The authors addressed some of the criticism and overall the manuscript has somewhat improved since the previous version. I am still not convinced that the manuscript represents a significant advance in science however I do appreciate author’s efforts to disentangle statistical links between Arctic stratospheric ozone and surface climate. Below I add some comments; hopefully the authors find them useful for further improvement of the manuscript.

First, contrary to what the authors assert, I don’t believe the connection between Arctic ozone and surface climate is “settled science”; I simply don’t think the authors approach this problem from the right perspective. In Calvo et al they did demonstrate that, as ozone variability increased from low Ozone Depleting Substances (ODS) period to high ODS period, this was followed by increased stratospheric cooling and stronger changes in surface climate. While their study may have caveats, for example because they only use one model, they could however with reasonable confidence attribute their surface climate response during the second period to increased stratospheric variability caused by increased ODS and low ozone. I don’t think they assumed a direct ozone-surface link because they carefully documented responses of zonal mean temperatures and winds consistent with the dynamical stratosphere-troposphere coupling, although they might have discussed the mechanism in a more clear way.

We have now revised our discussion of Calvo et al in the introduction to specifically note that the downward impacts are strongest when low ozone values are more present, which is associated with stronger dynamical variability of the vortex.

I also don’t see how the authors of the present manuscript addressed the statement from Ozone assessment, which they cite. It is well-established that extreme low ozone values, observed during some winters in the Arctic, are a result of chemical depletion, rather than stratospheric dynamics alone, see for example Manney et al. 2011. Thus, based on Calvo et al results, surface anomalies that follow low ozone episodes may be attributable to chemical ozone depletion. While the ozone assessment statement does not mention any mechanism, it is certainly consistent with stratosphere-troposphere dynamical coupling similar to what is apparently operating in the Antarctic. Thus I don’t see how the authors “explored the robustness” of the statement in the ozone assessment.

If the connection between Arctic ozone and the surface is "robust", then a variety of different methodological choices should all lead to the same conclusion, namely that a downward impact is present. If the existence of a downward effect is sensitive to the specific approach one takes, then that indicates a lack of robustness.
In summary, while I find that the part of the study concerning ASO-ENSO link has improved and is worth reporting, I still don’t find that the part concerning links between ASO and polar surface climate is equally exciting. Below are my suggestions:

1. The authors find strikingly large differences in ozone-climate coupling even between simulations by the same model. In Calvo et al they find similarly large differences in coupling between two periods when ozone was / was not depleted. During ozone depletion period the ozone variability was twice as large, owing to extreme low ozone events. This was linked to larger signal in stratospheric temperatures and thus in surface climate. I suggest that the authors test whether the spread shown in Figures 4 and 6 can similarly be attributed to different interannual variability between these periods. Specifically, do you see larger interannual variability in ozone (measured e.g. by interannual standard deviation) during years when ozone-climate coupling is larger? One could expect stronger coupling when there is larger variability, due to increased signal to noise ratio.

The RefC2 simulations aren’t available for all models from 1955, and therefore we aren’t able to apply the same analysis of Calvo et al but to the CCMI models. However we are able to compare the 41 year periods discussed in the text, and also the period 1985-2005 (as in Calvo et al) to the period 2072-2092 when ozone concentrations in the models are back to their values in the 1960s. This is documented in the figure below, which shows Arctic stratospheric ozone (latitude and height range as defined in the text) for each model (thin line) and the ensemble mean (thick black line). This is the time evolution of ASO before we perform the linear regression to focus on interannual timescales.

![Figure R1: timeseries of ASO pressure- and area-weighted average from 50hPa to 150hPa and 60N to 81.25N in each of the 14 integrations (thin lines) and in the ensemble mean (thick black line)](image)
Below is a histogram of the standard deviation of March ASOpole on interannual timescales for the period 1985-2005 and 2072-2092. The top row is after regressing out greenhouse gases and ODS changes, and the bottom is when we leave in this decadal variability. Each panel also includes the standard deviation averaged across the 14 models. The standard deviation of ASOpole is actually larger in 2072-2092 than in the period with elevated ODS concentrations. The interannual connection between Zpole and SLPpole is larger in the later period as well, and hence this is consistent with the reviewer’s intuition. However, this stronger connection cannot be due to heterogeneous chemical ozone depletion, as there is certainly less heterogeneous chemical ozone depletion in the period 2072-2092 than in the period 1985-2005. Results are similar if we use the 41-year periods as in the main body of the paper: the standard deviation averaged across the 14 models is 0.132 in the period 1970-2010 and 0.16 in the period 2052-2092. Note however that the mean standard deviation is somewhat less in the intervening period (0.128 for the period 2011-2051), even though the interannual relationship between Zpole and SLP was stronger in this period than in the period 1970-2010, and so there is no clear relationship between enhanced variance ASOpole and enhanced strat-trop coupling in the CCMI models. This is somewhat contrary to Calvo et al.

Calvo et al used one model – WACCM – and 3 of the 14 integrations we use here are from WACCM (though the model version is not necessarily the same). The red bars in the histogram below are for these 3 integrations of WACCM, and in the WACCM simulations as well the variance of ASOpole is larger in the period 2072-2092 than in the period 1985-2005. We do note that the increase in variance in WACCM is somewhat less than in most of the CCMI models, and hence it is possible that the difference between our analysis here and that of Calvo et al is due to the fact that Calvo et al focused on WACCM.

Figure R2: histogram of the standard deviation of ASO pressure- and area-weighted average from 50hPa to 150hPa and 60N to 81.25N across the 14
integrations (top) after regressing out ODS and greenhouse gases; and (bottom) without such a regression (as in figure R1). The left column is for the 1985-2005 period with robust chemical ozone depletion, and the middle column is for the 2072-2092 period after ODS concentrations are small. The right column is the difference between the middle and left column. The average of the 14 standard deviations is indicated. Red bars indicate WACCM integrations.

1. Further, can the authors attribute stronger coupling (and possibly larger variability) to different ozone levels and thus possibly to chemistry? The authors showed how the coupling changes between different periods (1970-2010, 2011-2051, 2052-2092) but it is difficult to understand their result without knowing what ozone values were during these runs. Is there, for example, any indication of chemical ozone depletion in those runs? One could test correlation coefficients against minimum ozone values achieved in those runs.

A timeseries of ozone values is shown in Figure R1, though note that for all results in the paper itself we perform a MLR analysis to statistically remove variability linearly associated with ODS and greenhouse gases. There is indeed an ozone minimum near 2000 when we do not apply the MLR.

