with different airflow. The three highest concentrations were related to (i) mineral dust transport from Sahara and the Middle East deserts, (ii) north/north westerly airflow from Turkey’s largest cultivated plain, Konya and (iii) mid-range pollution transport from the Turkish coast.
3) Influence of mineral dust transport on aerosol WSON concentrations was assessed. The crustally derived nssCa$^{2+}$ and anthropogenic NO$_3^-$ for dust events had arithmetic mean of 95.8 nmol m$^{-3}$ and 26.1 nmol N m$^{-3}$ which were almost four and two times higher than those of observed for non-dust events. The arithmetic mean of WSON (38.2 nmol m$^{-3}$) for dust events was 1.3 times higher compared to that observed for non-dust events (29.4 nmol m$^{-3}$).

4) Source apportionment suggested that aerosol WSON was mainly originated from anthropogenic sources including agricultural (43 %), secondary aerosols (20 %) and nitrate (22%), whereas, the two natural sources crustal material (10 %) and sea salts (5%) contributed 15 % to the WSON.

5) The total atmospheric deposition of water-soluble nitrogen (57.8 mmol N m$^{-2}$ yr$^{-1}$) was mainly via wet deposition (36.7 mmol N m$^{-2}$ yr$^{-1}$). In contrast the atmospheric fluxes of WSON and NO$_3^-$ were equally influenced by the dry and wet deposition modes. On average, WSON accounted for 36 % of the total atmospheric deposition of WSTN. From the beginning of 2000s to 2015, the atmospheric deposition of the dissolved inorganic nitrogen declined about 45 %, as a consequence there is a need to understand how DIN flux changed.
Appendix A

In this section, the authors briefly summarize the main features of the positive matrix factorization (PMF).

PMF receptor model was described in detail by Paatero and Tapper (1994), Paatero (2007) and EPA PMF 5.0 User Guide. The details of the algorithm are also provided by Paatero (2007). This multivariate tool decomposes data matrix (X: n rows in other words number of samples and m columns: number of species) into two matrices: (i) source contributions ($G = n \times p$) and (ii) source profiles ($F = p \times m$). This can be given as follow

\[ X = GF + E \]

where E and p denote the residual part and the number of factors extracted, respectively.

In order to run PMF, two input files are needed: (i) concentration and (ii) uncertainty. The first file includes concentrations whilst the second files contains uncertainty for each species. Uncertainty for PMF application can be calculated by different approaches such as ad hoc formula (Antilla et al., 1995), fixed fraction of the concentration (Paatero et al., 2014) or more complicated way as proposed by Polissar et al. (1998). No matter how it is calculated, if uncertainty is too high for one parameter, species will be categorized as bad by the PMF. For example, the precision of WSON for this study was found to be almost 3 times than that of arithmetic mean. If one uses the Eq.3 to calculate uncertainty of WSON for each data point, then it will be omitted by PMF owing to very high uncertainty values. Consequently, there will be no source apportionment for WSON. In order to obtain reasonable factor profiles for WSON, two step procedure was proposed. First, the usage of Eq.3 to eliminate WSON samples when their corresponding precisions are lower than mean R value of 0.3 (see Eq.4). Second, set the uncertainty to higher value for WSON (15 %) compared to the remaining species (5 %) since WSON inevitably exhibits very low precision (see Eq.1 and Eq.3).
After base run one has to estimate the quality of the obtained results from PMF (for more details see EPA PMF 5.0 user guide and Paatero et al., 2014). Base Model Displacement (DISP), Bootstrap (BS) and Bootstrap Displacement (BS-DISP) methods are the main tools to assess quality. It has been exhibited that three methods complement each other (for more details see Paatero et al., 2014). EFA PMF 5.0 provides aerosol data obtained from Baltimore and guides the applicant step by step to robustly use the source apportionment program of EPA PM 5.0. More details are given by EFA 5.0 user guide and it is accessible to the scientific community.

The authors declare that they have no conflict of interest.

Acknowledgments

This work was mainly supported by The Scientific and Technological Research Council of Turkey (TUBITAK). Required data were collected within the framework of the TUBITAK 113Y107 project. This study was also supported by the DEKOSIM (Center for Marine Ecosystem and Climate Research) Project (BAP-08-11-DPT.2012K120880) funded by Ministry of Development of Turkey. We would like to thank to Ersin Tursak, Pınar Kalegeri and Merve Açıkylol for helping during sample collection and analysis. Aerosol optical thickness, angstrom component and aerosol index values used in this study were produced with the Giovanni online data system, developed and maintained by the NASA GES DISC. We also acknowledge the MODIS and OMI mission scientists and associated NASA personnel for the production of the data used in this research effort. The authors would like to thank the two anonymous reviewers for their helpful comments which greatly improved the submitted manuscript.

M. Koçak developed the concept and designed the study. M. Nehir and M. Koçak performed the experiments, analyzed the data and prepared the manuscript.
