Abstract

Interaction of anthropogenic particles with radiation and clouds plays an important role on Arctic climate change. Mixing state of aerosols is a key parameter to influence aerosol-cloud and aerosol-radiation interaction. However, little is known on this parameter in the Arctic, preventing an accurate representation of this information in global models. Here we used transmission electron microscopy with energy-dispersive X-ray spectrometry (TEM/EDS), scanning TEM, scanning electron microscopy (SEM), nanoscale secondary ion mass spectrometry (NanoSIMS), and atomic forces microscopy (AFM) to determine the size and mixing properties of individual particles at 100nm - 10μm, with a particular focus on sulfate and carbonaceous particles. We found that non-sea salt sulfate particles with size range at 100-2000 nm were commonly coated with organic matter (OM) in summer. 20% of sulfate particles also had soot inclusions which only appeared in the organic coating. The OM coating is estimated to contribute to 63% of the particle volume on average.

Theoretical optical calculations from the Mie code suggest that absorption cross section of individual OM-coated particles significantly increased when assuming the OM coating as light-absorbing brown carbon (BrC). The microscopic observations suggest that OM modulates the mixing structure of fine Arctic sulfate particles, which may determine their hygroscopicity and optical properties.
1. Introduction

Surface temperatures are rising faster in the Arctic than the rest of the globe (IPCC, 2007). Although increased human-induced emissions of long-lived greenhouse gases are certainly one of the driving factors, air pollutants, such as aerosols and ozone, are also important contributors to climate change in the Arctic (Law and Stohl, 2007; Shindell, 2007). It is well known that aerosols from northern mid-altitude continents affect the sea ice albedo by altering the heat balance of the atmosphere and surface (Hansen and Nazarenko, 2004; Jacob et al., 2010; Shindell, 2007). These aerosols in Arctic atmosphere include sea salt, sulfate, particulate organic matter, and to a lesser extent, ammonium, nitrate, black carbon (BC) (Hara et al., 2003; Quinn et al., 2007) and mineral dust particles (Dagsson-Waldhauserova et al., 2013). Studies show black carbon (BC) in Arctic absorbs solar radiation in the atmosphere and when deposited on snow (Iziomon et al., 2006; Koch and Hansen, 2005; Sand et al., 2013; Shindell, 2007).

BC, commonly called “soot” is derived from the combustion sources such as diesel engines, residential solid fuel, and open burning (Bond et al., 2013). Some studies investigated the possible sources of these BC particles, including nature gas flaring (Qi et al., 2017) and ship emissions in the Arctic (Browse et al., 2013; Weinbruch et al., 2012) and emissions of biomass burning and fossil fuels in the northern hemisphere (Winiger et al., 2016; Xu et al., 2017). For example, Winiger et al. (2017) showed that 35% and 38% of the Arctic BC is from domestic activities and transport with minor contributions from gas flaring (6%), power plants (9%), and open fires (12%).

Recently, certain organic aerosols, referred to as brown carbon (BrC), have been recognized as an important light-absorbing carbonaceous aerosol after BC in the troposphere (Alexander et al., 2008; Andreae and Gelencser, 2006; Feng et al., 2013; Lack et al., 2012). BrC can be directly emitted from combustion sources or formed in the atmosphere via photo-chemical aging (Saleh et al., 2013; Updyke et al., 2012). More than 100 organic species were detected in the aerosols and polyacids were found to be the most abundant compound class, followed by phthalates, aromatic
acids, fatty acids, fatty alcohols, sugars/sugar alcohols, and n-alkanes (Fu et al., 2008).

Aging of secondary organic aerosols can significantly contribute to BrC during atmospheric transport (Laskin et al., 2015). Feng et al. (2013) estimated that on average, BrC accounted for 66% of total organic matter (OM) mass globally and its light absorption is about 26% of BC.