The reviewer hypothesized that models with more negative excursion of ASOpole (perhaps associated chemical ozone depletion) would be associated with enhanced coupling of ASOpole with PSpole. We now assess this hypothesis in the CCMI models in figure R3 below. Specifically, we compute minimum value in ASOpole in March in each integration relative to its mean value over each 41 year chunk for each model. This minimum value is shown in the x-axis. The y-axis shows the correlation of PSpole with ASO, with the top row the correlation of PSpole in March with ASO and the bottom row the correlation of PSpole in April with ASO. Each star is for one of the 14 integrations. If the reviewer's intuition is correct, we would expect a negative correlation, and in 3 of the 6 there is indeed a negative correlation (in the other 3 the correlation is essentially zero). However none of these negative correlations are statistically significant at even the 90% level. Hence while there is some indication that the reviewer's hypothesis is supported by the CCMI REFC2 runs, it is premature to include any of
this analysis in the paper itself as results aren’t statistically significant.

![ASO min Vs corr PS pole with ASO](image)

**Figure R3:** Comparison of the (x-axis) minimum value of ASOpole for each model and each 41 year chunk as compared to the mean value for that period to (y-axis) the correlation of ASOpole in March with PSpole in March (top) and April (bottom).

I also wonder what could be the cause for seemingly stronger coupling during some future runs (2052-2092). One could imagine that there are still episodes of chemical ozone depletions that, combined with increased Brewer-Dobson circulation in future, would lead to larger variability and stronger coupling. I guess negative answer to these questions would indeed indicate that the variability in coupling is due to internal variability, as the authors assert, but the tests proposed above could still give more insights.

This is a very good question, and we don’t have a good answer. The variance of ASOpole is indeed larger in the 2052-2092 period, and so is the variance in Zpole and also in Tpole (see Figure R4, with the figures constructed similar to Figure R2). However ODS concentrations are less in the period 2052-2092, and so this increased variance does not appear to be related to heterogeneous chemical ozone depletion. Note that the increases in variance for Zpole, Tpole, and ASO are all between 15% and 20%. Ultimately, we leave a thorough explanation for this finding for future work.
Figure R4: histogram of the standard deviation of polar cap geopotential height and temperature at 100hPa area-weighted average from 70N to the pole across the 14 integrations after regressing out ODS and greenhouse gases. The left column is for the 1970-2010 period with robust chemical ozone depletion, the middle column is for the 2011-2052 period, and the right column is after ODS concentrations are small. The average of the 14 standard deviations is indicated.

I appreciate large amount of work that authors put into the study but I nevertheless don’t find that the manuscript is complete without this additional (and rather straightforward) analysis.

We have made three changes to the manuscript:

1. The discussion of Calvo et al 2015 in the introduction has been improved: "In contrast, the coupled chemistry-climate simulations of Calvo et al. (2015) include a robust stratospheric-tropospheric response in low versus high ozone years if ozone depleting substance concentrations (ODS) follow those from 1985-2005: a positive phase of the North Atlantic Oscillation, a poleward shift of the North Atlantic tropospheric jet, and corresponding regional surface temperature anomalies. Downward coupling is not evident in the period 1955-1975 when ODS concentrations were lower, and they argue that the enhanced ODS concentrations lead to enhanced dynamical variability of the vortex and thus to stronger downward coupling. The fully-coupled
approach of Calvo et al. (2015) allows consistency between the evolving ozone distributions and dynamical conditions among other differences in the model configuration, which may explain the differences between their conclusions and those of studies prescribing ozone concentrations"

2. We have revised the end of section 3 to better emphasize that the connection between vortex variability and surface climate is stronger in a nearly ODS-free future than when ODS concentrations neared their peak.

3. We have also added to the discussion section: " Second, Calvo et al. (2015) argue that chemical ozone depletion leads to a more variable vortex and specifically to more extremely strong vortex events, which in turn leads to more robust stratosphere-troposphere coupling. However we find that variability of the vortex is actually larger in the future when ODS concentrations are lower and heterogeneous chemical ozone depletion should be less frequent. Specifically, the standard deviation averaged across all models for the period 1970-2010 is lower than for the period 2052-2092 for ASO, polar cap geopotential height, and polar cap height by 15% to 20%, and this increase in variability is driven both by more frequent positive and negative extremes. A thorough investigation of what drives this enhanced future stratospheric vortex variability in the CCMI models is beyond the scope of this work, though we note that Ayarzagüena et al. (2018) find little future change in sudden warming frequency in these models."

We have elected not to include more of the new analysis in this response in the text, as results were either difficult to interpret or not statistically significant. We have added one new figure to the text that better emphasizes that dynamical coupling is far stronger than any coupling between ASO and the surface however (see below). Because this dynamical coupling is so strong, trying to find evidence for the role of chemical ozone depletion separately from that of transport is rather difficult, though there is certainly room for future work.
Reviewer #2

Suggestions for revision or reasons for rejection (will be published if the paper is accepted for final publication)

Overall, my major concerns have been addressed and I recommend publication. I do have a few very minor comments/edits that the authors might address.

Page 5, Line 24: I don’t understand which part of this is named after the developers, or why it matters?

**Fixed. The reason it matters is that PC could also stand for partial correlation as in step 2, but in this case it does not.**

Page 5, Line 31: put a space between Linear and Mediation

**Fixed.**

Figure 2: note that some of the negative contours are not filled in and it would visually look better to fully saturate those colors.
Page 6, Line 14 and lines 31-32 are repetitive

We elected to leave the text as is.

Page 8, line 13-14: doesn't this speak more to non-stationarity than non-linearities?

We removed "nonlinear". The key point is that the connection between vortex variability and surface climate is stronger in the absence of ODS. We have revised the text accordingly.

Page 8, 17: not clear which relationship you are talking about here- ASO on surface climate?

Fixed.
Influence of Arctic Stratospheric Ozone on Surface Climate in CCMI models

Abstract. The Northern Hemisphere and tropical circulation response to interannual variability in Arctic stratospheric ozone is analyzed in a set of the latest model simulations archived for the Chemistry-Climate Model Initiative (CCMI) project. All models simulate a connection between ozone variability and temperature/geopotential height in the lower stratosphere similar to that observed. A connection between Arctic ozone variability and polar cap surface air pressure is also found, but additional statistical analysis suggests that it is mediated by the dynamical variability that typically drives the anomalous ozone concentrations. While the CCMI models also show a connection between Arctic stratospheric ozone and the El Niño Southern Oscillation (ENSO), with Arctic stratospheric ozone variability leading to ENSO variability one to two years later, this relationship in the models is much weaker than observed and is likely related to ENSO autocorrelation rather than any forced response to ozone. Overall, Arctic stratospheric ozone is related to lower stratospheric variability. Arctic stratospheric ozone may also influence the surface in both polar and tropical latitudes, though ozone is likely not the proximate cause of these impacts and these impacts can be masked by internal variability if data is only available for ∼ 40 years.

