15       **Abstract:**

16        Due to excessive anthropogenic emissions, heavy aerosol pollution episodes (HPEs) often  
17        occur during winter in the Beijing-Tianjin-Hebei (BTH) area of the North China Plain. Extensive  
18        observational studies have been carried out to understand the causes of HPEs; however, few  
19        measurements of aerosol vertical fluxes exist, despite them being the key to understanding vertical  
20        aerosol mixing, specifically during weak turbulence stages in HPEs. In the winter of 2016 and the  
21        spring of 2017, based on the light propagation theory and surface-layer similarity theory, aerosol  
22        vertical mass fluxes were measured by combining large aperture scintillometer (LAS) observations,  
23        surface PM<sub>2.5</sub> and PM<sub>10</sub> mass concentrations, and meteorological observations, including  
24        temperature, relative humidity (RH), and visibility, at a rural site in Gucheng (GC), Hebei Province,  
25        and an urban site at the Chinese Academy of Meteorological Sciences (CAMS) in Beijing located  
26        100 km to the northeast. The near-ground aerosol mass flux was generally lower in winter than in  
27        spring and weaker in rural GC than in urban Beijing. This finding provides direct observational  
28        evidence from the perspective of vertical aerosol fluxes for a weakened turbulence intensity in  
29        winter and in polluted areas such as GC. The HPEs included a transport stage (TS), an accumulative  
30        stage (AS), and a removal stage (RS). During the HPEs from January 25, 2017 to January 31, 2017,  
31        in Beijing, the mean mass flux decreased by 51% from 0.0049 mg m<sup>-2</sup>s<sup>-1</sup> in RSs to 0.0024 mg m<sup>-2</sup>s<sup>-1</sup>  
32        in the TSs. During the ASs, the mean mass flux decreased further to 0.00087 mg m<sup>-2</sup>s<sup>-1</sup>, accounting  
33        for approximately 1/3 of the flux in the TSs. A similar reduction from the TSs to ASs was observed  
34        in the HPE from December 16, 2016 to December 22, 2016 in GC. The weakened mass flux  
35        indicates that the already weak turbulence would be further weakened by aerosol pollution to a  
36        certain extent, which would further facilitate aerosol accumulation.

## 37 1 Introduction

38 Recently, due to the country's rapid development of industrialization and urbanization, China  
39 has experienced heavy aerosol pollution episodes (HPEs), particularly in the Beijing, Tianjin and  
40 Hebei (BTH) region, which is one of the most polluted areas in China (Zhang et al., 2012). The  
41 HPEs often last for a long duration in the BTH region and cover a wide area, particularly in winter;  
42 they also severely reduce near-ground visibility (Lei and Wuebbles, 2013) and can have detrimental  
43 effects on public health (He et al., 2018; Cao et al., 2012). This heavy pollution weather has received  
44 extensive attention in recent years, and many observational studies have been carried out (Zhong et  
45 al., 2018a; Sun et al., 2014; Wang et al., 2015; Guo et al., 2011; Zhang et al., 2009b; Huang et al., 2014).  
46 Modelling studies have also been performed to examine the regional transport of pollutants (Wang  
47 et al., 2014) and to study the important role of large-eddy convective turbulent mixing in the vertical  
48 transfer of pollutants from a field campaign in Beijing (Li et al., 2018). However, few studies on the  
49 turbulence contribution of the aerosol transport flux in the surface layer have been conducted.

50 Ground pollutant emissions are known as the main source of aerosols in the atmosphere.  
51 However, in previous studies, no measurements of ground emissions during heavy pollution events  
52 were collected. Surface emission data are currently required for model verification and pollution  
53 predictions, and these data are primarily obtained through emission inventories (Wu et al.,  
54 2012; Bond et al., 2004). The establishment of emission inventories is primarily based on emission  
55 activity and emission factor (EF) data (Akagi et al., 2011; Lu et al., 2011; Roden et al., 2006; Zhang  
56 and Tao, 2009). Emissions data are mainly obtained from statistical yearbooks (Zhang et al., 2009a).  
57 Some studies have used fixed EFs while others have implemented dynamic EFs (Bond et al.,  
58 2004; Zhang et al., 2009a). Many factors are considered in dynamic EFs, such as the size of a city,  
59 the degree of economic development, the type of fuel, the type of technology, the consumption of a  
60 product, the control technology, and so on, as well as estimates based on actual measured  
61 meteorological parameters and aerosol parameters (Chen et al., 2015; Karvosenoja et al., 2008; Shen  
62 et al., 2013). A numerical model has also been used to estimate average fleet emission factors in  
63 typical urban conditions (Ketzel et al., 2003; Krecl et al., 2018). The error in aerosol fluxes based on  
64 the use of emission inventories is very large (Liu et al., 2017; Zheng et al., 2017). Emission  
65 inventories constructed using the EF method provide only the total emission amount of atmospheric  
66 pollutants within a region. However, the emission data should be gridded to a suitable scale for air  
67 quality modelling and pollution predictions. Thus, near-surface aerosol emission data with a higher  
68 temporal and spatial resolution are urgently needed.

