

We thank both reviewers for their time and comments. We have made efforts to improve the manuscript accordingly, please find response for corresponding points below.

### **Reviewer #1**

5 **Brown carbon (BrC) represents an emerging category of particulate organic compounds that can absorb solar radiation effectively in the spectral range of UV light. Although BrC is increasingly evolved in climate models, its (direct) radiative forcing remains highly uncertain, partly due to underestimation of organic aerosol (OA) mass by chemical transport models and lack of knowledge on optical properties of both primarily emitted and secondarily formed organic aerosols. The manuscript by Wang et al. investigated the observational constraints on the simulation of BrC by**  
10 **GEOS-Chem. The authors found that their modelling results on BrC absorption could be improved through increasing the OA mass associated with biomass burning (BB\_OA), decreasing the mass absorption efficiency of BB\_OA, and adding an aging scheme for BB\_OA. The topic of this manuscript falls well within the scope of ACP. Although the manuscript does not provide much scientific insights into the discrepancy between simulated and observed OA mass, the idea of**  
15 **involving a photo-chemical scheme in chemical transport models to simulate degradation of BrC is interesting. It could be accepted for publication given the authors could address the following concerns.**

20 **1. Page 1, line 19-20. An exaggerated statement was made here. Comparison of simulated and observed BrC has been performed by previous studies (e.g., Atmos. Chem. Phys., 16, 3413–3432, 2016). The statement in line 10-11, page 4 is more proper.**

Our statement “this is the first study to compare simulated BrC absorption with direct ambient measurements” is correct given that previous studies have only had access to, and compared models with, indirect measurements. However, we have added text similar to that on page 4 to specifically indicate that we are referring to aircraft measurements here.

25

**2. Page 3, line 17-19. These two sentences are questionable since BrC existing as coating materials on BC cores also absorb light. In the case of BrC coating, although the lensing effect is reduced relative to clear coating, this reduction can be overwhelmed by the effect of BrC shell absorption (e.g., Science of the Total Environment, 599–600, 1047–1055, 2017).**

30 This is an interesting point. Given the limited measurements, it is not clear whether BrC coatings on BC cores also absorb light. We have added several sentences to discuss this point (page 3, line 22-24).

**3. Page 3, the last paragraph. There have been many ground-based studies in which BrC absorption was directly measured by approaches similar to those used in DC3 and SEAC4RS. However, these studies were not mentioned and were not used to constrain simulation results on BrC. Although**  
5 **these studies could not provide information on BrC vertical distribution, surface BrC absorption could still be useful for the evaluation of simulated BrC.**

We thank the reviewer for this suggestion. However, previous direct observations of surface BrC absorptions are not particularly helpful in constraining model simulations as nearly all of these studies report data at low temporal resolution (e.g. 1-week or 1-month averages) without co-measured species.  
10 This makes it difficult to identify the sources of BrC and evaluate the model.

**4. Page 5, line 26. Suggest adding “with an OA/OC range of ” before “1.34-1.65”.**

Added.

15 **5. Page 7, equation 3. What is the difference between  $w$  and the absorption Ångström exponent (AAE)? According to equation 5, they should be the same. Please avoid using different terminologies for the same parameter.**

They are different.  $w$  refers to the wavelength dependence of imaginary part of refractive index ( $k$ ); AAE refers to the wavelength dependence of absorption. These two kinds of wavelength dependence are  
20 different, since aerosol absorption is not linearly related to  $k$ .

**6. Page 7, line 10-11. This point, i.e., biomass burning refers to open burning and does not include biofuel, should be clarified when biomass burning/biofuel were used for the first time in section 3.**

We move this clarification to Section 3 (page 6, line 3).

25

**7. Page 8, line 20. Why are the observed mass concentrations for externally mixed OA alone? HR-TOF-AMS cannot measure internally and externally mixed OA separately.**

We have removed this sentence.

8. Page 10, the first paragraph. I am confused about sources of “the 80% bias”. According to the discussions in line 6-23, it seems that this bias could be primarily attributed to neither the underestimate of POA emission factor nor the underestimate of biomass burning SOA. But then the authors said that this bias was due to “the underestimate of either the POA emission factor or biomass burning SOA” (line 26-27). These descriptions need to be revised to keep consistent. To my understanding, this bias indicated that the POA emission factor was considerably underestimated for biomass burning, although the actual BC/OA emission ratio would not be as low as 0.027 for biomass burning. In addition, please check “BC/OA emission factor” used in this paragraph. I think all of them should be “BC/OA emission ratio”.

In our discussion on page 10, we conclude that the 80% bias could not be attributed to the underestimate of POA emission factor only nor the underestimate of biomass burning SOA only. This means the bias is likely due to the integrated influence of these 2 factors. We agree with the reviewer that “BC/OA emission ratio” is a better than “BC/OA emission factor” in this paragraph and change the phrasing throughout.

9. Page 13, line 24-25; and page 14, line 7. The authors are required to compare the AAE evolved here (which can be readily derived from the MAC values at different wavelengths) with those directly measured (e.g., Atmos. Chem. Phys., 15, 7841–7858, 2015), to see whether the assumed absorption wavelength dependence was reasonable.

Thank you for the suggestion. We add a short discussion at the end of this paragraph (page 13, line 28-31) to address this point.

10. Page 13, line 25-26. The statement that “we assume that biomass burning SOA is equally absorbing as primary OA from biomass burning” does not agree with the description in section 3.2 that “For SOA, we assume that only aromatic SOA absorbs light”, unless the authors assumed that all of the biomass burning SOA were from aromatic precursors.

We agree that this was unclear and now clarify this on page 7, line 26. The statement of SOA in Section 3.2 does not include biomass burning SOA.

30

**11. Page 15, line 7 and elsewhere in the manuscript. I don't think the model assumptions applied in "Modified\_Age" and "Modified\_Simple" were really constrained from US fires observed during SEAC4RS. In fact, SEAC4RS was only used to evaluate or validate these assumptions.**

The reviewer is correct. We clarify this point throughout the manuscript.

5

**12. Caption of Figure 7. Wavelength should be clarified.**

Added.

**Reviewer #2**

10 **General comments**

The paper of "Exploring the observational constraints on the simulation of brown Carbon" investigates the optical properties and DRE of BrC using GEOS-Chem model coupled with RRTMG model. They applied a photochemical scheme in the model to address the aging effect of BrC absorption and tested it against BrC absorption measurements from two aircraft campaigns.

15 This study aims to "explore how assumptions for BrC sources, processing, and properties impacts the comparisons with these observational constraints and estimate the resulting global direct radiative effect of BrC under these conditions". While the authors addresses the topics listed in the paper, it is not immediately clear how significant the results actually are.

20 First, they need more constraints from observations near sources in addition to the aircraft campaigns used in the study to test the photochemically whitening process for BrC absorption. Detailed comparison between Modified\_Age and Modified\_Simple should be provided to show the necessity and advantage of this aging scheme.

We agree with the reviewer that it would be helpful to have observational constraints near sources to further evaluate the whitening process. However, unfortunately, to date, there are no such appropriate measurements. Previous direct observations of BrC absorption at the surface have low temporal resolution and have not been accompanied by measurements of other species (e.g. CO, NO, NO<sub>x</sub>, etc.) needed to identify the photochemical aging state or transport time. We hope that future measurements (including perhaps during the upcoming FIREX and FireChem campaigns) will enable further evaluation of these schemes.

In Section 4.1, we show that the aging scheme improves the model simulation during the DC3 campaign. Both the Modified\_Age and Modified\_Simple schemes reflect the influence of aging on absorption, so a comparison between these two would not show the advantage of aging in capturing observations. In Section 5.2 we compare the simulated DRE between Modified\_Age and Modified\_Simple and find very small difference.

**Second, the authors argued “DRE of BrC has been overestimated previously due to the lack of observational constraints from direct measurements and omission of the effects of photochemical whitening”. However, they ignored some studies, which do not include this aging effect but show low DRE of BrC. For example, Hammer et al. (2016) estimated DRE of 0.03 W m<sup>2</sup> for BrC constrained by OMI UVAI values, which is even lower than the result in this work (doi:10.5194/acp-16-2507-2016). Comparison with such studies may help to understand the factors contributing to the uncertainties in BrC absorption and to verify this aging scheme.**

Thank you for raising this point. We have added a discussion of Hammer et al. 2016 to the end of Section 5. However we emphasize that this study used indirect measurements to constrain the BrC DRE, and uncertainties on these measurements are challenging to estimate.

**Finally, the MAC and the subsequently whitening process are strongly affected by the fraction of BrC associated with biomass burning. The authors assumed that the optical properties for biomass burning SOA are the same as those for biomass burning POA. But such assumption contradicts with their earlier statement that SOA is not absorber, at least not a significant absorber. Thus they may overestimate the fraction of BrC and underestimate the MAC for biomass burning OA.**

We agree with the reviewer that the text was unclear on this point. We now clarify this on page 7, line 27. The statement regarding SOA absorption in Section 3.2 was not meant to include biomass burning SOA.

**In summary, this paper is well written and is easy to follow along. Its topic fits ACP and it is worthy of publication in ACP subject to addressing these and specific comments below.**

### **Specific Comments**

**p. 1, line 23-24, the AAE is not constrained from absorption measurement**

The reviewer is correct. We have removed the sentence about AAE.

**p. 2, line 10-11, as stated above, there are also studies with low DRE of BrC**

We extend the DRE range here to represent all previous studies.

5 **p.4, line 28-30, the factor converting extract absorption to aerosol absorption is a function of aerosol size distribution. Is the factor of 2 consistent with the model assumption of OA size distribution in this study?**

The factor of 2 is related to the size distribution of BrC field measurements at 3 sites (Liu et al., 2013). In these measurements, the mass mean diameter (MMD) of OA is 500nm with standard deviation ( $\delta$ ) of 1.5  
10 – 2.4. With a standard deviation of 1.8, this MMD can be transferred to a count mean diameter (CMD) of ~180nm. This size distribution is very close to our assumption (CMD = 180nm,  $\delta=1.6$ ). We add a sentence to clarify this point in Section 2, page 4, line 20-31.

15 **p.7, line 15, what is the density of OA used in the model? Will the assumption of the GMD of OA strongly affect its MAC?**

The density of OA is assumed to be 1.3 g/m<sup>3</sup>. We add this to the text in Section 3.2, page 7, line 13.

The GMD of OA could affect its MAC strongly but this influence is non-linear. For example, with  $\delta=1.6$  and refractive index of BB BrC, a 50% decrease in GMD causes 1% difference in MAC, however, a 50% increase in GMD will increase MAC by 35%. As replied in last comment, we use the same GMD value  
20 as measured BrC in filed observations.

**p.8, line 16, from biomass burning and biofuel**

Changed (typo).

25 **p.9, line 24-25, high CH<sub>3</sub>CN and high CH<sub>3</sub>CN-OA may be due to the transport of plumes mixed with biomass burning and other sources. More evidence (e.g. enhancement ratio CH<sub>3</sub>CN/CO) is needed to support the conclusion of little contribution from sources other than biomass burning.**

There is no significant CH<sub>3</sub>CN/CO enhancement during the identified BP (the ratio during BP is only ~15% higher than the average during the campaign). However, we find not only high CH<sub>3</sub>CN and high CH<sub>3</sub>CN-OA correlation but also high OA-BC correlation, high BC and OA concentrations during BP. We think this is enough to identify the biomass burning influenced periods. We have clarified this point in the Section 4.1.

**p. 10, line 2-3, the difference between 145% and 36% is \_ 110%, not 80%**

The difference between 145% and 36% in this context is 80%. After a 36% increase, we still need ~80% increase to get the 145% difference:  $(1+0.36) \times 1.8 - 1 = 1.45$ .

10

**p.10, line 7-8, although lower than 0.03, the BC/OA of 0.027 should be still within the uncertainty range of biomass burning emission ratios**

We agree that this value should be within the uncertainty range of BC/OA emission ratio, but it seems unlikely that all fire emissions fall below the range of emission ratio (0.03-0.06) for biomass burning as given in GFED. Our statement does not preclude this possibility, we simply indicate that it is unlikely.