BC and BrC are often internally mixed with other non-absorbing aerosols, such as sulfate (Lack et al., 2012; Laskin et al., 2015). This internal mixing can enhance BC absorption by a factor of up to two (Bond et al., 2013) and change the activity of cloud condensation nuclei (CCN) in the Arctic atmosphere (Leck and Svensson, 2015; Martin et al., 2011). Spatial and temporal variations of aerosol composition, size distribution, and sources of Arctic aerosols were studied extensively in numerous ground-based, ship, and airborne observations (Brock et al., 2011; Burkart et al., 2017; Chang et al., 2011; Dall’Osto et al., 2017; Fu et al., 2008; Hara et al., 2003; Hegg et al., 2010; Iziomon et al., 2006; Karl et al., 2013; Lathem et al., 2013; Leck and Bigg, 2008; Leck and Svensson, 2015; Moore et al., 2011; Raatikainen et al., 2015; Wöhrnschimmel et al., 2013; Winiger et al., 2017; Zangrando et al., 2013). A few previous studies also looked at the mixing states of coarse aerosol particles in Arctic troposphere (Behrenfeldt et al., 2008; Chi et al., 2015; Geng et al., 2010; Hara et al., 2003; Leck and Svensson, 2015; Moroni et al., 2017; Raatikainen et al., 2015; Sierau et al., 2014), but those of fine non-sea salt particles, including the most important short-lived climate forcers - BC and BrC (Feng et al., 2013; Fu et al., 2008; Kirpes et al., 2018; Laskin et al., 2015; Leck and Svensson, 2015), are poorly characterized.

This lack of understanding prevents the validation of the simulation of BC and BrC aging and mixing state in current models under one of the major uncertainties (Browse et al., 2013; Samset et al., 2014; Zanatta et al., 2018).

In this study, we analyzed 21 samples collected on 7 to 23 August, 2012 in the Arctic. We used transmission electron microscopy with energy-dispersive X-ray spectrometry (TEM/EDS), scanning TEM, scanning electron microscopy (SEM), nanoscale secondary ion mass spectrometry (NanoSIMS), and atomic forces microscopy (AFM) to determine the size and mixing properties of individual particles.
on substrate, with a particular focus on sulfate and carbonaceous particles. The results are discussed in the context of aerosol-radiation and cloud interaction.

2. Experimental section

2.1 Field campaign

The Svalbard archipelago includes all landmasses between 74 and 81 degrees North and 10 and 35 degrees East. The islands cover 63000 km². Ny-Ålesund town is situated on the west coast of the largest island, Spitsbergen. Ny-Ålesund town is situated only 1200 km from the North Pole and represents a central platform for Arctic research. The sampling place represents remote Arctic conditions.

An individual particle sampler at Chinese Arctic Yellow River Station (78°55'N, 11°56'E) collected individual particles (Chi et al., 2015; Geng et al., 2010). The sampling site is about 2 km far away from the ZEP station (Dall’Osto et al., 2017). Two to three samples were regularly collected at 9:00, 16:00, 21:00 (local time) of each day, with a total of 46 samples between 7 and 23 August, 2012. 21 samples were analysed for TEM analysis (Table S1).

Aerosol particles were collected onto copper TEM grids coated with carbon film by a single-stage cascade impactor with a 0.5-mm-diameter jet nozzle and an air flow rate of 1.5 l min⁻¹ (Genstar Electronic Technology, China). This sampler has a collection efficiency of 50% at 200 nm and 31% at 100 nm aerodynamic diameter if the density of the particles is 2 g cm⁻³. Sampling times varied from twenty minutes to two hours in clean remote Arctic area. After collection, each sample was placed in a sealed dry plastic tube and stored in a desiccator at 20 ± 3% RH for analysis. Ambient laboratory conditions (17–23% RH and 19–21 °C) is effective at preserving individual hygroscopic aerosol particles and reducing changes that would alter samples and subsequent data interpretation (Laskina et al., 2015). The sample information was list in Table S1 that shows details of sample collection at the Arctic sampling site.