1 Introduction

The stratospheric ozone layer not only protects life on Earth from solar ultraviolet radiation but also controls stratospheric temperature, which in turn affects tropospheric weather and climate (World Meteorological Organization, 2014). Stratospheric ozone was increasingly depleted in the last few decades of the twentieth century over many regions of the globe and is not expected to fully recover for many decades (World Meteorological Organization, 2014). Arctic stratospheric ozone (ASO) has been relatively spared from the worst ozone destruction due to the relatively stronger wave forcing from the troposphere leading to relatively warm temperatures as compared to the Antarctic, though during some winters, depletion has been observed (Staehelin et al., 2001) comparable to that in the Antarctic (e.g., March of 2011, Manney et al., 2011). It is well established
that ozone depletion in the Antarctic stratosphere affects surface climate (Polvani et al., 2011; Waugh et al., 2015), though a clear link between Arctic ozone depletion and surface climate has not yet been conclusively established.

Recent modeling studies have examined the possible connection between Arctic spring ozone and surface climate using a range of approaches, and obtained mixed results. Cheung et al. (2014) investigated whether the extreme Arctic ozone depletion of 2011 had an effect on tropospheric climate with the UK Met Office operational weather forecasting model, and found similar spring tropospheric forecast skill when forcing the model with more realistic ozone concentrations or with climatological ozone. Karpechko et al. (2014) found a connection between the 2011 low Arctic stratospheric ozone anomalies with tropospheric climate in atmospheric GCM simulations, but the connection was only robust if ozone anomalies are imposed together with sea surface temperature anomalies. They argue that the stratospheric response to reduced ozone is too weak if the anomalous tropospheric wave driving that initially led to the strong vortex is not also included, such that the radiative perturbation due to ozone requires feedbacks in order to robustly modulate surface climate (e.g., Kirchner and Peters, 2003). Smith and Polvani (2014) found that only for a prescribed ozone forcing larger than that historically observed is the tropospheric response robust in their simulations. In contrast, the coupled chemistry-climate simulations of Calvo et al. (2015) include a robust stratospheric-tropospheric response in low versus high ozone years if ozone depleting substance concentrations (ODS) follow those from 1985-2005: a positive phase of the North Atlantic Oscillation, a poleward shift of the North Atlantic tropospheric jet, and corresponding regional surface temperature anomalies. Downward coupling is not evident in the period 1955-1975 when ODS concentrations were lower, and they argue that the enhanced ODS concentrations led to enhanced dynamical variability of the vortex and thus to stronger downward coupling. The fully-coupled approach of Calvo et al. (2015) allows consistency between the evolving ozone distributions and dynamical conditions among other differences in the model configuration, which may explain the differences between their conclusions and those of studies prescribing ozone concentrations. However, there is some ambiguity in the approach of Calvo et al. (2015) as to whether the surface anomalies are due exclusively to chemical depletion of ozone: ozone anomalies are usually accompanied by anomalies in the Arctic vortex (i.e., early or delayed breakup of the Arctic vortex for high ozone or low ozone respectively, Hurwitz et al., 2011) and vortex anomalies independent of ozone have been shown to influence surface conditions (Black and McDaniel, 2007; Ayarzagüena and Serrano, 2009; Hardiman et al., 2011). Hence the degree to which the surface anomalies found by Calvo et al. (2015) are related to chemical ozone depletion rather than the altered dynamical state of the vortex which also affects ozone concentrations is ambiguous.

Observational studies have also suggested that interannual variability in ozone affects surface climate. Ivy et al. (2017) find that extreme Arctic stratospheric ozone (ASO) anomalies in March are associated with Northern Hemisphere tropospheric climate in spring (March-April) in specific regions of the Northern Hemisphere, with the effects generally consistent with the modeling study of Calvo et al. (2015). However, a delayed or advanced final warming of the Arctic vortex can lead to some of the surface impacts found by Ivy et al. (2017) (e.g., Black and McDaniel, 2007; Ayarzagüena and Serrano, 2009; Hardiman et al., 2011), and it is not clear whether the surface response is due to the dynamical impact from the final warming as opposed to the radiative impact of the ozone anomaly that typically accompanies a final warming. Finally, Xie et al. (2016) suggest that ASO anomalies influence sea level pressure anomalies over the North Pacific which in turn modulates subtropical
sea surface temperatures. This subtropical sea surface temperature anomaly might then lead to improved predictability of the El Niño Southern Oscillation, though this response is delayed by a year for reasons not yet clear (Garfinkel, 2017).

Overall, the very recent 2018 WMO Ozone Assessment Executive Summary appendix states that “there are indications that occurrences of extremely low springtime ozone amounts in the Arctic may have short-term effects on Northern Hemisphere regional surface climate” (World Meteorological Organization, 2018), and the goal of this paper is to explore the robustness of these indications. Specifically, we revisit the connection between boreal spring Arctic stratospheric ozone variability on interannual timescales and surface climate using the coupled ocean-atmosphere-chemistry models participating in the Chemistry-Climate Model Initiative (CCMI) project. We analyze ~1722 model-years of output data, which helps provide context for the associations evident in the relatively short observational record and in previous modeling studies which analyzed shorter simulations. The CCMI project is the first multi-model project in which many atmosphere-chemistry models were coupled to an interactive ocean, and hence the downward coupling in oceanic regions can be explored for the first time in a multi-model framework. We demonstrate that while Arctic ozone does appear to be associated with surface variability, the connection is largely associated with the dynamical control of ozone in the lower stratosphere by the polar vortex. In addition, while Arctic ozone does appear to influence ENSO for up to two years later, this association is much weaker than that observed and likely is associated with ENSO autocorrelation. Overall, while Arctic stratospheric ozone may lead to surface impacts, these impacts are generally weak and can be masked by internal variability if data is only available for ~ 40 years.

2 Data and Methods

2.1 Data

We analyze the Modern-Era Retrospective analysis for Research and Applications reanalysis (MERRA Rienecker et al., 2011), the merged ozone product from SWOOSH v2.6 from 1984 through 2014 (Davis et al., 2016), and output from atmospheric chemistry-climate-ocean general circulation models (CCMs) participating in the CCMI project. Full details of the satellite observations underlying SWOOSH and the interpolation scheme used can be found in Davis et al. (2016); here we use the combined eqfillanomfillo3q product at 2.5 degree resolution with 31 vertical levels.

CCMI was jointly launched by the Stratosphere-troposphere Processes And their Role in Climate (SPARC) and the International Global Atmospheric Chemistry (IGAC) to better understand chemistry-climate interactions in the recent past and future climate (Eyring et al., 2013; Morgenstern et al., 2017). This modeling effort is an extension of CCMVal2 (SPARC-CCMVal, 2010), but utilizes up-to-date CCMs that also include tropospheric chemistry. The CCMI models used in this study are listed in Table 1. We consider the Ref-C2 simulations from models that are coupled to an interactive ocean and have uploaded their data to the British Antarctic Data Center server, and we also include the National Center for Atmospheric Research (NCAR) models (Morgenstern et al., 2017). Full details of the Ref-C2 simulations are described in Eyring et al. (2013); briefly, these simulations span the period 1960–2100, impose ozone depleting substances as in World Meteorological Organization (2011), and impose greenhouse gases other than ozone depleting substances as in RCP 6.0 Meinshausen et al. (2011). As we are interested in the surface impact of ozone anomalies over both land and ocean areas, we consider coupled ocean-atmosphere models
only where surface impacts can occur in a self-consistent manner with the stratospheric ozone variability. In contrast, nearly all of the CCMVal2 models imposed sea surface temperatures (Morgenstern et al., 2010). The standard deviation of surface temperature variability in the Nino3.4 region for the models is shown in Figure 1, and the amount of variability in all models considered here is within 50% of that observed. One additional CCMI model included a coupled ocean (CHASER), however the ENSO in this model is too weak: the standard deviation of the Nino3.4 index in this model is 0.2 Kelvin as compared to the observed value of 0.85 Kelvin, and we therefore exclude it from this paper. Finally, we have examined the power spectral density for surface temperature in the Nino3.4 region in these models, and in all cases there is a peak between 2 and 5 years in general agreement with observations (not shown).