15

**p. 10, line 29-30, only biomass burning OA is increased in FixBB. This won't affect the estimation of BrC absorption, but overestimates its contribution to total AAOD (the analysis in Sec. 5) as BC mass is still underestimated.**

In our analysis of DC3 data, we adjust both the OA and BC biomass burning mass concentrations upwards to match the observations (as indicated in the previous sentence). A further increase to OA is applied to correct for an underestimate in the OA emission factors and/or missing biomass burning related SOA. Therefore biases in biomass burning are addressed for BC and OA and correctly reflected in the AAOD calculations.

25

**p. 14, line 17-18, the peak in the middle troposphere from SEAC4RS is not reproduced**

The sentence "... during DC3 and SEAC4RS except for altitudes above 10 km." is changed to "... during DC3 and SEAC4RS at the altitudes with enough data points below 10 km."

**p. 15, line 25, any explanation for high BrC absorption contribution in NA and Russia? The discrepancy between model and the observation is large as seen from the figure.**

5 This is an interesting point. The absorption properties and/or BrC contribution to total OA may be different for different fires/biofuel combustion sources. Our model assumptions constrained from the US fires are able to capture the observed BrC absorption contributions in Europe, but have large discrepancy in Alaska and Russia. This suggests that the BrC absorption properties and/or BrC contribution to total OA could be very different between Alaska/Russia and US/Europe. Due to the limitation of measurement data, we are not able to undertake any further analysis of this discrepancy, but we add text acknowledging  
10 these discrepancies in page 15, line 17-18.

**Abstract.** Organic aerosols (OA) that strongly absorb solar radiation in the near-UV are referred to as brown carbon (BrC).

15 The sources, evolution, and optical properties of BrC remain highly uncertain, and contribute significantly to uncertainty in the estimate of the global direct radiative effect (DRE) of aerosols. Previous modeling studies of BrC optical properties and DRE have been unable to fully evaluate model performance due to the lack of direct measurements of BrC absorption. In this study, we develop a global model simulation (GEOS-Chem) of BrC and test it against BrC absorption measurements from two aircraft campaigns in the continental U.S. (SEAC4RS and DC3). To our knowledge, this is the first study to compare simulated  
20 BrC absorption with **direct aircraft measurements**. **We show that BrC absorption properties estimated based on previous laboratory measurements agree with the aircraft measurements of freshly emitted BrC absorption, but overestimate aged BrC absorption.** In addition, applying a photochemical scheme to simulate bleaching/degradation of BrC improves model skill. The airborne observations are therefore consistent with a mass absorption coefficient (MAC) of freshly emitted biomass burning OA of  $1.33\text{m}^2\text{g}^{-1}$  at 365nm coupled with a 1 day whitening e-folding time. Using the GEOS-Chem chemical transport model  
25 integrated with the RRTMG radiative transfer model, we estimate that the top-of-atmosphere all-sky direct radiative effect (DRE) of OA is  $-0.344\text{Wm}^{-2}$ , 10% higher than that without consideration of BrC absorption. Therefore, our best estimate of the absorption DRE of BrC is  $+0.048\text{Wm}^{-2}$ . We suggest that the DRE of BrC has been overestimated previously due to the lack of observational constraints from direct measurements and omission of the effects of photochemical whitening.

## 1 Introduction

30 Carbonaceous aerosols, including both black carbon (BC) and organic aerosols (OA), are among the largest sources of uncertainty in the estimate of the global direct radiative effect (DRE) and forcing (DRF) of aerosols. BC is the principle light-absorbing aerosol in the atmosphere, whereas OA is generally considered as “white carbon” which scatters light without corresponding absorption. However, a fraction of OA is also found to efficiently absorb light, predominately at near-UV

wavelengths (Kirchstetter et al., 2004; Hecobian et al., 2010; Arola et al., 2011). This absorbing OA, referred to as brown carbon (BrC), has primarily been associated with biofuel or biomass combustions (Andrea et al., 2006; Ramanathan et al., 2007; Washenfelder et al., 2015). These BrC emissions are typically mixed with co-emitted BC and non-absorbing OA, challenging the measurement community's ability to evaluate the optical properties of ambient BrC. Additional sources of BrC, including the photo-oxidation of volatile organic compounds (VOCs) and aqueous-phase chemistry in cloud droplets, typically produce less absorbing BrC, with properties that are even more uncertain (Graber et al., 2006; Ervens et al., 2011; Wang et al., 2014; Laskin et al., 2015). A few studies have attempted to simulate BrC in global models and estimate its DRE (Park et al., 2010, Feng et al., 2013; Lin et al., 2014; Wang et al., 2014; Jo et al., 2015; Saleh et al., 2015). These estimates range from +0.03 to +0.6 Wm<sup>-2</sup>, corresponding to up to 40% of the total absorption of carbonaceous aerosol across studies.

5  
10 Due to our poor understanding of the sources, optical properties, chemistry, and mixing state of BrC, the uncertainty surrounding the global absorption from BrC remains high.

Most modelling studies follow a similar approach to simulating BrC: some fraction of OA is assumed to be BrC, and assigned different optical properties from non-absorbing OA. The assumed optical properties of BrC are based on laboratory measurement of organics extracted in water, acetone, methanol, or other organic solvents. However, these properties are not well constrained by laboratory studies. First, measured absorption properties differ significantly among studies (Wang et al., 2014). Even within a study, different combustion conditions (e.g. burning temperature) can also lead to up to a factor of two difference in absorption properties (e.g. the imaginary part of refractive index, or mass absorption coefficient) (Chen and Bond, 2010). Previous modelling studies have typically used either the lower or higher bound from laboratory studies to estimate the minimum or maximum absorption properties of BrC (Feng et al., 2013; Lin et al., 2014). In addition, it is unclear what fraction of the OA is BrC and how this differs with source and ambient combustion conditions (Pokhrel et al., 2017). In laboratory studies organics are not always fully soluble; typically, 40%-90% of the total material can be extracted, depending on the solvent (e.g. ~40% can be extracted in water and more than 90% can be extracted in methanol, Chen and Bond, 2010). The absorption properties of the insoluble fraction are unknown. Thus previous modelling studies have applied a range of assumptions: Lin et al., (2014) assumed all primary organic aerosols (POA) from biofuel and biomass emissions and all secondary organic aerosols (SOA) from biogenic and anthropogenic emissions to be BrC; Feng et al. (2013) assumed 66% of biofuel/biomass POA to be BrC; Wang et al. (2014) assumed 25% of biomass burning and 50% of biofuel POA as well as aromatic SOA were brown. There is tenuous scientific support for these assumptions. In addition, extrapolating laboratory experiments to real-world combustion sources may also lead to large uncertainties.

15  
20  
25

Recent studies show that the BrC absorption from biofuel or biomass sources is likely affected by combustion efficiency (Chen and Bond, 2010; Saleh et al., 2014; Pokhrel et al., 2016; 2017). A number of modelling studies have attempted to connect BrC absorption to emission properties, by using the modified combustion efficiency (MCE, a function of CO/CO<sub>2</sub>) (Jo et al., 2016), or the BC/OA ratio (Park et al., 2010; Saleh et al., 2015). These approaches should better represent the temporal and spatial variability of BrC emissions and properties, however, in practice these parameterizations are difficult to apply in models given the lack of information regarding burn conditions in emissions inventories. The variability of quantities such as BC/OA or

30

MCE in these inventories reflects differences in fuel types (and the associated emission factors), not burn conditions. Therefore, these studies fail to describe the variation in emissions of BrC within a given fuel type.

Both of these methods focus primarily on the sources of BrC, however chemical transformation and the mixing state of BrC also play an important role in controlling BrC absorption. In laboratory studies, the absorption of BrC is found to both increase during the formation or chemical aging of certain types of OA, and decrease during oxidation or photolysis (Zhong and Jiang, 2011; Flores et al., 2014; Lee et al., 2014; Liu et al., 2016). Field studies provide evidence that BrC may be formed in clouds or during convective transport, due to aqueous phase chemistry or condensation (Gilardoni et al., 2016; Zhang et al., 2017). Observations also indicate that biomass burning BrC absorption decreases with photochemical aging with a lifetime of ~1 day (Forrister et al., 2015; Wang et al., 2016). It is likely that the absorption and DRE of BrC would change significantly if these chemical processes were included in models. For the mixing state, the key question is whether BrC is internally or externally mixed with BC. Previous studies typically assume that BrC is externally mixed with BC (Liu et al., 2013). When considering BC only, the internal mixing is widely idealized as a core-shell morphology (Jacobson, 2001; Bond and Bergstrom, 2006). When coated by other materials, typically inorganic and non-absorbing OA, the absorption of BC will be enhanced by the lensing effect (Jacobson, 2001; Bond et al., 2006). However, if BrC coats BC, Mie calculations show a lower absorption enhancement for BC. At the same time, the absorption of BrC itself will decrease since there is less externally-mixed BrC left in the atmosphere. As a result, the mixing state of BrC will affect the absorption of not only the BrC but also the BC. This influence is sensitive to the absorption properties of BrC, which are highly uncertain, as we have discussed, and also the proportion of externally/internally mixed BrC, which to our knowledge, has not been measured in the atmosphere. Saleh et al. (2015) investigate this influence and conclude that for a single particle with fixed size (BC=150nm and BrC=200nm) the global mean absorption DRE of BrC decreases by 45% when assuming complete internal mixing (compared to complete external mixing). In this case, BrC is assumed to not absorb light when serving as the coating material on BC cores. This assumption is challenging to test given current analytical measurement capabilities. If BrC shells absorb light, there would be a higher absorption enhancement for BC when BrC coats BC.

Observational constraints on BrC are scarce, thus making it a challenge to test and improve models based on observational evidence. Although the absorption of aerosols is widely measured in the form of absorption aerosol optical depth (AAOD) by satellite or ground-based measurement, these observations include the absorption of both BrC and other aerosols (primarily BC). In our previous work (Wang et al., 2016), we presented a method to distinguish the absorption contributions of BrC and BC. However, the method can only be used for multiple-wavelength absorption observations with 2 wavelengths longer than 600nm and at least 1 in the near-UV. Such measurements are currently limited and exhibit large uncertainties. In addition, absorption measurement at very low wavelengths where BrC dominates absorption would also help constrain the abundance and properties of BrC, however these wavelengths are not available for current remote sensing observations. Recently, during two aircraft campaigns (DC3 and SEAC4RS, see details in Section 2) BrC absorption was directly measured. This provides an opportunity to test the model assumptions. However, properties of BrC, including absorption, chemical transformation, and mixing state, are still challenging to evaluate because of the uncertainty surrounding the simulation of OA mass. Models fail

to reproduce the observed magnitude and variation of OA mass concentrations (Heald et al., 2011; Spracklen et al., 2011; Tsigaridis et al., 2014). Thus, it can be challenging to untangle whether any discrepancy between modelled and observed BrC absorption should be attributed to BrC properties or OA mass concentrations. Furthermore, uncertainties surrounding the simulation of BC (Koch et al., 2009; Bond et al., 2013; Wang et al., 2014), may also impact a combustion-based approach (MCE or BC/OA) to simulating BrC.

Given the above context, it is highly challenging to develop and test an accurate model simulation of BrC. A reasonable approach is to test the simplest assumptions for BrC modelling. In this study, we develop a model simulation of BrC, test it against BrC absorption measurements from two aircraft campaigns in the U.S. (SEAC4RS and DC3), and optimize it to match these observational constraints. To our knowledge, this is the first study to compare simulated BrC absorption and its vertical variation with direct, continuous aircraft measurements. We explore how assumptions for BrC sources, processing, and properties impacts the comparisons with these observational constraints and estimate the resulting global direct radiative effect of BrC under these conditions.

## 2 Aircraft observations

In this study, we compare our model results to the DC-8 airborne measurements from two campaigns: DC3 and SEAC4RS. The DC3 (Deep Convective Clouds and Chemistry) campaign was conducted from May 18<sup>th</sup> to June 22<sup>nd</sup> in 2012, over the central and southeastern U.S (Barth et al., 2015). The SEAC4RS (Studies of Emissions, Atmospheric Composition, Clouds and Climate Coupling by Regional Surveys) campaign occurred in a similar region during August 6<sup>th</sup> to September 23<sup>rd</sup> in 2013 (Toon et al., 2016). Flight tracks are shown in Figure 1. BrC absorption and related aerosol measurements of interest were made by the same instruments during these two campaigns.