2.2 TEM measurement
Individual particle samples were examined by a JEOL JEM-2100 transmission electron microscopy operated at 200 kV with an energy-dispersive X-ray spectrometry (TEM/EDS). TEM can observe the mixing structure of different aerosol components within an individual particle on the substrate because electron beam transmit through the specimen to form an image. EDS spectra were acquired within a maximum time of 30 s to minimize potential beam damage and collect particle X-ray spectra with sufficient intensity. TEM grids are made of copper (Cu) and covered by a carbon-reinforced substrate, so Cu is excluded from the quantitative analyses of the particles. Because of the substrate contribution, C content in TEM grid coated by carbon film is overestimated in EDS spectra of individual particles.

The distribution of aerosol particles on TEM grids was not uniform, with coarser particles occurring near the center and finer particles occurring on the periphery. Therefore, to ensure that the analyzed particles were representative, five areas were chosen from the center and periphery of the sampling spot on each grid. Through a labor-intensive operation, 2002 aerosol particles with diameter < 10 µm in 21 samples were analyzed by TEM/EDS. To check composition of individual particles, EDX was manually used to obtain EDS spectra of individual particles. Because of the time-consuming in the experiment, we only checked elemental compositions of 20-30 particles. After the procedure, we can easily identify particle types (e.g., sulfate, soot, OM, and sea salts) through particle morphology in the samples (Chi et al., 2015). In total, EDS spectra of 575 particles containing sulfate, soot, or OM were manually selected and saved in the computer for elemental composition analysis. Copper (Cu) was excluded from the analyses because the TEM grids are made of Cu. Elemental mapping and line profile of individual aerosol particles were obtained from the EDX scanning operation mode of TEM (STEM) (Figure 1). Particles examined by TEM were dry at the time of observation in the vacuum of the electron microscope. In our study, the effects of water and other semi-volatile organics were not considered as they evaporate in the vacuum.

iTEM software (Olympus soft imaging solutions GmbH, Germany) is the image analysis platform for electron microscopy. In this study, it was used to manually or
automatically obtain area, perimeter, and equivalent circle diameter (ECD) of individual particles through identifying boundary of every particle in TEM images.

2.3 NanoSIMS measurement

Three samples listed in Table S1 were analyzed using a nanoscale secondary ion mass spectrometry (NanoSIMS) 50L (CAMECA Instruments, Geneviers, France) instrument after the TEM analysis. A micro-cesium source was used to generate Cs⁺ primary ions, with an impact energy of 16 kV for sample interrogation. The primary beam was stepped across the sample to produce element specific, quantitative digital images. The Cs⁺ primary ion beam was used to obtain $^{16}$O⁻, $^{12}$C$^{14}$N⁻, $^{14}$N$^{16}$O⁻, $^{32}$S⁻, $^{35}$Cl⁻, and $^{16}$O$^{23}$Na⁺ ions in this study. The NanoSIMS analysis can obtain ion mapping of particles with nanometer spatial resolution over a broad range of particle sizes (Figure S1). Because the substrate of TEM grid is carbon, CN⁻ is adopted to represent organic matters in individual particles (Chi et al., 2015; Ghosal et al., 2014). S⁻ is used to infer the presence of sulfates in individual particles (Li et al., 2017). In the three samples, the NanoSIMS obtained ion mapping of 32 sulfate particles.

2.4 SEM and AFM measurement

Because TEM could not vertically observe OM coating and sulfate core, we conducted one special experiment using a Zeiss ultra 55 scanning electron microscopy (SEM) with EDS. TEM grids was mounted onto an aluminum SEM stub and directly observed in secondary electron image mode. SEM analysis was operated at 10 kV of extra high tension (EHT) and 9.7 mm of work distance (WD). Processes such as sample moving, analysis region selection and imaging were controlled by computer. The specimen stage in SEM was tilted at the range of 0-75°, and then we vertically observed thickness of OM coating and sulfate core on the substrate. To verify vertical property of individual S-rich particles impacting on the substrate, we observed two typical samples using the SEM (Table S1).

