This is an interesting paper that suggests a possible explanation for typical model over-prediction of surface ozone over CONUS (Figure 7). It is not clear however if model simulations are improved both in terms of surface O3 predictions, as well as O3 vertical profiles (especially in the boundary layer and just above the boundary layer). While comparisons with measured vertical profiles of JNO2 are shown in Figure 3, no corresponding comparisons of vertical profiles are shown for O3. It would be useful to show these comparisons (and provide histograms as is done for JNO2) with simultaneous aircraft O3 measurements, especially given the overprediction of JNO2 in the boundary layer in the GOES simulation compared to the CNTR simulation for the NOMADSS flights (Figure 3).

In terms of model evaluation, it would be also useful to show comparisons of the modeled Ox vs NOz relationship against observations (as is done in Travis et al., 2016) as a check on modeled ozone production efficiency.