The OA absorption (hence the BrC) was directly measured from liquid extracts of aerosol samples. The samples with aerodynamic diameter smaller than 4.1 $\mu\text{m}$  were collected on Teflon filters every 5 minutes. Water extracts were transferred to an LWCC-TOC system (Liquid Waveguide Capillary Cell coupled to a Total Organic Carbon analyzer). The absorption spectra of the extracts were measured in the 200 to 800nm wavelength range; these measurements are referred to as H<sub>2</sub>O\_Abs. The detection limit and uncertainty of H<sub>2</sub>O\_Abs is 0.031 Mm<sup>-1</sup> and 20% respectively, at 365nm. The insoluble fraction of the samples was sequentially extracted in methanol following the same method as water extracts. This part of the absorption is referred to as MeOH\_Abs and has a detection limit and uncertainty of 0.11 Mm<sup>-1</sup> and 37% at 365nm. The total absorption of OA is determined by summing H<sub>2</sub>O\_Abs and MeOH\_Abs as reported at 365nm. A multiplication factor of 2 is applied here to convert the solution absorption to aerosol absorption, reflecting the enhanced absorption by aerosols in the Mie regime versus molecules in the liquid extract (Zhang et al., 2017). This factor corresponds to the measured size distribution at 3 sites (Liu et al., 2013); this size distribution is similar to that assumed in the model (discussed in Section 3). An important assumption here is that essentially all of the BrC can be extracted in water and methanol, which is supported by laboratory experiments (Chen and Bond, 2010). Further details on these measurements can be found in Liu et al. (2015).

In addition to OA absorption, the mass concentrations of aerosols and gases were measured throughout the two campaigns. Sub-micron OA (and inorganic aerosols) were measured by a high resolution time-of-flight Aerodyne Aerosol Mass Spectrometer (AMS, DeCarlo et al., 2006) with an estimated uncertainty of 38%. The transmission of particles through the AMS aerodynamic lens is ~100% on the range 50-550 nm and then declines up to above 1  $\mu\text{m}$ , and is referred to approximately as  $\text{PM}_{10}$  (Dunlea et al., 2009). BC accumulation mode mass concentrations were measured with a Single Particle Soot Photometer (SP2, Schwarz et al., 2008) with an estimated uncertainty of 30%; these measurements were made off a different inlet and sampling line with good transport efficiency only up to 3  $\mu\text{m}$  total particle diameter (50% transport efficiency at 3  $\mu\text{m}$ ). Carbon monoxide (CO) and acetonitrile ( $\text{CH}_3\text{CN}$ ) were measured with a Diode laser spectrometer and PTR-MS with uncertainties of 2% and 20%, respectively. Details on all of these measurements, as well as other aerosol and gas measurements made during the campaigns, can be found in Barth et al. (2015) and Toon et al. (2016).

### 3 Model description

#### 3.1 The GEOS-Chem model with RRTMG

We use the global chemical transport model GEOS-Chem (Bey et al., 2001) coupled with the rapid radiative transfer model for GCMs (RRTMG, Iacono et al., 2008) in this study. Our simulations use the GEOS-FP assimilated meteorology from the Goddard Earth Observing System (GEOS) at the NASA Global Modeling and Assimilation office. The global simulations use v10-1 of GEOS-Chem with a horizontal resolution of  $2^\circ \times 2.5^\circ$  and 47 vertical levels. When comparing with aircraft measurements, we perform nested simulations over North America ( $10^\circ\text{--}60^\circ\text{N}$ ,  $130^\circ\text{--}60^\circ\text{W}$ ) at  $0.25^\circ \times 0.3125^\circ$  horizontal resolution. RRTMG is a radiative transfer model which calculates both longwave and shortwave atmospheric radiative fluxes. This calculation is coupled to GEOS-Chem and conducted every 3 hours. Details of the implementation of RRTMG in GEOS-Chem are available in Heald et al. (2014).

The simulation of POA and BC mass are based on the standard GEOS-Chem simulation with modifications described in Wang et al. (2014). The model assumes 50% of anthropogenic and 30% of emitted biomass burning organic carbon (OC) is hydrophobic and the remaining is hydrophilic. Hydrophobic OC converts to hydrophilic OC with an e-folding time of 1.15 days, equal to an aging rate of  $\sim 10^{-5} \text{ s}^{-1}$ . The POA is inferred from simulated primary OC by applying an OA/OC mass ratio of 2.1 (Turpin and Lim, 2001; Aiken et al., 2008; Canagaratna et al., 2015). This represents average atmospheric OA/OC composition. Freshly emitted POA is less oxidized (with an OA/OC range of 1.34-1.65; Canagaratna et al., 2015), however aging occurs quickly in the atmosphere, in particular for biomass burning OA (Cubison et al., 2011; Forrister et al., 2015). The simulation of BC includes a source-specific treatment. For the fossil fuel BC, we assume 80% are emitted as hydrophobic, and convert to hydrophilic with an aging rate related to  $\text{SO}_2$  and OH levels in the atmosphere:

$$k = \alpha [\text{SO}_2][\text{OH}] + b \quad (1)$$

where  $\alpha = 2 \times 10^{-22} \text{ cm}^6 \text{ molec}^{-2} \text{ s}^{-1}$  and  $b = 5.8 \times 10^{-7} \text{ s}^{-1}$  (Liu et al., 2011; Wang et al., 2014). The biofuel and biomass burning BC is assumed to be emitted as 70% hydrophilic and 30% hydrophobic with an aging e-folding time from hydrophobic to

hydrophilic of 4 hours (note that throughout our analysis “biomass burning” refers to open burning and does not include biofuel). The details of the BC scheme and evaluation against BC mass concentrations can be found in Wang et al. (2014). Our simulation of SOA is from the standard GEOS-Chem simulation, which is based on reversible partitioning of semivolatile products of aromatic and biogenic VOC oxidation (Pye and Seinfeld, 2010; Pye et al., 2010).

5 The global anthropogenic emissions of BC and POA follow the Bond et al. (2007) emission inventory (8.7 TgC yr<sup>-1</sup> for POA and 4.4 TgC yr<sup>-1</sup> for BC, globally). For the North America region, The EPA National Emission Inventory for 2011 (EPA/NEI11) is used. We also implement the annual scaling factors from the EPA’s air pollutant emissions trends data (<https://www.epa.gov/air-emissions-inventories/air-pollutant-emissions-trends-data>) and a 17% decrease for SO<sub>2</sub> and a 30% decrease for BC, suggested by Kim et al. (2015), who conducted an analysis of the aerosols during SEAC4RS. The resulting anthropogenic POA and BC emissions from the contiguous United States total 0.58 TgC yr<sup>-1</sup> and 0.26 TgC yr<sup>-1</sup> for 2013. Since the EPA/NEI11 inventory does not separate fossil and biofuel emissions, we apply the fossil/biofuel emission ratios from the Bond et al. (2007) emission inventory and the seasonal cycle of residential emission from Park et al. (2003) to separate these two emission types. This produces an annually averaged fossil/biofuel emission ratio of 8 for BC and 1.2 for OC in US. The biomass burning emissions of BC and POA follow the year-specific daily mean GFED4s (Global Fire Emissions Database with small fires) inventory (Van der Werf et al., 2010, Giglio et al., 2013), contributing 0.1 TgC yr<sup>-1</sup> of BC and 1.42 TgC yr<sup>-1</sup> of POA in US in 2012, 0.15 TgC yr<sup>-1</sup> of BC and 2.24 TgC yr<sup>-1</sup> of POA in US in 2013. The biogenic VOC emissions are simulated online based on the MEGAN2.1 (Model of Emissions of Gases and Aerosols from Nature) scheme (Guenther et al., 2012). The anthropogenic VOC emissions are based on the combination of Reanalysis of the Tropospheric chemical composition (RETRO) global emission inventory (Pulles et al., 2007) and EPA/NEI11 inventory for United States.

### 20 3.2 Treatment of BrC optical properties

Most previous BrC modelling studies assume some fraction of OA to be BrC and assign it different optical properties from non-absorbing OA. Unlike this approach, we assign absorption properties for all OA, thus convolving two unknowns into a single assumption. This simplifies our analysis, given that the total absorption from OA equals the absorption from BrC:

$$\begin{aligned}
 Abs_{BrC} &= Abs_{OA} = MAC_{OA} \cdot Mass_{OA} \\
 &= MAC_{BrC} \cdot Mass_{BrC} = MAC_{BrC} \cdot f \cdot Mass_{OA}
 \end{aligned}
 \tag{2}$$

MAC is the mass absorption coefficient.  $f$  is the fraction of OA mass that is BrC.  $MAC_{OA}$  is the optical property typically measured in laboratory studies, which includes information on both  $MAC_{BrC}$  and the contribution of BrC to OA ( $f$ ). Here, to determine  $MAC_{OA}$ , we take the OA properties from the Global Aerosol Data Set (GADS) database (Kopke et al., 1997) with updates from Drury et al. (2010), except for the imaginary part of refractive index ( $k$ ).

30 Little evidence to the contrary, we assume that fossil fuel POA is not absorbing. To date, there are no field observations that indicate POA associated with fossil fuels is light-absorbing (Laskin et al., 2015) except measurements in Beijing (Yan et al., 2017). For biofuel and biomass burning POA, we use the experimental results from Saleh et al. (2014) to parameterize the imaginary part of the refractive index. In that study,  $k$  is related to the BC/OA mass ratio from biofuel and biomass emissions:

$$w = \frac{0.21}{\frac{BC}{OA} + 0.07} \quad (3)$$

$$k_{550} = 0.016 \lg\left(\frac{BC}{OA}\right) + 0.04 \quad (4)$$

Where  $w$  refers to the wavelength dependence of  $k$ ,  $k_{550}$  is the imaginary part of refractive index at wavelength of 550nm. For other wavelengths ( $\lambda$ ),  $i$  can be calculated as:

$$5 \quad k = k_{550}(550/\lambda)^w \quad (5)$$

The BC/OA emission ratio is associated with both combustion fuel type and burning conditions. In the GFED4s emission inventory, the BC/OA emission ratio ranges from ~0 to 0.23 for biofuel (however the majority of points range lie between 0.06 and 0.16, the 10<sup>th</sup> and 90<sup>th</sup> percentiles) and 0.03 to 0.06 for biomass burning. These ranges are not large because the variability in burn conditions, which is likely to dominate the variability in BC/OA emission ratio, is not represented. We use global average BC/OA emission ratios in the model for each source: 0.12 for biofuel and 0.05 for biomass burning. This simple assumption reflects the average burning conditions globally but not for specific fires. The assumed BC/OA ratio is further used to derive the wavelength-dependent  $k$ . The size distribution of OA is assumed to be log-normal, with a geometric median diameter (GMD) of 180 nm and standard deviation ( $\delta$ ) of 1.6. The density of OA is assumed to be 1.3 g cm<sup>-3</sup>. Based on these values, the MAC of OA at 365 nm is calculated to be 1.19 m<sup>2</sup>g<sup>-1</sup> for biofuel OA and 1.28 m<sup>2</sup>g<sup>-1</sup> for biomass burning OA. The OA-AAE of the 300&600 nm wavelengths pair is 2.6 for biofuel OA and 3.1 for biomass burning OA. These assumptions will be evaluated in the following comparisons with observations. We choose this approach for our model simulation of BrC because relationships between the absorption of OA and the BC/OA ratio have been confirmed by field measurements (Wang et al., 2016; Gilardon et al., 2016).

For SOA, we assume that only aromatic SOA absorbs light since experiments show most light-absorbing SOA is related with aromatic carbonyls (Jaoui et al., 2008; Desyaterik et al., 2013; Zhang et al., 2014), and since absorption from biogenic SOA in the field (in the same region and years studied here) has been found to be negligible compared to even mild biomass burning influence (Washenfelder et al., 2015). We specify the absorption properties of aromatic SOA based on our earlier study (Wang et al., 2014); these are among the highest values from laboratory experiments (MAC=1.46 m<sup>2</sup>g<sup>-1</sup> at 365nm, Zhang et al., 2013). We note that the model does not include biomass burning SOA.