AFM images were acquired in air with a digital nanoscope IIIa instrument operating in the tapping mode, were used to observe surface morphology of individual
aerosol particles. The tapping AFM has a cantilever and conical tip of 10 nm radius. By using AFM, a general image of the particles is taken at 10 µm full scan size, which generally includes 1-2 particles depending on the exact location. In this study, we are only interested in the sulfate-containing particles. AFM provides surface information and morphology of 17 particles but no composition. Samples were firstly quickly examined by the TEM under low magnification mode. In case, the operation roughly identified S-containing particles and didn’t damage the secondary sulfate particles under the electron. Because TEM grids have coordinates letters, we can exactly find the same particles on the substrate in AFM examined in TEM experiments. The procedures can exclude sea salt particles in the AFM image. As a result, the same samples observed by TEM were then examined in AFM to obtain 3-D image of secondary sulfate particles and their volume. Because individual particles collected in Arctic air were scattered on the substrate, we only obtained 17 effective data. After we obtained AFM images of sulfate particles, the software can provide ECD and equivalent sphere diameter (ESD) of the analyzed particles. Based on these data, we estimate one good linear correlation between ESD and ECD of sulfate particles impacting on the substrate. The value was further used to correct all the analyzed particles in TEM images (Chi et al., 2015).

2.5 Calculation of BrC optical properties

The refractive index used for the non-light-absorbing sulfate component was set to \( m=1.55 \) (Seinfeld and Pandis, 2006). The refractive index of organic matter (as BrC) is not known so we considered three scenarios: strongly absorbing (1.65-0.03i at 550 nm), moderately absorbing (1.65-0.003i at 550 nm), and non-absorbing OM (1.65 at 550 nm) (Feng et al., 2013). BHCOAT code by Bohren and Huffman (1983) was used to calculate the optical properties, including scattering cross section (SCS), absorption cross section (ACS), and single scattering albedo (SSA), assuming a core-shell structure. We firstly calculated these parameters assuming a sulfate core and OM shell structure only (ignoring some of the particles that contain soot core). We then calculated the parameters considering those particles with soot cores and shell of sulfate and OM mixture. The refractive index of BC is set to be 1.95-0.79i at 550 nm.
The refractive index of the shell was calculated from those of the OM and sulfate on basis of their volume fractions in individual particles (Bond et al., 2013).

2.6 Lagrangian particle dispersion model

In order to determine the particle origins, the lagrangian particle dispersion model FLEXPART-WRF 3.1 (Brioude et al., 2013) was used. The FLEXPART-WRF model is using meteorological parameters from WRF dynamical simulation. The domain resolution is 50×50 km with 64 vertical levels.

The FLEXPART-WRF simulations were launched in a backward mode over 10 days, with the Chinese Arctic Yellow River Station as an origin. For each simulation (one per sample), 20000 pseudo-particles were released in a small volume around the station position. Each single particle position evolution backward in time was determined by Lagrangian dispersion calculation. Based on the TEM experiments, we found that there were more S-rich with OM coating particles in the samples collected on August 11, 12, 14 and 15, 2012. Therefore, we did FLEXPART-WRF simulation of these four days. The emission intensity in the Arctic area has been also shown in Figure S2.