### 2.2 Methods

This study focuses on the impact of ASO on the troposphere on interannual timescales, and in order to remove any impacts on longer timescales due to climate change or ozone depleting substances, we first use multiple linear regression to remove the linear variability associated with greenhouse gases and ozone depleting substances from all time series (i.e., the same regression is applied to ozone, surface pressure, temperature, and polar cap heights). We use the equivalent CO$_2$ from the RCP6.0 scenario to track greenhouse gas concentrations (Meinshausen et al., 2011) and the effective equivalent stratospheric chlorine (EESC) following Newman et al. (2007, Eq.1, assuming a 5.5yr age-spectrum) to track ozone depleting substances on multi-decadal timescales. For consistency, this same multiple linear regression procedure is applied to MERRA/SWOOSH data.

Most models used in this study archive data over a period of 140 years, while the observational record available in either MERRA or SWOOSH extends for less than 40 years. To allow for a more natural comparison of model output to observations...
we first perform the multiple linear regression as described above, and then divide the output from the CCMI models into periods of 41 years, to more closely match the data availability of MERRA/SWOOSH. Specifically, we divide the data of each of the CCMI models into three time periods: 1970-2010, 2011-2051, 2052-2092. The net effect is that we have 42 model-chunks of identical size (41 years) that we can meaningfully compare to observations (3 periods and 14 models). For each data source we analyze the variables: temperature, geopotential height, surface air pressure, and the zonal mean ozone volume mixing ratio.

We define a zonal mean index of Arctic stratospheric ozone (ASO) following Xie et al. (2016) as the area-weighted average of zonal mean ozone from 60°N to 81.25°N and mass-weighted from 150hPa to 50hPa. The poleward limit of the region used to define ASO is set at 81.25°N to match the data available from SWOOSH. For ENSO we use surface air temperature in the region bounded by 5°S-5°N and 190°E-240°E (i.e., the Nino3.4 region), as sea surface temperature was not available for all models at the time we downloaded the data. Note that the observed negative correlation between ENSO and ASO at a lag of 20 months is essentially unchanged if we use air temperature as opposed to sea surface temperature.

The statistical significance of the correlation between two auto-correlated time series is computed using the two-tailed Student’s t-test at the 95% confidence level: The effective number of degrees of freedom \( N_{eff} \) used in the Student’s-t test is approximated following Pyper and Peterman (1998), Li et al. (2013), and Li et al. (2012):

\[
N_{eff} = \frac{1}{N} + \frac{2}{N} \times \sum_{j=1}^{N/4} \frac{N-j}{N} \times \rho_{xx}(j) \times \rho_{yy}(j)
\]  

(1)

where \( N \) is the sample size, and \( \rho_{xx} \) and \( \rho_{yy} \) are the auto-correlation vectors of ENSO and ASO. The summation in equation 1 is performed up to \( N/4 \) following the recommendations of Pyper and Peterman (1998). In addition, Pyper and Peterman (1998) find that substituting \( N_{eff} \) with \( N_{eff} - 2 \) provided a better balance between estimates of \( N_{eff} \) and error rates, thus improving the validity of the student’s t-test.

In order to assess the causality of the surface impacts contemporaneous with and following ASO anomalies, we form a causal effect network following Pearl causality (Pearl, 2000). The relative benefits and drawbacks of Pearl causality and Granger causality are discussed in Runge et al. (2017) and Samarasinghe et al. (2018). For our particular application we are interested in evaluating whether ASO or dynamical variability (which we track using area-weighted geopotential height from 80N to the pole at 100hPa, i.e., Zpole) leads to ENSO variability with leads of 10 to 27 months, i.e., whether ENSO has parents.

The causal effect networks analysis is based on a two-step algorithm. The first step is the PC algorithm (named after its developers, Peter Spirtes and Clark Glymour; Spirtes and Glymour, 1991), which is used to find the “parents” of ENSO from 10 to 27 months prior, with a null hypothesis that ENSO has no parents. The significance threshold used is \( \alpha = 0.05 \) (not the same \( \alpha \) used in the t test - Runge et al. (2017)) and maximum combinations of conditions (i.e., \( q_{max} \)) is set to 10. The PC step starts by initializing the preliminary parents \( P(X^t_j) = (X_{t-1}, X_{t-2}, ..., X_{t-\tau_{max}}) \) (where \( X \) includes the timeseries of ENSO, ASO, and Zpole) and iteratively removes variables \( X^t_{t-\tau} \) that do not pass the accepted significance threshold \( \alpha \). It is tested again for different combinations of parents until the algorithm converges for a link \( X_{t-\tau} \rightarrow X^t_j \) and the null hypothesis is rejected.
The second step of the algorithm is to evaluate the parents’ causality strength, which is done with two different methods in order to assess robustness: MCI and Linear Mediation (Runge et al., 2015, 2017). The MCI step is based on partial correlations, and specifically calculates the correlation between ENSO and each of its parents after regressing out the influence of all other parents identified from the PC step. The statistical significance of the partial correlation result is tested with a two-tailed t test with \( \alpha = 0.05 \) (Runge et al., 2017). The Linear Mediation procedure as implemented here forms a multiple linear regression for ENSO using the parents identified in the PC step as regressors (Runge et al., 2015). In this step there is no statistical threshold. Thus, we get a score for all the parenting candidates and the coefficients of the multiple-linear regression procedure indicate the relative importance of each parent.

Full details of the algorithm are described in Runge et al. (2017) and a Python implementation of the algorithm as used in this study is the freely downloadable TIGRAMITE version 3.0 (https://jakobrunge.github.io/tigramite/). From the above-mentioned Python package we use two main functions: PCMCI and LinearMediation, the latter of which enables us to test sensitivity of the PCMCI results.

3 Effect of Arctic stratospheric ozone (ASO) on polar surface climate

We first consider the connection between ASO and zonally averaged temperature and geopotential height (Figure 2ab) in MERRA and SWOOSH data. Higher values of ASO are associated with elevated geopotential height and warmer temperature over the polar lower and mid-stratosphere, and lower geopotential heights and colder temperatures in the tropical lower and mid-stratosphere in reanalysis data (Figures 2ab). This effect is consistent with previous work that has shown that transport controls lower stratospheric ozone concentrations (Douglass et al., 1985; Hartmann, 1981; Rood and Douglass, 1985; Hartmann and Garcia, 1979; Silverman et al., 2017).