25 All of the above assumptions, for both POA and SOA, are the initial properties for our model simulations. The goal of this study is to investigate whether these assumptions are consistent with the absorption properties in the real atmosphere. To distinguish with other simulations described below, we call this the Base simulation.

### 3.3 Chemical aging of biomass burning BrC

In the Base simulation, we assume that the absorption properties of organic aerosol are fixed. To investigate the influence of chemical aging, we perform additional simulations with assumptions derived from our previous study (Wang et al., 2016). In that study, we found that the BrC absorption of biomass burning plumes observed at T3 site of the Green Ocean Amazon campaign (GoAmazon2014/5) exhibited a ~1-day photochemical lifetime (in sunlight). This photochemical lifetime is

qualitatively consistent with the study of Forrister et al. (2015), who investigate the Rim fires during SEAC4RS. To our knowledge, these two field studies are the only ones to investigate the change in BrC absorption during chemical aging. To include this aging effect in the model, we assume that the absorption of OA decreases at a rate related to OH:

$$Abs_{BrC, t+\Delta t} = Abs_{BrC, t} \cdot \exp\left(-\frac{[OH] \cdot \Delta t}{5 \times 10^5}\right) \quad (6)$$

- 5 where  $Abs_{BrC,t}$  and  $Abs_{BrC,t+\Delta t}$  are the absorption of BrC at time  $t$  and  $t+\Delta t$  (in days),  $[OH]$  is the concentration of OH in molec  $cm^{-3}$ . As both of these studies found that the absorption did not decrease beyond some minimum threshold, we do not allow absorption to drop below a specified minimum (1/4 of the starting point). We add this scheme to the Base simulation described above to conduct a model simulation with aging (Base\_Age).

### 3.4 Mixing of BC and OA

- 10 As discussed in section 1, BC and OA are likely to be internally mixed in a form reasonably well modelled with core-shell morphology (China et al., 2014). This morphology enhances the absorption of BC through lensing, and this enhancement depends upon the absorption properties of the shell material (including BrC). However, this is challenging to represent accurately, given uncertainties in the coating thickness and composition. Furthermore, considering the low BC/OA emission ratio from biomass burning and **biofuel**, together with the typical coating thickness (Moffet and Prather, 2009; Schwarz et al.,
- 15 2008; Perring et al., 2016), the majority of OA from these sources is generally externally mixed with BC. Indeed multiple field studies have reported that BC is only present in a few percent of the biomass burning particles, and that the large majority of the emitted particles do not contain BC (Kondo et al., 2011; Perring et al., 2017). Therefore, we treat BC and OA as externally mixed in our simulation. We apply a constant absorption enhancement for BC (1.1 for fossil BC, 1.5 for biofuel/biomass burning BC), as described in Wang et al. (2014), based on a series of laboratory and field observation, regardless of whether
- 20 the coating shell absorbs light or not. As a result, this value likely represents some average state which includes the influence of BC-OA internal mixing. Our assumption of externally mixed OA with an associated absorption enhancement for BC may overestimate OA absorption since the OA which coats BC is double-counted; however given that the majority of the OA is likely externally mixed this overestimate in absorption is modest, and likely negligible for air masses influenced predominantly by biofuel and biomass burning sources.

## 25 4 Comparing simulated BrC to aircraft observations

- In this section, we evaluate our assumptions for BrC by comparing the GEOS-Chem nested model simulations with aircraft observations from the DC3 and SEAC4RS campaigns. The region included in the analysis is the central and southeast US, which is shown in Figure 1. We focus on this subset of the measurements because: 1) aircraft measurements from both DC3 and SEAC4RS cover this region; and 2) the emissions inventories for this region have been evaluated by a series of SEAC4RS
- 30 studies (resulting modifications described in Section 3.1). **Dry aerosol absorption is used when comparing model with**

observations, since hygroscopic growth is not considered in the measurements. Before evaluating the simulation of OA absorption, we first need to explore the fidelity of the simulation of OA mass.

#### 4.1 DC3 Campaign

We first compare the Base simulation to observations. Figure 2 compares the median vertical profile of modelled sulphate, BC, and OA mass concentrations with the DC-8 aircraft measurements during the DC3 campaign. Our simulation reproduces the median vertical distribution of observed sulphate and BC, but underestimates OA by about a factor of two at low altitudes (< 3 km). To investigate the source of this bias, we show all the observed 1-minute-average data points together with model results as a “points-to-points” plot in Figure 3. The model reproduces the BC observations (normalized mean bias (NMB) = -5%) except for some occasional peaks, which are challenging to capture given the limitations of model temporal and spatial resolution. We note here that the model skill in capturing this variability improves in the nested grid ( $R=0.54$ ) compared to the global  $2^\circ \times 2.5^\circ$  grid ( $R=0.48$ ), with little change in NMB. In comparison, the bias in the simulation of OA is much larger, with an overall NMB of -45%. The unbiased simulation of sulphate and BC suggests that the model generally captures the transport, deposition, and primary emissions (fossil, biofuel and biomass burning) of aerosols. Therefore, the underestimate of OA is more likely associated with biased emission factors for POA and/or an underestimate of SOA. A key question is whether this bias is associated with absorbing or non-absorbing sources of OA.

According to the emission inventories used here, biofuel contributes very little OA in this region (< 3% of the total POA source during the campaign). This is consistent with a negligible demand for heating during spring and summer in the Southeast US. We therefore conclude that it is highly unlikely that the substantial OA underestimation identified in Figures 2c and 3b is associated with biofuel sources. To investigate whether an underestimate in fire emissions contributes to the bias, we also show the measured acetonitrile ( $\text{CH}_3\text{CN}$ ) concentrations in Figure 3c. Acetonitrile is a tracer for biomass burning and biofuel emissions (Andreae and Merlet, 2001). We calculate the hourly correlations between  $\text{CH}_3\text{CN}$  and OA, and BC and OA to help to identify whether the OA during plumes are associated with fires. When  $\text{CH}_3\text{CN}$  peaks, OA peaks, BC peaks and high  $\text{CH}_3\text{CN}$ -OA correlation are observed, we can be confident that biomass burning dominates the sources of OA. We observe two such periods (BP1 and BP2), which are shown with green shading in Figure 3. BP1 is a period with a series of  $\text{CH}_3\text{CN}$  peaks measured in the central US. The correlations between  $\text{CH}_3\text{CN}$  and OA are continuously high ( $R^2 = 0.5 - 0.9$ ) throughout the period. Both modelled BC and OA are dominated by biomass burning and enhanced during BP1, but underestimate the measurements. This suggests that the model does not capture the strength of these plumes. The simulated mass of BC from fires needs to increase by 130% to match observations. This bias could be associated with transport (including excessive dilution), inaccuracies in the amount or intensity of burning in the emissions inventory or in the emission factor for fire sources of BC. In contrast, the mass of biomass burning OA needs to increase by 210% to match the observations; this is ~80% more than for BC. BP2 is a 1-hour period dominated by a biomass burning plume observed in the southeast US, with very high  $\text{CH}_3\text{CN}$ -OA correlation ( $R^2 = 0.84$ ). The model is able to represent the BC concentrations during this period quite well (<10% underestimate), though if we attribute this entire bias to the biomass burning source, it implies a 36% increase in that source.

Similarly, the mass of biomass burning OA needs to increase by 145%, which is also ~80% more than for BC (similar to BP1). Since the influence from transport and errors in fuel burned should be very similar for BC and OA, the higher bias in simulated OA suggests that either the biomass burning BC/OA emission ratio is overestimated, or that biomass burning constitutes a large source of SOA which has been neglected in the model. If all of the 80% difference is due to the overestimate of BC/OA emission ratio, the BC/OA emission ratio would need to be reduced to 0.027 to meet the observations; this value is lower than the emission ratio for any fire type in the GFED4s emission inventory. It is therefore unlikely that this difference can be attributed entirely to an overestimate of the BC/OA emission ratio. A number of studies have explored the formation of SOA in biomass burning plumes. Yee et al. (2013) conduct photo-oxidation experiments in their chamber, and find that the formation of SOA from oxidation of phenol, guaiacol and syringe can be larger than 25% of the co-emitted biomass burning POA. Ortega et al. (2013) investigate the biomass burning smoke from fuels combusted during the FLAME-3 study and find that the net increase in mass due to biomass burning SOA is  $42 \pm 36\%$  of the biomass burning POA. However, compared to the laboratory studies, aircraft field measurement show much less SOA formation. Cubison et al. (2011), Jolleys et al. (2012), and Shrivastava et al. (2017) have reviewed all aircraft field studies of SOA formation in BB plumes, and found that the increase in total OA from SOA production is most often undetectable, with a smaller fraction of the cases showing increases or decreases with aging, which are a small fraction of the initial POA. Some studies have included simple biomass burning SOA schemes in their models. Hodzic and Jimenez (2011) assume a simplified biomass burning SOA scheme in the CHIMERE model (VOC is oxidized by OH with a constant rate); their simulation estimates that biomass burning SOA contributes 11% of the total SOA in Mexico City. Kim et al. (2015) used the same scheme for the SEAC4RS period and concluded that biomass burning SOA contributed 1% of the OA in this region, and comparable to 10% of the biomass burning POA. Therefore it is unlikely that the majority of the 80% bias can be attributed to SOA formation from fires. The small bias in the simulation of BC during BP2 suggests that the emission factor for BC from biomass burning is not substantially biased. Rather, it is likely that the bias in BC (particularly in BP1) results from an underrepresentation of total emissions from these fires. In both BP1 and BP2, after adjusting both BC and OA mass concentrations upwards to eliminate this bias, we still need to increase OA by an additional 80% to account for the underestimate of either the POA emission factor or biomass burning SOA. This 80% represents the upper limit on missing OA associated with biomass burning, given that other sources likely contribute to background concentrations.

Based on above analysis, we first increase the biomass burning OA mass by 210% and 145% during BP1 and BP2, respectively, to fix the model bias associated with these specific fire plumes. We then increase the biomass burning OA mass by 80% for all the remaining data (including background biomass burning OA), likely to account for the bias from the POA emission factor and any missing biomass burning SOA. This modified simulation of OA mass (referred to as FixBB) reflects the highest possible biomass burning contribution. In Figure 2c, this modified model (same as Modified\_Age, described at the end of this section) still underestimates the vertical profile of OA mass. This underestimate can be observed as underestimated OA peaks in Figure 3b but not in the corresponding BC concentrations in Figure 3a, and is therefore unlikely to be related to combustion sources (fossil fuel, biofuel, or biomass burning). This suggests that the remaining underestimate of OA is related to

anthropogenic and/or biogenic secondary sources, which are not a source of BC. This is consistent with previous work which suggests a general underestimate of SOA in the GEOS-Chem simulation (Heald et al., 2011). Furthermore, OA absorption is not enhanced during these peaks, suggesting that this SOA is not strongly absorbing and these biases are not relevant to our analysis of absorption which follows.

5 Figure 2d compares the simulated median vertical profile of OA absorption with measurements from the DC3 campaign. Note that this vertical profile may not be entirely representative since there are very few data points (< 10) available at some altitudes. It is also important to note that the OA particle size may differ between model and observations. The size distribution assumed in the model is for fine mode particles, and would not include the absorption from coarse mode OA (>1 $\mu$ m diameter). The biomass burning source contributes ~90% of the total absorption from OA in our simulation. The model underestimates the

10 OA absorption at both high and low altitudes. At altitudes above 10 km, some of the observations show abnormally high OA absorption considering the correspondingly low sub-micron OA mass. The model fails to capture these high values even by applying the highest absorption properties from laboratory studies for OA. Zhang et al. (2017) analyzed the inflow and outflow of OA absorption during DC3 and conclude that the high absorption aloft may relate to coarse mode OA or OA formation during convective transport. A number of studies also suggest that aqueous-phase chemistry in cloud droplets at high altitudes

15 can produce absorbing OA (Ervens et al., 2011; Desyaterik et al., 2013). These sources of OA are not included in our simulation and given the limited observational constraints provided by this dataset, we do not consider this data further in our study, but agree with Zhang et al. (2017) that further investigation of high altitude BrC is needed. The absorption enhancement in both observations and model around 4.5km is related to biomass burning; this is confirmed by elevated observed acetonitrile concentrations at this altitude. The high concentrations at this altitude are influenced by the fire plumes during BP1.