3. Results

3.1 Composition and sources of aerosol particles

We summarized average elemental weight and frequency of individual arctic particles derived from the TEM/EDX. The result shows that O, Na, S, and Cl in individual particles are dominant elements (Figure S3). On basis of the composition and morphology of individual particles, we classified the particles into four major groups: Na-rich (i.e. NaCl, Na₂SO₄, and NaNO₃), S-rich (i.e. ammonium sulfate and sulfuric acid), and carbonaceous (soot and organic matter (OM)). The classification criteria of different particle types and their sources have been described in a separate study (Li et al., 2016). S-rich particles representing secondary inorganic particles (e.g., SO₄²⁻, NO₃⁻, and NH₄⁺) are transformed from gaseous SO₂, NOₓ, and NH₃. OM can be divided into primary organic matter (POM) and secondary organic matter (SOM). SOM is produced from the chemical oxidation of volatile organic compounds (VOCs).
and exhibits OM-coating on S-rich particles. Na-rich particles in the marine air are from sea spray and have typical near cubic shape. Soot particles, which contain C with minor O, appear as a chain-like aggregate of carbon-bearing spheres. Our previous study well characterized aging mechanism of sea salt particles in summer Arctic air (Chi et al., 2015). In this study, we focused on S-rich, soot, and OM particles as the major none-sea salt particle (NSS-particle) in the analyzed samples, which are approximately 29% by number of all analyzed particles (Figure S4).

### 3.2 OM coating on sulfate particles

TEM observations revealed a common core-shell mixing structure in fine sulfate particles (Figure 1a). Elemental mapping of such internally mixed sulfate particles showed C signals in the coating (C map, Figure 1b) and S and O signals in the center (S and O map, Figure 1c, d). The elemental line profile of a sulfate particle also shows sulfate core and C coating (Figure S5). Furthermore, ion maps of individual particles from the NanoSIMS further exhibited $^{12}\text{C}\text{^{14}N}$ signals in the coating (red color in Figure 1e, f) and $^{32}\text{S}^-$ signals in the core (green color in Figure 1e, g). These results provide strong evidence that the coating is organic matter (OM) and the core is sulfate.

A majority of the analyzed NSS-particles have a sulfate core and OM coating (Figures 1 and 2); 20% of them also contain small soot inclusions but they only appeared in organic coating, rather than as the core mixed in sulfate (Figure 2b); In the samples collected in 12, 15, and 17 August, we also observed a few chain-like soot aggregates but with only 1.3% by number fraction in all analyzed particles (Figure S4, S6). Considering the remoteness of the sampling site, such soot particles are likely to be of local origin, including shipping and flaring (Gilgen et al., 2017; Peters et al., 2011).

16% of the analyzed sulfate particles with satellite particles (Figure 2a) were detected in 11 samples collected during 9-15 August. NanoSIMS analysis suggests that these satellite particles have strong $^{32}\text{S}^-$ (Figure 3a, c) and $^{16}\text{O}^-$ signals (Figure 3d) as well as weak $^{12}\text{C}\text{^{14}N}^-$ signals (Figure 3a, b). The CN$^-$ signal in Figure 3b suggested
that the satellite particles also contain OM. Previous studies suggested that these satellite particles are acidic sulfate (Buseck and Posfai, 1999; Iwasaka et al., 1983). Our study shows that these acidic satellites not only contain sulfuric acid but also OM or organic acids. Indeed, polyacids in Arctic aerosol particles were found to be the most abundant compound class, followed by phthalates, aromatic acids, and fatty acids (Fu et al., 2008).

AFM was used to obtain 3D image of individual secondary particles impacting on the substrate. Figure 4a shows that the secondary particles normally have smooth surface which is different from uneven surface of the Arctic fresh and aged NaCl particles (Chi et al., 2015). Furthermore, we observed particle thickness through tilting the specimen stage up to 75° in SEM. Figure 4a-b both shows that the secondary particles look like thin pancake sticking on the substrate. Furthermore, the sections of two secondary particles in the AFM images shows that the highest heights of particles are only 0.15 (green line) and 0.26 (red line) of the corresponding horizontal size (Figure 4a). As a result, S-rich core has a similar thickness as OM coating. Here we can conclude that shape of individual particles was modified when they impacted on the substrate following the airflow. Therefore, the measured ECDs of individual particles in TEM images are much larger than the real particle diameter.