The CCMI ensemble-mean (i.e., the mean of all 42 sub-models) correlation between March ASO and March geopotential height and temperature is shown in Figure 3. The CCMI models capture the connection between the two phenomena, and the magnitude is similar to that observed though somewhat weaker in the lower stratosphere. In order to more meaningfully compare the relatively short observational record to the model output, we divide the model output into 41 year chunks (see section 2), and focus on coupling of ASO with polar cap 100hPa geopotential height and temperature in Figure 4a. The x-axis of Figure 4a shows the correlation of ASO with 100hPa polar cap temperature. The reanalysis is indicated with a yellow asterisk, the CCMI multi-model mean with a large black x, and each 41-year chunk of each model is indicated with a single x. In March, the multi-model mean correlation is weaker than that observed, but individual models simulate a tighter coupling than that observed. Strikingly, a different 41 year subsample of the same model can alternately simulate essentially no coupling of ASO with lower stratospheric temperatures (the ’x’es near the bottom left of the distribution) or coupling that is similar in magnitude to that observed. The y-axis of Figure 4a shows the correlation of ASO with 100hPa geopotential height in March. Models with a tighter connection between ASO and polar cap temperatures also feature a tighter connection between ASO and polar cap geopotential height, and the connection in reanalysis data falls well within that simulated by CCMI models. Results are similar for April as well (Figure 4b). This validates the fidelity of the coupling between these phenomena in the
CCMI models. It is beyond the scope of this paper (which focuses on monthly mean data) to determine the dominant direction of causality, though process-driven studies of observational data have indicated that lower stratospheric ASO anomalies are driven by transport (e.g., Douglass et al., 1985). Anomalous transport can occur both on large spatial scales where the same wind field that advects the ozone across the vortex barrier into the pole also leads to a warmer pole, and also on smaller scales where the causality of the connection between zonal mean temperature and ASO is less obvious. The strength of this connection is quantitatively similar for the period 1970-2010 when ODS concentrations were high and for the period 2052-2092 when imposed ODS concentrations are lower (Figure S43ab), suggesting that heterogeneous chemical ozone depletion plays a relatively minor role as compared to transport for the connection between ASO and polar vortex variability.

Does ASO affect the troposphere? Figure 6a shows the correlation of surface air pressure anomalies with ASO in March. Higher concentrations of ASO are associated with elevated surface air pressure anomalies over the polar cap and over Greenland, and with reduced surface air pressure further south in the Atlantic sector; overall the pattern resembles the negative phase of the North Atlantic Oscillation (consistent with Ivy et al., 2017, the feature over the North Pacific will be discussed in section 4). This relationship can be summarized by computing the correlation of surface air pressure anomalies area-weighted from 80N and poleward with ASO, and we show the result from MERRA and from all of the CCMI models on the x-axis of Figure 4c. The correlation in MERRA data is 0.41 (statistically significant at the 95% level), which is larger than in most, but not all, of the CCMI models. CCMI models show a stronger relationship in April instead (Figure 4d); the mean correlation across all models increases from 0.1 in March to 0.14 in April. While these correlations are statistically significant at the 95% level, the variance explained is low. Hence while the CCMI multi-model mean simulates a weaker connection between ASO and polar cap SLP in March than is observed, the observed association is enveloped by the range of CCMI models and the relationship between ASO and polar cap SLP in the CCMI models is still statistically significant at the 95% level (in agreement with Calvo et al., 2015).

What may explain the diversity in the strength of the coupling between ASO and polar cap SLP among the models? To provide a possible answer to this question, we repeat on the y-axis of Figure 4cd the correlation of ASO with polar cap height at 100hPa (the y-axis of the top row). There is a statistically significant relationship between coupling of ASO with 100hPa polar cap height and with the impact of ASO on the surface. Namely, 41-year model subsamples in which the connection between ASO and stratospheric polar cap height is stronger also simulate a stronger connection between ASO and polar cap SLP. Specifically, the correlation between these two is 0.43 in March and 0.58 in April (Figure 4cd), though clear outliers do exist. Hence the strength of the coupling between ASO and polar cap SLP is dependent on coupling between ASO and polar cap height at 100hPa. This dependence suggests that there is ambiguity as to whether ASO is indeed the proximate cause for the surface climate anomalies evident on the x-axis of Figure 4cd. Specifically, ozone anomalies are usually accompanied by anomalies in the Arctic vortex (Figure 4ab) and previous work has shown that spring Arctic vortex anomalies independent of ozone can influence surface conditions (Black and McDaniel, 2007; Ayarzagüena and Serrano, 2009; Hardiman et al., 2011). We now demonstrate that vortex anomalies are associated with polar cap SLP anomalies in the CCMI models as well, and then try to isolate statistically the relative importance of ASO.
We first show that stratospheric polar cap geopotential height and temperature are even more strongly related to tropospheric variability than ASO. The y-axis of Figure 4ef considers the correlation of 100hPa polar cap height with polar cap SLP across the CCMI models as compared to that observed. The correlation of 100hPa polar cap geopotential height with polar cap SLP is more than double the corresponding correlation of polar cap SLP with ASO for both the multi-model mean of the CCMI models (0.57 as compared to 0.1 in March, and 0.39 as compared to 0.14 in April), and for reanalysis data. Results are similar for the correlation of 100hPa polar cap geopotential temperature with polar cap SLP (on the x-axis): the correlation of ASO with polar cap SLP is also weaker than that of 100hPa polar cap temperature with polar cap SLP. This effect is highlighted visually in Figure 5, which compares 100hPa polar cap height with polar cap SLP for each model integration on the top row and ASO with polar cap SLP on the bottom row. It is clear that the connection between 100hPa geopotential height and surface conditions is far stronger than that between ASO and surface conditions.

It could well be that the apparent connection between ASO and polar cap SLP is just a byproduct of the tight connection between polar cap stratospheric geopotential height with both parameters, rather than a direct connection. We address this issue by using linear regression to statistically remove the portion of polar cap SLP variability and ASO variability that is linearly related to stratospheric polar cap geopotential height for each model, and then consider whether there remains any lingering connection between ASO and polar cap SLP. The results are displayed on the x-axis of the bottom row of Figure 4. The correlation of ASO with polar cap SLP is now negative both for most CCMI models and also for observations - high ozone is associated with lower heights over the pole - opposite of the relationship when Z was not regressed out. This statistical argument indicates that there is no distinct pathway whereby ASO affects the polar troposphere, but rather it affects the polar troposphere through its coupling to the dynamics of the lower stratospheric polar vortex.