20 To investigate the absorption properties of biomass burning OA, we select the data during BP1 as we are confident that nearly all of the OA absorption is related to biomass burning in this period. Figure 4 compares OA absorption from simulated biomass burning OA with measurements during BP1. The Base modeled biomass burning OA absorption is moderately correlated ( $R = 0.56$ ) with the observations but overestimates them by ~10%. This overestimation increases to more than a factor of 2 after the underrepresentation of fire OA is corrected (FixBB). This suggests that the model assumption for  $MAC_{OA}$  is too high if no

25 whitening process is included. Given this overestimate, we perform an additional simulation which includes photochemical “whitening” of BrC (described in Section 3.3, FixBB\_Age); the results are shown as green points in Figure 4. By applying the aging scheme, the correlation between modeled and observed absorption increases ( $R = 0.60$ ), and the model is brought into much better agreement with observations (NMB= -4%). We note that if the 80% increase in biomass burning sourced OA included in FixBB is attributed solely to an overestimate of the BC/OA ratio (which we previously note seems unrealistic) this

30 would imply an 8% decrease in the MAC following the Saleh et al. (2014) parameterization used here. **This suggests that our initial assumption of  $MAC_{OA}$  is not significantly biased by the potential overestimate of the global BC/OA ratio used in our simulation.**

Figure 4 suggests that our initial assumption of  $MAC_{OA}$  for biomass burning only needs to increase by 4% when including the whitening process (decrease by 71% if not considering aging) to match the observations in BP1. At 365 nm, the best  $MAC_{OA}$

to represent the measurements is  $1.33\text{m}^2/\text{g}$  with aging (this is the MAC for freshly emitted OA) and  $0.37\text{m}^2/\text{g}$  without aging. The  $0.37\text{m}^2/\text{g}$  value is around the lower end of previous experimental studies, whereas  $1.33\text{m}^2/\text{g}$  falls close to the median of previous experimental studies. **This supports the idea that OA from fresh BB emissions exhibits similar absorption properties as observed in laboratory studies, but that including an aging process is important for simulating OA absorption in the ambient**

5 **atmosphere.** Given that there are only three OA absorption measurements available during BP2, we cannot repeat this analysis for BP2. For the other periods not dominated by biomass burning, the correlation between modeled and observed OA absorption is very low ( $R < 0.1$ ). OA absorption is typically lower during these periods and represents a mix of biomass burning and biofuel influences, the combination of which reproduces the magnitude of observed OA absorption.

After applying a series of new model assumptions, which include increasing fire OA mass, decreasing the biomass burning  $\text{MAC}_{\text{OA}}$ , and adding an aging scheme, we conduct a new simulation (Modified\_Age). **The simulated vertical profile of OA absorption in this simulation is now able to capture the measurements.** Since the observational constraints on  $\text{MAC}_{\text{OA}}$  and the aging scheme only affect absorption but not aerosol mass, the simulated OA concentrations in FixBB, FixBB\_Age and Modified\_Age are the same.

## 4.2 SEAC4RS Campaign

15 The SEAC4RS campaign offers us the opportunity to test our updated simulation developed based on DC3 measurements with a new dataset. Figures 5 and 6 show the vertical profiles and points-to-points plot for DC-8 aircraft measurements during SEAC4RS. Similar to DC3, our model generally captures the median vertical profile of sulphate (Figure 5a) and BC (Figure 5b). During SEAC4RS, biogenic SOA constitutes a much larger source of OA in the model (compared to DC3). Consistent with DC3, the Base simulated OA absorption captures the observations at low altitudes but is too low at high altitudes. The  
20 observed absorption at high altitudes is much lower than observed in DC3. Zhang et al. (2017) suggest that this is because measurements during SEAC4RS are less influenced by convection than DC3, thus there may be less secondary formation of BrC during convective transport. Note that there are very few data points available at altitudes above 4 km. The Base model underestimates the OA mass observations, but with a much lower bias ( $\sim 50\%$ ) than seen during DC3. Similarly, the model bias for BC is modest (NMB= $-30\%$ ). There is therefore weaker evidence for missing or underestimated fire activity in the  
25 GFED4s inventory during SEAC4RS. Furthermore, Figure 6c shows that there are no coincident peaks with both elevated  $\text{CH}_3\text{CN}$  and CO correlated each other. In our selected region during SEAC4RS there is no clear period which is dominated by biomass burning. The Rim fires occurred on 26-27 August 2013. During this period, CO is underestimated by more than 400% in the model, which indicates that the model fails to reproduce the fire plumes from the Rim fires. However, as shown in Figure 1, these measurements are located around the northwest US and are not included in our analysis.

30 When applying the same modified model assumptions constrained from DC3 (Modified\_Age simulation), the model simulation of observed OA concentrations (Figure 5c) improves. When only considering altitudes below 4km (where there are sufficient measurement data points), OA absorption is very similar between Base and Modified\_Age simulations, both able to capture the observed values. However, the mean bias in OA mass concentrations between the model and observation decreases

from -42% to -28% when moving from the Base to the Modified\_Age simulation. This confirms that the modifications applied based on the DC3 campaign in 2012 are generally appropriate for this region.

Washenfelder et al. (2015) analyzed measurements of OA absorption at a surface site within the study region (central Alabama) and during a similar time period (June 2013) of SEAC4RS. They found that most of the OA absorption was associated with biomass burning with little contribution from biogenic SOA, consistent with our analysis of the aircraft data. They suggest a biomass burning  $MAC_{OA}$  of  $1.35\text{m}^2\text{g}^{-1}$ , very close to ours. However, as their site was rarely affected by biomass burning (~6% of all OA), the identification of biomass burning OA absorption properties from this site is challenging and may not be regionally representative.

#### 4.3 Recommendations for OA absorption properties

Although the assumption of a relationship between BrC absorption and the BC/OA ratio, which is applied in our simulations, has been observed in several studies, including both laboratory (Saleh et al., 2014; Pokhrel et al., 2017) and field measurements (Wang et al., 2016; Gilardoni et al., 2016), the specific relationship (e.g. slope) differs among these studies. Based on the above analysis, our assumed MAC for fresh biomass burning OA at 365nm (based on Saleh et al., 2014) needs to be increased by 4% to reproduce the observations from DC3 and SEAC4RS (when including an aging scheme). As discussed in Section 4.1, this suggests that the absorption properties of freshly emitted OA are very similar to those from laboratory experiments. As a result, we retain the absorption wavelength dependence based on Saleh et al. (2014), but increase the  $MAC_{OA}$  by 4% in the model. Our recommended  $MAC_{OA}$  for biomass burning is therefore  $1.33\text{m}^2\text{g}^{-1}$  at 365nm,  $0.77\text{m}^2\text{g}^{-1}$  at 440nm and  $0.35\text{m}^2\text{g}^{-1}$  at 550nm with the suggested aging scheme described in Section 3.3. We assume that biomass burning SOA is equally absorbing as primary OA from biomass burning. All of these numbers can be translated to the form of  $MAC_{BrC}$  if the contribution of BrC to OA is known or specified. For example, the  $MAC_{OA}$  of  $1.33\text{m}^2\text{g}^{-1}$  is equivalent to a  $MAC_{BrC}$  of  $2.66\text{m}^2\text{g}^{-1}$  with BrC contribution of 50% to total OA. 2012 and 2013 were not exceptionally low or high fire years in the United States. During DC3 and SEAC4RS, fires in the United States (e.g. 12586 fires in June 2012, data from [www.globalfiredata.org](http://www.globalfiredata.org)) were somewhat more frequent than the last 10-years average (e.g. average 9831 fires in June). The difference between 2012 and 2013 and 10-years average emissions in our research region during the measurement period are not large (22% and 34% higher in 2012 and 2013 respectively, compared to the 10-year average). This suggests that our conclusions based on the constraints from these two campaigns can be generalized to other biomass burning seasons in United States. Given that the measurements only constrain absorption at one wavelength, we cannot evaluate the model assumed AAE. Previous field and laboratory studies show a large range of BrC AAE of 2 to 9 (Laskin et al., 2015). Our model assumptions (3.1 for biomass burning OA at 300&600nm wavelength pair) is around the lower end of this range.

The spring and summer in the southeast U.S. are not substantially impacted by biofuel emissions, therefore the measurements during the DC3 and SEAC4RS campaigns are not suitable for evaluating the absorption from biofuel OA. Given that we see no model bias when biofuel influence exceeds the biomass burning influence (typically during low absorption background OA periods), we retain our assumptions in Section 3.2 for biofuel OA. Therefore, our recommended value for biofuel  $MAC_{OA}$  is

1.19m<sup>2</sup>g<sup>-1</sup> at 365nm, 0.76m<sup>2</sup>g<sup>-1</sup> at 440nm and 0.39m<sup>2</sup>g<sup>-1</sup> at 550nm. We assume that there is no “whitening” of biofuel OA with aging given that, to date, there is no field evidence to support this. These assumptions require further testing against measurements with significant biofuel influence.

During both DC3 and SEAC4RS, anthropogenic SOA contributes very little absorption in the model (~4% in DC3 and < 1% in SEAC4RS4) despite the fact that we apply upper-limit assumptions regarding the absorption properties of SOA. In our analysis of DC3, there remain several underestimated OA mass peaks even after increasing biomass burning OA mass. These peaks are likely due to secondary biogenic or anthropogenic sources. During SEAC4RS, there are also some peaks with substantial simulated biogenic SOA; observed absorption is not elevated during these peaks. Therefore, we conclude that the absorption from biogenic and anthropogenic SOA is negligible in the Southeast U.S, consistent with SOAS results (Washenfelder et al., 2015). This may not be true in other regions.

Using the above model configuration (Modified\_Age simulation), the model is able to reproduce the vertical profile of OA absorption during DC3 and SEAC4RS at altitudes below 10 km that include more than 340 data points. Our optimized MAC<sub>OA</sub> is comparable with previous BrC model studies. Feng et al. (2013) assume that 66% of the OA from biofuel and biomass burning is BrC. They applied 2 different sets of assumptions for the absorption properties of BrC: a moderately absorbing BrC with MAC = 0.63m<sup>2</sup>g<sup>-1</sup> at 450nm, and a strongly absorbing BrC with MAC = 1.6m<sup>2</sup>g<sup>-1</sup> at 450nm. These numbers are 0.41m<sup>2</sup>g<sup>-1</sup> and 1.06m<sup>2</sup>g<sup>-1</sup> when transferring MAC<sub>BrC</sub> to MAC<sub>OA</sub>, the median of which (0.74 m<sup>2</sup>g<sup>-1</sup>) is similar as our assumptions at 450nm. Jo et al. (2015) assume different BrC to OA contributions for different biomass burning and biofuel fuels, resulting in a range of MAC<sub>OA</sub> of 0.65–5.01 m<sup>2</sup>g<sup>-1</sup> at 365nm. The assumptions of Saleh et al. (2015) and Wang Q. et al. (2016) are also based on the laboratory results from Saleh et al. (2014) but use the modeled BC/OA mass concentration ratio instead of emitted BC/OA ratio. The modeled BC/OA mass concentration ratio reflects the mixed contribution of various sources and the effect of differential removal during transport; it is not equivalent to the initial emission properties of carbonaceous aerosol. They assume that all OA from biofuel and biomass burning is BrC and apply a MAC = 2.5m<sup>2</sup>g<sup>-1</sup> for biofuel OA and 3.1m<sup>2</sup>g<sup>-1</sup> for biomass burning OA at 550nm. These values are much higher than ours and higher than any of the previous experimental studies. Although some of these modelling studies compare their simulated total AAOD with observations, none evaluates their assumptions with direct BrC absorption measurements.