To calibrate the particle diameter, we obtained volume of dry particles on the substrate and then calculated their equivalent sphere diameter (ESD) in the AFM images (Figure 4c). ESD distribution of the secondary Arctic particles displayed a peak at 340 nm, ranging from 100 nm to 2000 nm (Figure 4d). The core particles, as sulfate or soot, had a peak at 240 nm and 120 nm, respectively (Figure 4d). In the core-shell particles, we knew size in all the analyzed particles and further calculated volume of sulfate, OM, and/or soot within individual particles. We can estimate that OM on average accounted for 56% (11-100%) of the dry sulfate particle volume. Our result shows that the OM volume increases following the particle size increase (Figure S7).

4. Discussion

4.1 Mixing mechanism of organic, soot, and sulfate
Lagrangian particle dispersion modeling using the FLEXPART-WRF 3.1 showed that air masses arriving at the sampling site during our field measurement periods were likely originated from the Greenland and North America (Figure 5). Previous studies reported that air masses from North America or Greenland during the summer contain higher concentration of black carbon, OM, and sulfate (Burkart et al., 2017; Chang et al., 2011; Fu et al., 2008; Moore et al., 2011; Park et al., 2013). Indeed, there is strong emission intensity of OC and SO$_2$ around the Arctic area from emission simulation as shown in Figure S2. However, Weinbruch et al. (2012) observed soot particles when cruise ships were present in the area around Ny-Ålesund town. It is possible that soot particles on the ground base are mainly sourced from the ship emissions, although some of them may be transported long distance from out of Arctic area in the free troposphere (Figure S2).

The sulfate core-OM shell structure observed in the Arctic summer atmosphere is similar to those in the background or rural air in other places (Li et al., 2016; Moffet et al., 2013). Based on the images from electron microscopies, we can infer that OM coating thickness in the arctic atmosphere was comparable with them in rural places. During the transports, organic coatings on sulfates were considered as the secondary organic aerosols and their mass increases following particle aging and growth (Li et al., 2016; Moffet et al., 2013; Sierau et al., 2014). Normally, new particle formation events can occur in up to 51% of the days during the summer months in the Arctic atmosphere (Dall’Osto et al., 2017). On the other hand, the sulfate/OM particles with soot inclusions are probably formed in a similar way as those found elsewhere (Li et al., 2016) – e.g., soot particles may have acted as nuclei for secondary sulfate or organic uptake during their transports (Riemer et al., 2009). Similarly, Moffet et al. (2013) found that soot inclusions occurred in OM coating when OM coating on sulfates built up through photochemical activity and pollution buildup the Sacramento urban plume aged. Beside the OM coating in the Arctic particles, Leck and Svensson (2015) found some biogenic aerosols like gel-aggregate containing bacterium in ultrafine particles.

TEM images show that most of the dry internally mixed sulfate particles display
sulfate core and OM coating on the substrate (Figures 1 and 2). According to liquid-liquid phase separation (LLPS) in individual particles addressed by You et al. (2012), organic and inorganic species in these particles can keep LLPS under 90% in the Arctic atmosphere. The work also reported that LLPS can occur in the atmosphere when the O:C ratio of the OM is roughly d 0.5. The result indicates that the secondary OM in the coating might be not highly aged. Therefore, we speculate that most of secondary OM formed in Arctic instead of the upwind North America. Indeed, some studies reported that there are various sources of organic precursors during the Arctic summertime, such as biogenic VOCs from ice melting and open water (Dall’Osto et al., 2017) and anthropogenic VOCs from shipping emissions (Gilgen et al., 2017). The dependence of OM volume on particle size (Figure S4) suggests that the suspended sulfate particles are important surface for secondary OM formation.

The thick OM coating in individual particles may influence IN and CCN activities of secondary sulfate particles (Lathem et al., 2013; Martin et al., 2011). For example, some studies found that an increase in organic mass fraction in particles of a certain size would lead to a suppression of the Arctic CCN activity (Leck and Svensson, 2015; Martin et al., 2011). Moreover, OM as particle surfaces can significantly influence ice nucleation (IN) efficiencies of sulfate particles (Wang et al., 2012).