The bottom row of Figure 4 uses linear techniques to deduce that any influence of ASO on surface climate is mediated through the dynamics of the lower stratospheric polar vortex; however, there could be feedbacks between ASO, the lower stratospheric polar vortex, and surface climate. For example, the x-axis of Figure 7 shows the correlation between polar cap temperature and polar cap surface pressure for the period 1970-2010 in blue, for the period 2011-2051 in green, and for the period 2052-2092 in red. The correlation between polar cap temperature and surface conditions is stronger in the future when ODS concentrations are minimal and heterogeneous chemical ozone depletion less common (among other changes in the climate). Similar results are found for the correlation of polar cap geopotential height and polar cap surface pressure (y axis), and also for the upper troposphere (not shown). Indeed, the correlation of ASO with polar cap surface pressure is also marginally higher in a future with low ODS concentrations than in the historical period (Figure 5), further suggesting that heterogeneous chemical ozone depletion is not a crucial factor for a strong downward impact. We leave for future work an explanation for this relationship.

### 4 Effect of Arctic stratospheric ozone (ASO) on ENSO

Xie et al. (2016) recently suggested that Arctic stratospheric ozone anomalies influence North Pacific sea level pressure anomalies which in turn affects subtropical sea surface temperatures, and the subtropical sea surface temperature anomalies modulate...
ENSO through the seasonal footprinting mechanism approximately 20 months later. Their conclusions were based on the limited observational record and model experiments with one model, and we now consider whether CCMI models capture this association in order to assess the robustness of this effect. The CCMI models included in our study contain both ozone variability and an internally generated ENSO (Figure 1), hence they are the first multi-model ensemble which simulates the relevant underlying processes.

We begin with the lagged-correlation of ASO and ENSO for lags ranging between -40 to 40 months using MERRA/SWOOSH data (figure 8a) following Xie et al. (2016) in order to establish context for the CCMI models. ENSO is positively correlated with ASO seven months later (at lag equal to -7), such that e.g., El Niño leads to more ozone seven months later. The more robust relationship is a negative correlation between ASO and ENSO 20 months later (at lag equal to 20) such that e.g., more ASO leads to a La Niña 20 months later, though this relationship is not statistically significant at the 95% level using a two-tailed Student’s t-test. Xie et al. (2016) noted that the strongest observed connection between ASO and ENSO is March ASO with ENSO 20 months later, and hence we show the lagged-correlation between March ASO and ENSO in figure 8b. The correlation of ENSO in January with ASO two months later in March is 0.2, and the correlation of ASO in March with ENSO ~18 months later is nearly -0.5. All of these relationships are in agreement with Xie et al. (2016), though we find that this relationship is slightly less statistically significant than Xie et al. (2016).

Do the CCMI models capture these relationships between ASO and ENSO? We first focus on the multi-model mean lagged correlation between ENSO and ASO in Figure 9. The lagged-correlation function between ASO and ENSO reveals the same general lead/lag behavior as seen in the MERRA/SWOOSH model but generally with much weaker correlations. The positive correlation at lag=-4 (Figure 9a) exceeds 0.1, corresponding to El Niño leading to enhanced ASO after 4 months, and this effect is highly statistically significant and is consistent with that found in CCMVal models (Cagnazzo et al., 2009). Hence the models are able to capture the forcing of ASO anomalies by ENSO, with El Niño leading to enhanced ASO and La Niña leading to reduced ozone (Cagnazzo et al., 2009).

The lagged-correlation also contains a negative peak at a lag of +10 months, and statistical significance is maintained from a lag of 6 months up to a lag of 22 months. This result is in agreement with the feature seen in MERRA/SWOOSH and Xie et al. (2016). However the correlation at positive lags in the multi-model mean is a factor of five weaker than that observed; furthermore, the correlation is strongest not 20 months after the ASO anomalies, but rather 10 months later. We have also computed the correlation coefficients between March ASO and ENSO in order to focus on the season where the observed relationship peaks (Figure 9b). A statistically significant negative correlation is found when ASO lead ENSO by 8-14 months. An additional, smaller yet also statistically significant, negative local peak is obtained at a lag of 20 month (at Nov(1) on Figure 9b), qualitatively in agreement with the observed relationship but much weaker in magnitude.

The multi-model mean lagged-correlations differ from that observed in two aspects: they are weaker and also peak at earlier lags. This does not necessarily imply that the models are inconsistent with the observed effect, as some models do show a relationship that resembles that observed. To highlight this effect, we compare adjacent 41 year sub-samples for a given model. The results are shown in the bottom four rows of Figure 8. Figure 8cegi is constructed analogously to Figure 9, but it focuses on two different 41 year sub-samples from the same integration for two models. These two sub-samples indicate an opposite
lead/lag relationship between ENSO and ASO between adjacent sub-samples for the same integration. For example, WACCM run #3 over the years 2011-2051 indicates a similar lead-lag relationship as the one observed in MERRA/SWOOSH (figure 8c). Yet, over the years 2052-2092 (Figure 8e), the exact same model integration suggests that any apparent modulation of ENSO by ASO is weak and only appears at much shorter lags. Another example for the intra-model variability is evident in the results of the NIWA-R3 model (Figure 8gi). NIWA-R3 simulates a lead-lag relationship that does not resemble the observed one over the years 2011-2051, whereas for the years 2052-2092 the lead/lag relationship shows some similarities. Thus, these two sub-samples of the same model are different from each other and therefore gives different results when comparing to MERRA/SWOOSH. Similar results are evident if we focus on the lagged correlation of March ASO with ENSO (right column of Figure 8).

The model spread in the connection of ASO with ENSO 10-20 months later does not appear to be associated with stratospheric dynamical or temperature variability, as e.g., the correlation between ASO and stratospheric temperature and geopotential height is qualitatively similar in these experiments. Specifically, these specific sub-samples from WACCM (compare Figures 2cd to Figures 2ef) and NIWA (compare Figures 2gh to Figures 2ij) both show a positive correlation between ASO and polar cap geopotential and temperature. Hence internal tropospheric or oceanic variability appears to be the source of the difference in the connection between ASO and ENSO. That internal tropospheric or oceanic variability can mask the connection between ASO and ENSO over a 41 year period suggests that the observational polar ozone record is too short to reach firm conclusions as to the connection between ENSO and ASO. More specifically, it is possible that internal climate variability could have contributed to the apparent observed effect. The possible role of internal variability can be reduced as much as possible by computing the multi-model mean of the correlations (by averaging over all lagged-correlation coefficients), and as discussed above the multi-model mean correlation is much weaker and peaks sooner than that observed.