Simulating the whitening process of BrC as we do in our Modified\_Age simulation comes at a computational cost of adding extra species or tracking absorption in a model, something which may not be practical for all 3D models. If we neglect the whitening of BrC with aging in our simulation, we must further reduce the MAC<sub>OA</sub> for biomass burning to match the observational constraints. In this case, we estimate an average MAC<sub>OA</sub> for biomass burning of 0.37m<sup>2</sup>g<sup>-1</sup> at 365nm, 0.23m<sup>2</sup>g<sup>-1</sup> at 440nm and 0.10m<sup>2</sup>g<sup>-1</sup> at 550nm; we call this the Modified\_Simple simulation. Another approach to simplify the whitening process for models may be to apply constant whitening factors with altitude to the simulated absorption; the consistency of these factors may require additional observational support.

## 5 Global Implications

The model assumptions applied in Modified\_Age and Modified\_Simple are constrained and tested against conditions influenced by US fires observed during DC3 and SEAC4RS. We assume that such constraints are generalizable though the combustion conditions may differ in other regions. We test this assumption in Section 5.1 by comparing our global simulation with AAOD observations outside of the United States. In this analysis, we conduct Modified\_Age and Modified\_Simple simulations with a horizontal resolution of  $2^{\circ} \times 2.5^{\circ}$ , using 2014 meteorology, and 10 year averaged biomass burning emissions (2005-2014).

### 5.1 Surface absorption and AAOD of BrC

We use the results from Modified\_Age to conduct the analysis in this section. Both of the Modified\_Age and Modified\_Simple simulations are optimized to meet the observational constraints, and therefore exhibit very similar average surface absorption. Figure 7 shows the global distribution of surface OA dry absorption contributions (= BrC absorption contribution) to total absorption from aerosols at 370nm. The modeled contribution ranges from 5% to 72% globally, with an average value of 32%. The circles in Figure 7 show the BrC absorption contributions from observations at 8 surface sites. These data are derived from multiple-years' multiple-wavelength absorption measurements from Aethalometers (AE, Magee Scientific, <http://www.mageesci.com>), using a BC-BrC absorption separation method. Details of this methodology and the specific datasets can be found in Wang et al. (2016). Although the model assumptions were optimized based on measurements in the U.S., the model is able to represent the BrC absorption contribution at sites in Europe. However, the model shows much higher BrC absorption contributions than observations in other fire-rich regions (e.g. Amazon and Siberia). The simulated contributions reflect 10-years averaged values over all seasons, but the measurements over these 8 sites are not continuous and usually cover several months in a year. Therefore, this is not an exact comparison between the model and these measurements. Figure 8 shows the global distribution of simulated column BrC-AAOD and the contribution of BrC-AAOD to total AAOD at 440nm. The BrC-AAOD at 440nm ranges from  $\sim 10^{-5}$  to 0.05, with a global mean of 0.002. BC still dominates the total AAOD in most regions. The contribution of BrC-AAOD to total AAOD at 440nm ranges from 15% to 70%, with the global mean of 46%. The Aerosol Robotic Network (AERONET) provides a worldwide measurement network of AAOD at four wavelengths (440, 675, 870, and 1020 nm). However, several shortcomings limit its use for constraining modeled BrC-AAOD, which include the uncertainties on AERONET retrievals, possible inconsistencies between assumptions in the retrieval scheme and our model, poor data availability, no data at low wavelengths where BrC dominates absorption, and the influence from dust. Details of the processing and the uncertainty issues surrounding AERONET AAOD are discussed in Wang et al. (2016). When assuming only BC absorbs light, the modeled AAOD has a moderate correlation with AERONET AAOD at 440nm ( $R = 0.54$ ). This correlation is smaller than that at 675nm ( $R=0.59$ ) where OA contributes nearly no absorption. After including the absorption from BrC, the correlation of AAOD at 440nm increases to  $R = 0.60$ ; this increase in model skill qualitatively supports our description of BrC absorption.

These comparisons suggest that our simulation, optimized based on observations in the United States, is not substantially biased in other regions of the world. However, we emphasize that we have developed a simple approach to modeling BrC and more observations are needed to refine this simulation for other regions where sources and optical properties may differ.

## 5.2 Estimating the direct radiative effect (DRE) of BrC

5 Figures 9a and c show the DRE of total OA from the Base and Modified\_Age simulations. The global mean value of all-sky DRE is  $-0.290 \text{ Wm}^{-2}$  and  $-0.344 \text{ Wm}^{-2}$  in Base and Modified\_Age, at the top of atmosphere. This number is  $-0.392 \text{ Wm}^{-2}$  when assuming OA does not absorb light. Therefore the global mean absorption DRE from OA (BrC) is estimated to be  $+0.102 \text{ Wm}^{-2}$  and  $+0.048 \text{ Wm}^{-2}$  in Base and Modified\_Age. In the Modified\_Age simulation, biofuel and biomass burning sources contribute 60% and 40% respectively to the global absorption DRE of BrC. The absorption DRE of BrC from our best  
10 (Modified\_Age) simulation ( $+0.048 \text{ Wm}^{-2}$ ) is about 30% of the DRE from BC ( $+0.17 \text{ Wm}^{-2}$ ). The aging process significantly impacts our estimate of the absorption DRE; the global absorption DRE is 43% higher when using the same optical assumptions but excluding the aging scheme in Modified\_Age. We also find that the global mean absorption DRE is very similar using the Modified\_Simple scheme ( $+0.049 \text{ Wm}^{-2}$ ) or the Modified\_Age scheme, both of which are observationally constrained.

The DRE could be underestimated due to two reasons: First, we attribute all the mass bias of OA to biomass burning OA  
15 during fire plumes without considering other sources. This may overestimate the contribution of biomass burning in our analysis, thereby underestimating the MAC of biomass burning OA when constrained by absorption observations in fire plumes. Using a potentially underestimated MAC globally could result in the underestimate of the global DRE. Second, we neglect some very high OA absorption at high altitudes ( $> 10 \text{ km}$ ). Zhang et al. (2017) suggest that this contributes a local DRE of  $0.65 \pm 0.34 \text{ Wm}^{-2}$ . However it is unclear how important this convectively-formed BrC is globally, therefore we neglect it here,  
20 implying that our estimate of absorption DRE of BrC is a lower estimate.

In contrast, the DRE could also be overestimated for two reasons: First, if we assume that biofuel BrC is subject to the same aging process as biomass burning BrC, the global absorption DRE would be 37% lower than our estimate. Second, we assume that BrC is completely externally mixed with other aerosols. This will overestimate the absorption since the BrC coated on BC is also counted (via an absorption enhancement factor). Assuming the shell thickness is  $\sim 60\%$  of the core radius (observed in  
25 field measurements, Cross et al., 2010; Shirawa et al., 2010), and all coated material is BrC for biofuel/biomass burning related BC, the absorption DRE of BrC will be  $\sim 15\%$  lower. This effect is likely even smaller given that BrC may contribute little to the coating material compared to non-absorbing OA and nonorganic aerosols.

Our estimate of BrC DRE is near the lower bound of previous studies which have not been evaluated against direct measurements of BrC absorption. Saleh et al. (2015) apply BrC absorption properties based on the modelled BC/OA ratio and estimate the absorption DRE from BrC to be  $+0.12 \text{ Wm}^{-2}$  to  $+0.22 \text{ Wm}^{-2}$ . Jo et al., 2016 use the modified combustion efficiency (MCE, a function of  $\text{CO}/\text{CO}_2$ ) to determine BrC absorption, and estimate the absorption BrC DRE to be  $+0.11 \text{ Wm}^{-2}$ . These  
30 values are similar to the absorption DRE of BrC estimated from our Base simulation, prior to optimization against observations. Hammer et al. (2016) estimate an absorption BrC DRE of  $+0.03 \text{ Wm}^{-2}$ , which is the lowest value from previous studies, and

lower than our estimate. We note that their model is constrained by satellite observations of the ultraviolet aerosol index (UVAI) which is not specific to BrC; furthermore, uncertainties on the UVAI product are not well understood. More widespread direct measurements of BrC absorption may offer opportunities to evaluate the UVAI product.

In this study, we do not estimate the DRF, which is the difference between pre-industrial and present-day DRE, given the challenges in identifying the anthropogenic fraction of biomass burning emissions. Several previous studies report the absorption DRF for BrC: +0.04  $\text{Wm}^{-2}$  to +0.11  $\text{Wm}^{-2}$  by Feng et al. (2013) and +0.22  $\text{Wm}^{-2}$  to +0.57  $\text{Wm}^{-2}$  by Lin et al. (2014).

## 6 Conclusions

We use the GEOS-Chem model coupled with RRTMG model to investigate the mass optical properties and direct radiative effect of brown carbon (BrC). Our model assumptions for the optical properties of BrC are based on the laboratory study of Saleh et al. (2014) and constrained by the aircraft measurements from the DC3 campaign in the US. These assumptions are further tested against observations made during the SEAC4RS campaigns.

Our model captures the magnitude and vertical distribution of sulphate and BC mass concentrations during both DC3 and SEAC4RS. However, the model underestimates the OA mass concentrations in both campaigns. By analyzing the fire plumes in the observations, we find the biomass burning OA is likely to be underestimated by 80% due to the bias in OA emission factors and/or missing biomass burning related SOA. After fixing the OA mass from biomass burning, our model is able to represent the variation of OA absorption in fire plumes, but substantially overestimates the magnitude. Applying an aging scheme where OA photochemically whitens further increases the correlation between modeled and observed absorption and decreases the model bias. These comparisons, suggest fire emissions are characterized by an  $\text{MAC}_{\text{OA}}$  of 1.33 $\text{m}^2/\text{g}$  at 365nm, 0.77 $\text{m}^2/\text{g}$  at 440nm and 0.35 $\text{m}^2/\text{g}$  at 550nm, which decreases with aging. The optical properties for biofuel emissions are not well constrained by these datasets, and we retain our original assumptions based on Saleh et al. (2014) with biofuel  $\text{MAC}_{\text{OA}}$  of 1.19 $\text{m}^2/\text{g}$  at 365nm, 0.76 $\text{m}^2/\text{g}$  at 440nm and 0.39 $\text{m}^2/\text{g}$  at 550nm. Using these assumptions, we estimate a global mean top-of-the-atmosphere DRE of -0.344  $\text{Wm}^{-2}$  for OA, and an absorption DRE of +0.048  $\text{Wm}^{-2}$  for BrC, all-sky conditions. These properties and the resulting estimated DRE are lower than values from most previous modeling studies, however, none of these studies have been constrained by or evaluated against direct BrC absorption measurements.

Although the model can reproduce the aircraft observations from DC3 and SEAC4RS when using the above model configuration, further studies, especially global, direct measurements, are necessary to build a credible simulation of BrC. First, current emission inventories do not provide enough information to accurately apply combustion condition based BrC absorption properties. Emission measurements representative of varying burning conditions as well as different fuel types are needed. Second, we extend the model assumptions constrained from regional observations (mainland US) to a global simulation. It is not clear whether BrC properties are consistent world-wide. Third, more studies are required to investigate the contribution of biomass burning SOA and its absorptivity. Fourth, the absorption assumptions for biofuel OA must be more thoroughly evaluated. It is also not clear whether the whitening process also affects the absorption of biofuel OA. Last, our

simulations do not include OA absorption from fossil fuels. Fossil OA has only been identified as light-absorbing in Beijing (Yan et al., 2017). However, applying this assumption for fossil OA world-wide in the model would substantially increase background OA absorption, leading to a considerable model overestimate of OA absorption observed during aircraft campaigns (Section 4) and OA absorption contributions from surface sites (Section 5.1). Therefore, to further constrain the global impacts of BrC, additional field measurements representative of various source influences (fossil, biofuel OA, SOA) are required.

## 7 Data availability

All data of aircraft measurements used in this paper were collected as part of the NASA DC3 and SEAC4RS missions and are available to the general public through the NASA data archive (<https://www-air.larc.nasa.gov/cgi-bin/ArcView/dc3> and <https://www-air.larc.nasa.gov/cgi-bin/ArcView/seac4rs>). The GEOS-Chem model results are available from the corresponding author upon request.