4.2 Potential impact of OM on optical properties of sulfate-containing particles

The internal mixing of soot, sulfate, and OM can change optical properties of individual particles in the atmosphere. Recent studies showed that BrC has been detected in the OM in the polluted and clean air and even in upper troposphere (Laskin et al., 2015; Wang et al., 2018). Feng et al. (2013) further calculated the contribution up to 19% of the optical absorption of the strongly absorbing BrC in global simulations which is after the absorption BC aerosols. Although we didn’t directly measure the optical absorption and BrC in the Arctic atmosphere, various colored OM (e.g. nitrated/polycyclic aromatics and phenols), referred as BrC, were
detected in the Arctic atmosphere in different seasons (Fu et al., 2008; Wöhrschtimmel et al., 2013; Zangrando et al., 2013) and in surface ice or snowpack (Browse et al., 2013; Doherty et al., 2013; Hegg et al., 2010). We also noticed that the $^{12}$C$^{14}$N$^{-}$ signal generally occurred in all analyzed OM coating in sulfate particles (Figure 1e-f) which can represent nitrogen-containing OM in the coating (Herrmann et al., 2007). The nitrogen-containing OM indicates that the OM coating could contain certain amounts of secondary BrC (Laskin et al., 2015).

To better understand optical properties of OM coating in sulfate particles, we assumed OM coating to be strongly absorbing (case 1), moderately absorbing (case 2) or non-absorbing OM (case 3) with a refractive index of 1.65-0.03i, 1.65-0.003i, and 1.65 at 550 nm according to Feng et al. (2013). Based on the size measurements shown in Figure 4, we can calculate volume of soot, sulfate, and OM within each particle. We input volume of each component and the corresponding refractive index into Mie code and then we calculated optical properties of each NSS-particle analyzed in the samples. Based on optical data statistic of 575 particles, Figure 6 shows that the OM coating is strongly absorbing BrC (referred to case Abs1), as by Feng et al. (2013), the average absorption cross section (ACS) of individual particles is estimated to be 2.67×10^{-14} \text{m}^2. This value is 8.30 times higher than the aerosol ACS (3.22×10^{-15} \text{m}^2) when assuming that the BrC is moderately absorbing (referred to case Abs2, Figure 6b). However, the scattering cross section (SCS) of individual particles only shows a small change (Figure 6a). Figure 6c also shows that the single scattering albedos (SSAs) of individual particles are 0.92, 0.99, and 1 when assuming the BrC as strongly, moderately and non-absorbing (cases SSA1 to SSA3). These results indicate whether we consider organic coating as BrC may have a significant influence on the absorption properties of individual particles. If we further consider the absorption of BC, the ACS is further enhanced by about 3.11 and 16.5 times on average for case Abs1 and Abs2. Comparisons of optical absorptions in different cases shown in Figure 6b indicate that BC in individual particles still play a role for particle optical absorption.

Current climate models estimated the radiative force of Arctic BC (Sand et al.,
2013; Shindell, 2007; Winiger et al., 2017; Zanatta et al., 2018), but none specifically considered optical properties of Arctic BrC. Our study well revealed OM coating on sulfate and soot particles and this detail microphysical complexity of aerosol particles will be useful to construct the atmospheric radiation and CCN/IN simulation in Arctic atmospheric models in the future.