Xie et al. (2016) propose a specific mechanism between ASO and ENSO, and we now evaluate whether this mechanism is operating in the CCMI models. Specifically, they argue that higher ASO leads to higher SLP over the North Pacific in March and April (red box on Figure 6ab), which directly leads to warmer sea surface temperatures in the subtropical North Pacific (red box on Figure 6c) as the cold continental winds off Eurasia are weakened. This warming of the subtropical North Pacific then leads to a La Niña event due to the seasonal footprinting mechanism (Vimont et al., 2003). It is difficult to deduce any evidence for these effects in the multi-model mean surface pressure and sea surface temperature response (Figure 10), though the multi-model mean correlation between ASO and ENSO was also weak. Even if we focus on the model sub-samples that did succeed in capturing a relationship between ASO and ENSO (e.g., WACCM run #3 for the years 2011-2051 and NIWA-R3 over the years 2052-2092), there is no better agreement with the observed SLP and surface temperature anomalies than in the model sub-samples that failed to capture the observed relationship between ASO and ENSO (Figure 6). The correlation between April surface temperature in the red boxed region of Figure 6c with March ASO averaged across all CCMI models is 0.02, and while individual model sub-samples simulate correlations as large as the observed correlation of 0.3, there is no significant relationship between the models that simulate greater warming in this region in response to enhanced ASO and the relationship between ASO and ENSO 20 months later. Hence there is no evidence that the mechanism of Xie et al. (2016) is present in the CCMI models.
One might hypothesize that the apparent relationship between ASO and ENSO ∼ 20 months later is driven by the autocorrelation of ENSO: El Niño (which typically drives higher ASO) is often followed by a La Niña event a year or two later, and one might therefore suppose that the La Niña event 20 months after the high values of ASO is due to internal oceanic ENSO dynamics and does not involve the stratosphere (e.g., Garfinkel, 2017).

We test this hypothesis using Pearl causality as described in Section 2.2; briefly, we test whether ENSO has a “parent” ASO. The results of the causality test are shown in Figure 11, a heat map of parents of ENSO where only statistically significant parents are indicated. Figure 11a shows results for the PCMCI algorithm, and Figure 11b shows results for the Linear mediation algorithm (see section 2.2).

For the observational data (i.e., SWOOSH 1984-2014) we can see that ENSO has two parents: ASO 20 and 22 month prior to ENSO. This connection is obtained from both MCI and Linear Mediation, and it is a negative connection. This result is in agreement with both Xie et al. (2016) and our correlation results (Figure 8a), albeit with lower regression coefficients and correlations: for the MCI step we get a score of -0.17 for ASO(-20) and -0.19 for ASO(-22), and in the linear mediation -0.21 for ASO(-20) and -0.22 for ASO(-22). These regression coefficients are lower than the simple lag-correlation of ENSO with ASO (-0.32 in our study and -0.35 in Xie et al. (2016), both for ASO (-20)).

In the CCMI ensemble, ASO is not a parent of ENSO over the historical period for any model for lags near -20 (and in fact is a parent with the opposite sign in one model). In contrast, ENSO(-10) is a parent for half of the models, and for these models both the MCI step and the linear mediation give similar results. For later time periods, ASO is a parent of ENSO for some models for lags near -20, such that the observed relationship between ASO(-20) and ENSO is simulated on occasion, though in other models ENSO(-10) is a more important parent. Hence over the period 2011 through 2092 the tendency noted by Xie et al. (2016) is evident in some of the CCMI models, though the magnitude of the connection is much weaker than observed.

The association between ASO and ENSO in the CCMI models does not appear to be related to dynamical changes in the Arctic vortex. The red lines in Figure 8b and Figure 9b indicate the lagged correlation between March 100hPa polar cap geopotential height and ENSO. El Niño is associated with higher March geopotential height at zero lag in the CCMI models (though not in observations over this time period; Hu et al., 2017; Domeisen et al., 2019; Garfinkel et al., in press), but there is no indication that higher geopotential height (typically associated with high values of ASO) leads to La Niña a year later. Furthermore, Zpole is not a parent of ENSO for any lead between 10 months and 27 months in observations, and is also not a parent for most models either. (Recall that polar cap SLP is more strongly affected by polar cap geopotential height than ASO.)

Overall, the CCMI models do show a tendency of ASO variability to lead ENSO variability, but the effect is much weaker than that observed. This does not imply that the models are inconsistent with observations, as individual models do capture associations as strong as that observed. Rather, internal climate variability could be contributing to the apparent observed connection between ASO and ENSO.
5 Conclusions

The effects of Antarctic stratospheric ozone depletion on surface climate are well studied and have been shown to play a dominant role in recent trends of Southern Hemisphere surface climate (Polvani et al., 2011; World Meteorological Organization, 2014; Waugh et al., 2015). While trends in Arctic stratospheric ozone (ASO) are weak, interannual variability in the Arctic is larger than in the Antarctic. However, the tropospheric impacts of this interannual variability in the Arctic stratospheric ozone layer have proven difficult to isolate, with different studies reaching opposite conclusions. Here we use the CCMI models to establish context for the observed connection between interannual ASO changes and polar tropospheric variability and ENSO. We focus on the CCMI models for two main reasons: First, ~1722 model-years of output data are available, which helps provide context for the associations evident in the relatively short observational record and in previous modeling studies which analyzed shorter simulations. Second, the CCMI project is the first multi-model project in which many atmospheric models were coupled to an interactive ocean and chemistry, and hence the downward coupling in oceanic regions can occur in a physically meaningful manner.

Increased Arctic stratospheric ozone is associated with an increase in both polar cap temperatures and geopotential height over the polar lower and mid-stratosphere, in the CCMI models. Models with a stronger connection between ASO and polar cap temperatures also tend to simulate a stronger connection between the ASO and polar cap geopotential height. The strength of the connection between ASO and polar stratospheric temperature and height in the CCMI models straddles the strength of the observed connection between ASO and polar stratospheric temperatures and heights, suggesting that there is no discrepancy between the models and the observations.

ASO was also found to be significantly correlated with polar cap surface pressure anomalies, in agreement with Calvo et al. (2015). However these correlations are weak in the multi-model mean, and hence ASO may not be particularly useful for prediction of surface climate. Furthermore, the proximate cause of this surface impact is ambiguous as polar cap height anomalies can also lead to surface impacts. In fact, the association between polar cap surface pressure anomalies and 100hPa polar cap geopotential height is stronger than that between polar cap surface pressure anomalies and ASO, and if we regress out from polar cap surface pressure anomalies any linear influence associated with 100hPa polar cap geopotential height, then there is no apparent relationship with ASO. This suggests that there is no distinct effect of ASO on the polar troposphere per se, and rather the connection between ASO and tropospheric variability is mediated through its covariability with the Arctic stratospheric vortex. The presence of realistic coupling between ozone and wind/temperature fields may account for the difference in conclusion between the study of Calvo et al. (2015) - who find a robust connection between ASO and the surface in a model which simulates ozone-dynamics interactions - and those of Cheung et al. (2014), Karpechko et al. (2014), and Smith and Polvani (2014) who find little tropospheric response to a fixed ozone perturbation decoupled from the dynamics in the stratosphere.