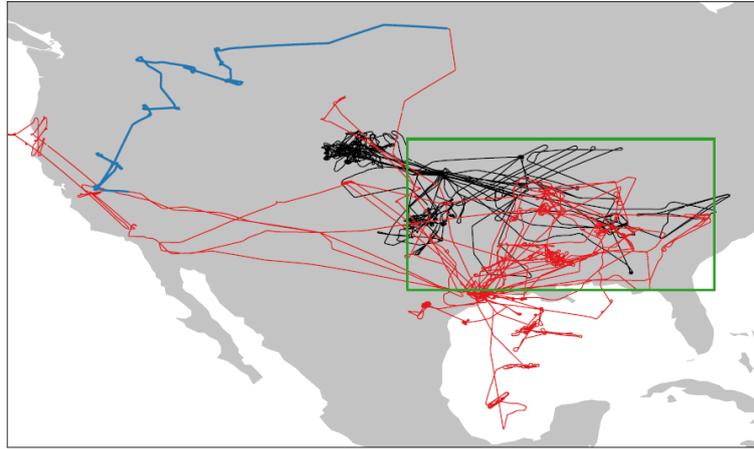

Figure 1. The flight tracks during the DC3 (black) and SEAC4RS (red) campaigns in 2012 and 2013, respectively. The blue tracks indicate the SEAC4RS data influenced by Rim fires on August 26-27. The green box indicates the region of focus for our analysis (see Section 4 for details).

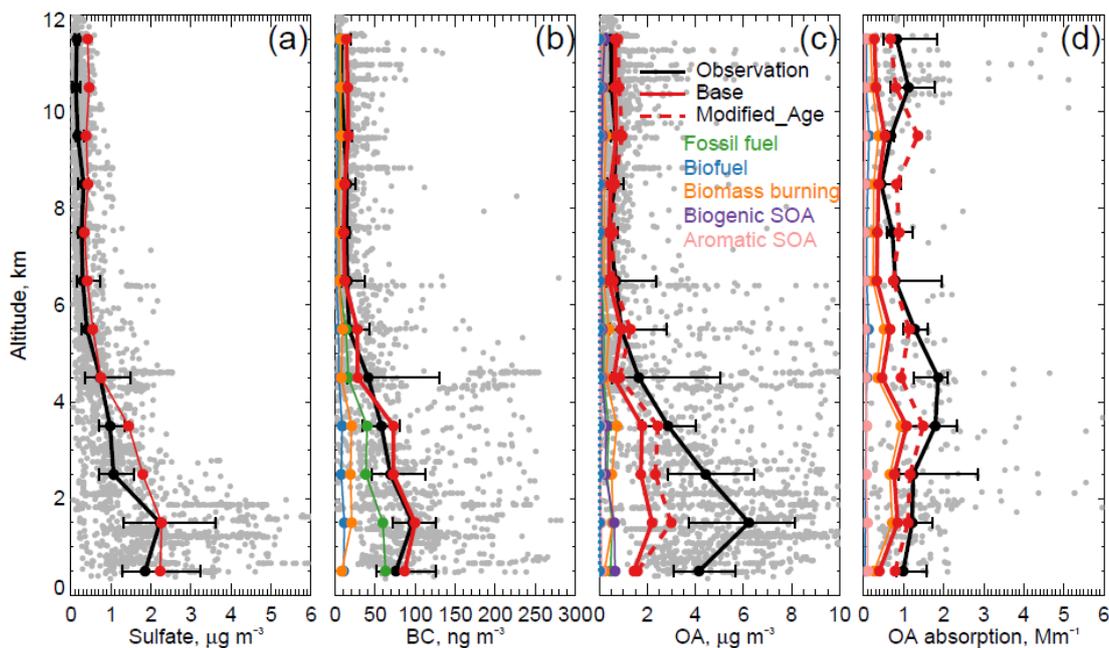

Figure 2. The median vertical profile of (a) sulfate, (b) BC, (c) OA mass concentration and (d) OA absorption, shown in 1 km bins, from the DC-8 aircraft measurement during DC3 campaign in the region shown in Figure 1. Observations (black) are compared to the Base simulation (red) and source-specific contributions to that simulation, as well as to the optimized Modified\_Age simulation (red dashed). Error bars show the 25<sup>th</sup> and 75<sup>th</sup> percentiles of measurements in each vertical bin. Gray points show the original measurements (1-minute averaged values for a, b and c, 5-minutes averaged values for d). The ranges of x-axes are set to emphasize the vertical profile, so several data points higher than the maximum values of x-axes are not shown. Details regarding the model simulations of Base and Modified\_Age can be found in Sections 3.2 and 4.1.

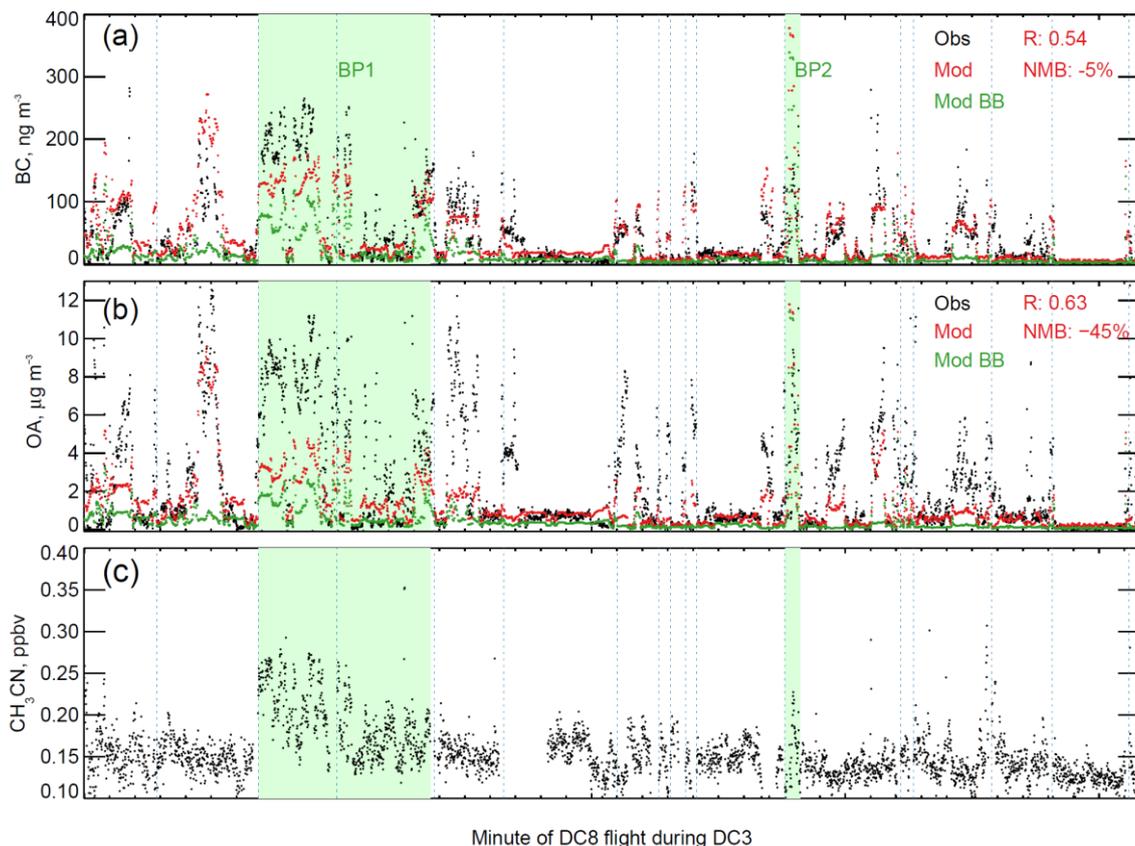

Figure 3. Points-to-points comparison between 1-minute averaged observed (black) and simulated (red) (a) BC and (b) OA made aboard the DC-8 aircraft during the DC3 campaign in the region shown in Figure 1. The simulated total mass concentrations (red) as well as mass concentrations associated with biomass burning only (green) are from the Base simulation. The observed concentrations of acetonitrile are also shown (c). The blue dashed lines separate different flights. The green shading indicates two biomass burning dominated periods (BP1 and BP2, discussed in Section 4.1).

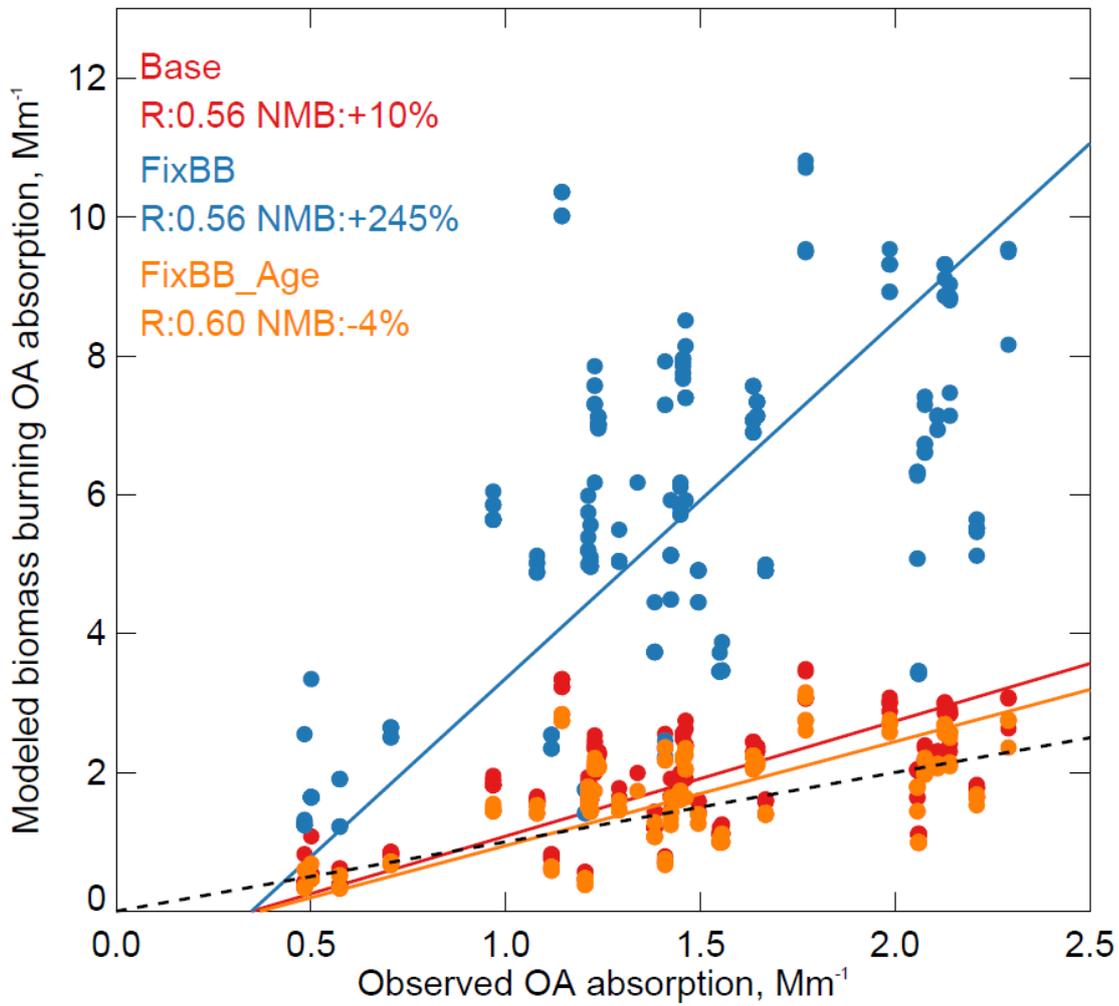

Figure 4. Correlation between observed and modelled OA absorption during the BP1 interval (see Figure 3) of the DC3 campaign. The 1-to-1 line is shown as a dotted black line, the best-fit lines are shown as solid lines. NMB: normalized mean bias between the simulation and observations. Details of the model simulations can be found in Section 4.1.