5 Summary

Different individual particle techniques, such as TEM/EDS, STEM, SEM, NanoSIMS, and AFM, were applied to study S-rich, soot, and OM particles in the Arctic air in summer. These particles accounted for approximately 29% (varied 10-35% in different samples) by number of all analyzed particles in Arctic air. TEM observations revealed a common core-shell mixing structure in fine internally mixed sulfate particles. Ion maps of individual particles from the NanoSIMS further exhibited $^{12}\text{C}^{14}\text{N}$ signals in the coating and $^{32}\text{S}$ signals in the core. These results provide strong evidence that the coating is OM and the core is sulfate. 20% of them also contain small soot inclusions but they only appeared in organic coating, rather than as the core mixed in sulfate. AFM and SEM with tilted stage at 75° were used to observe vertical section of individual secondary particles impacting on the substrate. We found the secondary particles look like thin pancake sticking on the substrate, suggesting that the measured ECDs of individual particles in TEM images are much larger than the real particle diameter. In this study, we calibrated the particle diameter and calculated their ESD of individual particles. ESD distribution of the secondary Arctic particles displayed a peak at 340 nm, ranging from 100 nm to 2000 nm. The core particles, as sulfate or soot, had a peak at 240 nm and 120 nm, respectively. Furthermore, we can estimate that OM on average accounted for 63% of the dry NSS-particle volume. Based on these data, Mie code was used to calculate optical properties of internally mixed sulfate/OM particles when we considered OM as non-absorbing, moderately absorbing BrC, and strongly absorbing BrC.
Author Contributions: WL and ZS designed the study. YZ and XS collected aerosol particles. WL, HY, and JZ contributed laboratory experiments and data analysis. HY and WL performed optical calculation and wrote part of first draft. PT and MD provided the online measurement data of new particle formation and growth. JS and XZ coordinated the field campaign. All authors commented and edited the paper.

Figures Captions

Figure 1 TEM Observations of a secondary particle and NanoSIMS intensity threshold maps of an aerosol particle with sulfate core and OM coating. (a) Bright-field TEM image of an internally mixed particle; (b) elemental carbon (c) sulfur and (d) oxygen maps of the internally mixed particle shown in 1(a); (e) Overlay of $^{12}$C$^{14}$N$^{+}$ and $^{32}$S$^{-}$ ion maps in an internally mixed particle; (f) CN$^{-}$ map (g) S$^{-}$ (h) O$^{-}$ secondary ion maps. Ion maps with a set of aerosol particles were shown in Figure S1.

Figure 2 TEM images of individual particles containing sulfate, OM, and soot. (a) Low magnification TEM image showing sulfates, sulfate with OM coating, and reacted NaCl particles. (b) an internally mixed particle of sulfate and soot with OM coating (c) a particle with sulfate core and OM coating.

Figure 3 NanoSIMS intensity threshold maps of individual aerosol particles surrounded by satellite particles. (e) Overlay of $^{12}$C$^{14}$N$^{+}$ and $^{32}$S$^{-}$ ion maps of individual particles. (f) CN$^{-}$ (g) S$^{-}$ (h) O$^{-}$ maps. Four particles were indicated by white, pink, blue, and red arrows.

Figure 4 Secondary particles on the substrate. (a) 3-D AFM image of secondary sulfate particles. The colorful arrows represent particles surface properties of the particle section. (b) SEM image of S-rich with OM coating obtained from $75^\circ$ tilt of the SEM specimen stage (c) The near linear relationships between ECD and ESD based on S-rich particles with thick OM coating by Atomic force microscopy. (d) Size distribution of individual particle with OM coating and sulfate cores based on the estimated ESD diameter from TEM image. Sizes of soot particles are equal to the equivalent circle diameter.

Figure 5 FLEXPART-WRF PES on August 11, 12, 14, and 15, 2012. Black square is showing the WRF domain used to initiate the FLEXPART-WRF simulation.

Figure 6 Box-and-whisker plots showing optical parameters of all analysed particles assuming sulfate core and BrC shell (not considering soot cores in the particles) versus soot-containing particles, i.e., sulfate+BrC+soot (20%) particles. For the sulfate+BrC+soot, we assume a soot core and sulfate+BrC shell. (a) Scattering cross section (b) Absorption cross section (c) Single scattering albedo. Top to bottom makers in the box-and-whisker represent max, 99%, 75%, mean, median, 25%, 1%, min values.