Enhanced ASO appears to lead to La Niña 10 to 20 months later in observations (in agreement with Xie et al. (2016)) and in the CCMI models, though the association in the CCMI models is much weaker than that observed, strongest at earlier lags, and likely associated with the autocorrelation of ENSO and not actually forced by ASO per se. Furthermore, the exact same CCMI model integration can alternately simulate an association quantitatively similar to that observed or no association.
Rather, internal climate variability can cloud any connection between ENSO and ASO when only 40 years of data are available, and much longer time-periods are needed to average over the large internal variability present. Finally, some of the observed connection of ASO with ENSO is due to autocorrelation of ENSO, as when we form a multiple linear regression to predict ENSO using ENSO at -10 months lag in addition to ASO at lags of near -20 months, the regression coefficient of ASO with ENSO drops by around one-third if ENSO autocorrelation is included.

This work raises several questions for future work. First, establishing the direction of causality between stratospheric polar cap ozone and temperature/height anomalies in the CCMI is beyond the scope of this work, as daily data is needed to resolve the key processes. However previous work has suggested that dynamical transport drives ozone anomalies in the lower stratosphere (Douglass et al. (1985), Hartmann (1981), Rood and Douglass (1985), Hartmann and Garcia (1979), Silverman et al. (2017)). Such transport occurs in large scale eddies and in polar downwelling that includes a balanced temperature perturbation, and also in smaller scale mixing across the vortex edge where the wind field and temperature field are not necessarily balanced. Second, Calvo et al. (2015) argue that chemical ozone depletion leads to a more variable vortex and specifically to more extremely strong vortex events, which in turn leads to more robust stratosphere-troposphere coupling. However we find that variability of the vortex is actually larger in the future when ODS concentrations are lower and heterogeneous chemical ozone depletion should occur less frequently. Specifically, the standard deviation averaged across all models for the period 1970-2010 is lower than for the period 2052-2092 for ASO, polar cap geopotential height, and polar cap height by 15% to 20%, and this increase in variability is driven by both more frequent positive and negative extremes (e.g. Figure 5). A thorough investigation of what drives this enhanced future stratospheric vortex variability in the CCMI models is beyond the scope of this work, though we note that Ayarzagüena et al. (2018) find little future change in sudden warming frequency in these models. Third, the robustness of the effect of ASO on ENSO is still unclear. The observed effect between them does appear robust when evaluated in the framework of Pearl causality, however the connection is not robust in the CCMI models once other potential parents of ENSO are taken into account, and hence any nonlinear impact may be missed. Fourth, it is conceivable that the range of variability in stratospheric dynamics (i.e., the NAM) may be larger if ozone is interactive than when it is not, as a similar effect appears to be present in the Southern Hemisphere (Dennison et al., 2015). Finally, the mechanism whereby polar stratospheric variability (whether dynamical or in ozone) influences the tropospheric circulation is beyond the scope of this work, though we suspect that it will be very difficult to tease out mechanisms from the CCMI models due to tropospheric feedbacks reinforcing any initial response forced by the stratosphere (Garfinkel et al., 2013; Garfinkel and Waugh, 2014; Kidston et al., 2015).

Overall, (1) there is a strong connection between ASO and lower stratospheric temperature and geopotential height, and this connection likely mediates the connection between ASO and tropospheric changes; (2) the CCMI models capture most aspects of the connections that have been found in observations though not necessarily with the same magnitude as that observed, with differences possibly due to internal variability; and (3) ASO may contain predictive information for ENSO up to two years later, but any additional skill ASO contributes is modest.
Figure 1. Standard deviation of surface temperature in the Nino3.4 region in the CCMI models. The multiple dots for NIWA, WACCM and CAM4Chem represent different integrations of the same model. The standard deviations in CHASER is much less than that observed, and hence this model was excluded from further analysis.

Author contributions. OH performed all data analysis and helped prepare the manuscript. CIG helped prepare the manuscript and provided overarching guidance and ideas. SZZ performed the Pearl Causality calculation. The other co-authors carried out the numerical experiments and provided feedback on the paper.

Figure 4. The connection between correlations of ASO anomalies and anomalies in various metrics of the stratosphere and troposphere. In each subplot the X- and Y-axis represent correlation of two measures. Each x represents a different 41 year chunk of model output, and reanalysis/observational data is represented by asterisks. The first row compares the correlation of ASO with polar cap stratospheric temperature(T) with the correlation of ASO with polar cap geopotential height(Z) in (a) March and in (b) April. The second row compares the correlations of ASO and polar cap height (Z) with ASO and polar cap surface pressure(PS). The third row compares the correlations of polar cap Z and PS with polar cap T with PS. The forth and final row is similar to the second row except that polar cap Z is regressed out.
Figure 5. A scatter plot of (y-axis) polar cap surface pressure with March (x-axis; top) polar cap geopotential height and (x-axis; bottom) Arctic stratospheric ozone. April polar cap surface pressure is used for the top row, and March polar cap surface pressure is used for the bottom row, corresponding to the month with strongest coupling. Each year of each CCMI integration is marked with a diamond. All correlations are statistically significant at the 95% level as given by a two-tailed student-t test, as are the differences in correlation between the top row and bottom row.

Figure 6. Correlation coefficient between ASO anomalies and surface pressure (PS) or surface temperature (TS) anomalies, for MERRA/SWOOSH, WACCM-R3, and NIWA-R3, where R3 indicates the third realization. The left and center columns represent the correlation between ASO and surface pressure. The region of interest discussed in section 4 is marked by the red frame, and is defined by 20-50N and 150-200W. The leftmost column shows the correlation between March ASO and March surface pressure, and the center column shows the correlation between March ASO and April surface pressure. The rightmost column shows the correlation between the March ASO anomalies and April near-surface temperature. The region of interest discussed in section 4 is marked by a red frame, and is defined by 15-40N and 130-180W. In all the plots, the black dots mark the areas in which the correlation is statistically significant at the 95% level. The contour interval is 0.065.
Figure 7. Correlation between stratospheric variability and polar cap surface pressure (PS), with simulations conducted during the period 1970-2010, 2011-2051, 2052-2092 in separate colors in (a) February, (b) March, and (c) April. For the x-axis, the correlation is conducted with polar cap temperature at 100hPa, and for the y-axis, the correlation is conducted with polar cap geopotential height at 100hPa.
Figure 8. Lagged-correlation between ASO and ENSO for (a-b) MERRA/SWOOSH, (c-f) WACCM-R3, (g-j) NIWA-R3. The left column shows the lagged-correlation for all calendar months, and the right column shows the association between March ASO of every year and ENSO of every month across all years. The green lines mark the student’s t-test 95% confidence level - correlations that exceed the upper green line or are more negative than the lower green line are statistically significant. The red line in subplot (b) represents the correlation between March polar geopotential height and ENSO.
Figure 9. As in Figure 8 but for the multi-model mean.

Figure 10. As in Figure 6 but for the Multi-model Mean.

Figure 11. Pearl Causality analysis of the parents of ENSO using the (a) PCMCI algorithm and (b) using the PC algorithm with linear mediation. See Section 2.2 for details of the algorithm. Observations are in the bottom row, and each of the CCMI models is shown separately. Parents of ENSO are shown in color, with darker shades for more robust parents.