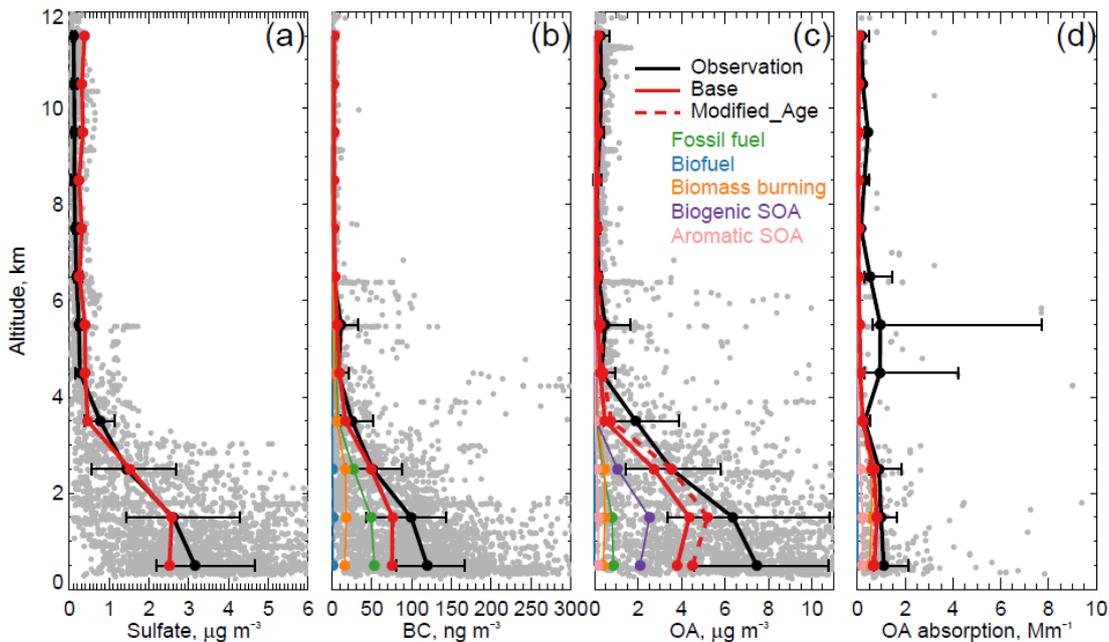

Figure 5. The median vertical profile of (a) sulfate, (b) BC, (c) OA mass concentration and OA absorption (d), shown in 1 km bins, from the DC-8 aircraft measurement during SEAC4RS campaign in the region shown in Figure 1. Observations (black) are compared to the Base simulation (red) and source-specific contributions to that simulation, as well as to the optimized Modified\_Age simulation (red dashed). Error bars show the 25<sup>th</sup> and 75<sup>th</sup> percentiles of measurements in each vertical bin. Gray points show the original measurement data points (1-minute averaged values for a, b and c, 5-minutes averaged values for d). The ranges of x-axes are set to emphasize the vertical profile, so several data points higher than the maximum values of x-axes are not shown. Details of model simulations of Base and Modified\_Age can be found in Section 3.2 and 4.1.

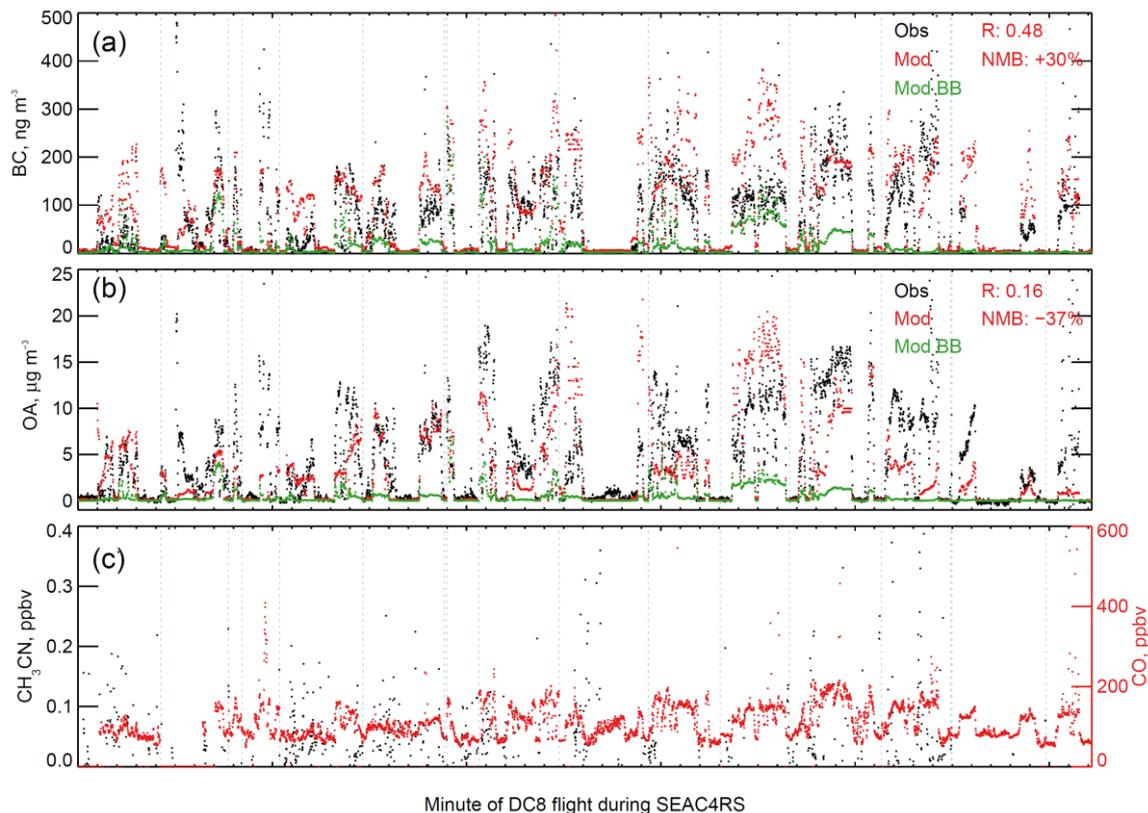

Figure 6. Points-to-points comparison between observed and modelled (a) BC and (b) OA made aboard the DC-8 aircraft during the SEAC4RS campaign in the region shown in Figure 1. The modelled total mass concentrations (red) as well as mass concentrations associated with biomass burning only (green) are from the Base simulation. The observed concentrations of acetonitrile and CO are also shown (c). The blue dashed lines separate different flights.

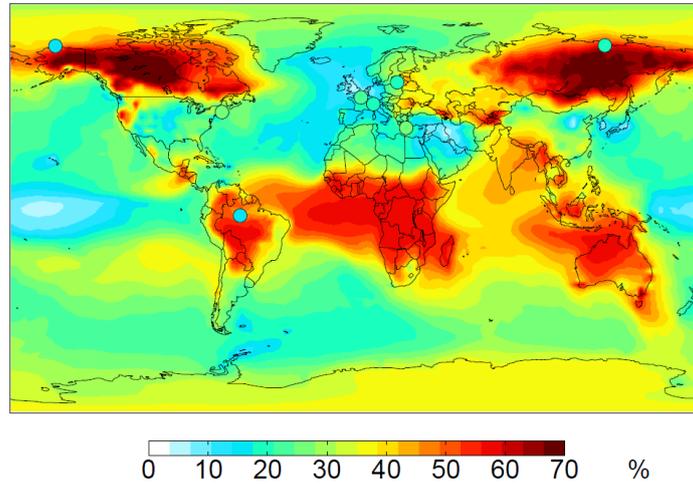

Figure 7. Global distribution of simulated BrC dry absorption contribution to total dry aerosol absorption at 370nm at the surface for 2014. Results are from the Modified\_Age simulation. The circles show the retrieved results from multiple-wavelength absorption measurements at 8 surface sites (see Section 5.1 for details).

5

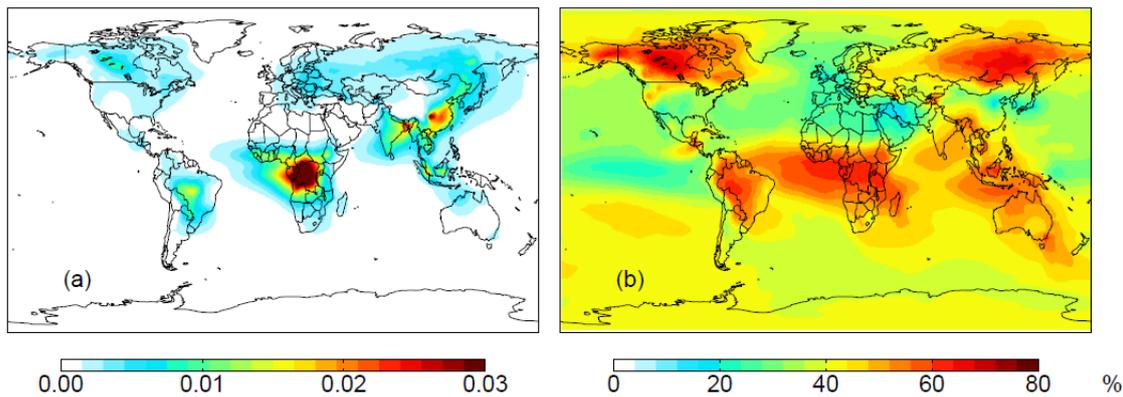

Figure 8. Global distribution of simulated 2014 annual mean (a) BrC-AAOD, and (b) contribution of BrC-AAOD to total AAOD at 440nm. Results are from the Modified\_Age simulation.

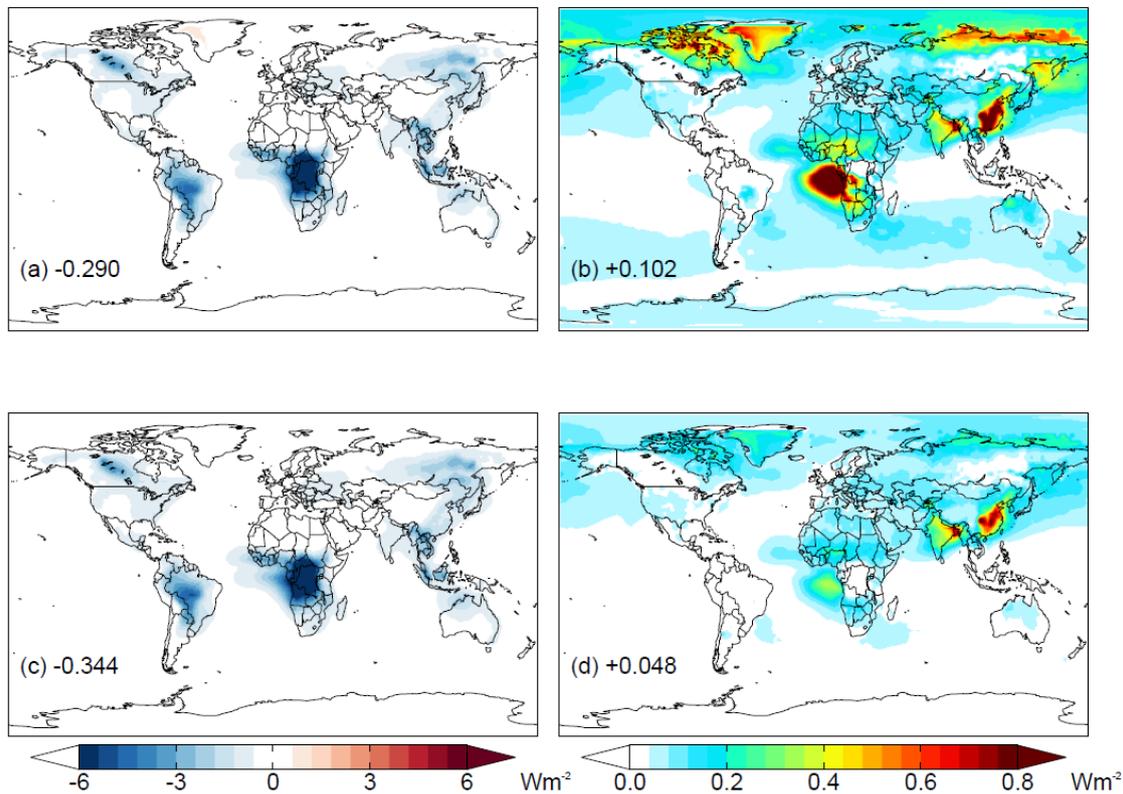

Figure 9. The global annual mean OA DRE (a and c) and BrC absorption DRE (b and d) at the top atmosphere (TOA) in 2014 from Base (a and b) and Modified\_Age (c and d) simulations. Numbers indicate the global mean value in  $Wm^{-2}$ .