69 Many methods have been used to obtain aerosol flux data. For the upward transport of aerosols  
70 near the surface layer, the aerodynamic method was adopted in the early years, and the aerosol  
71 concentration gradient at different heights was measured and then calculated based on the similarity  
72 theory of the near-surface layer or calculated by the boundary layer box model, which can be based  
73 on meteorological data (Ceburnis et al., 2016; Hourdin et al., 2015; Zhang and Li, 2014). The  
74 emission rates of bioaerosols were also estimated from spore counts and molecular tracers (Elbert  
75 et al., 2007). The abundance of microbes and meteorological data were measured, and an estimate  
76 may be derived of the sea-air exchange of microorganisms (Mayol et al., 2014).

77 With the use of instruments for measuring the number of aerosol particles during recent years  
78 (for example, the GP-WCPC3787 particle counter by TSI), the eddy covariance (EC) method has  
79 been applied, and measurements of the aerosol particle number flux have become possible. The

80 vertical transport flux of the aerosol particle number density  $F_p$  is denoted as a cross-correlation  
81 between the aerosol particle number concentration  $N'$  and the vertical wind speed  $w'$  (Ripamonti et  
82 al., 2013). Based on this principle, the vertical velocity fluctuations and the fluctuations in the  
83 aerosol particle number density can be measured. As a result, the vertical transport flux of the  
84 aerosol particle number density has been measured in many cities, such as in Toronto, Canada  
85 (Gordon et al., 2011), Stockholm, Sweden (Vogt et al., 2011b), Helsinki, Finland (Ripamonti et al.,  
86 2013), London, UK (Harrison et al., 2012), the Blodgett Forest Observatory in the United States  
87 (Farmer et al., 2011), and measurements of sea salt aerosol fluxes in northern Europe (Brooks et al.,  
88 2009; Sproson et al., 2013). These results have shown the quantitative relationship among urban  
89 aerosol fluxes, urban vehicle emissions, and meteorological conditions (Jarvi et al., 2009) and have  
90 been used to determine sea salt aerosol transport characteristics and provide further knowledge of  
91 aerosol properties (Nemitz et al., 2009). These measurements have been mainly collected in cities  
92 because of their anthropogenic contributions to aerosol emissions. These data can be used as routine  
93 model inputs. Direct eddy covariance measurements of aerosol exchanges in tropical forests, where  
94 primary biological aerosol particles represent a substantial fraction of the airborne particulate matter  
95 (Graham et al., 2003), were also performed by Ahlm et al. (2010a and 2010b) and Whitehead et al.  
96 (2010), potentially giving a proxy for microbial emissions in tropical ecosystems.

97 Although measurements of urban aerosol particle number density fluxes have been collected,  
98 the current eddy correlation method only provides fluxes for the aerosol particle number density at  
99 a point. We know that the underlying surface of a city is very complex, and thus the aerosol particle  
100 flux is not homogeneous in the horizontal. For a complex underlying surface such as a city, these  
101 point measurements are not very representative. Therefore, it is of great importance to design an  
102 aerosol flux measurement system with an accurate spatial representation.

103 The use of eddy correlation principles to measure sensible heat fluxes has been widely  
104 performed (Lee, 2004). Current sensible heat fluxes can also be obtained using a large aperture  
105 scintillometer (LAS) based on the light propagation theory and similarity theory (Zeweldi et al.,  
106 2010). This configuration makes it possible to achieve aerosol mass flux measurements using the  
107 light propagation theory and similarity theory. Recently, we measured the imaginary part of the  
108 atmospheric equivalent refractive index structure parameter based on the light propagation theory  
109 (Yuan et al., 2015). The results showed that the imaginary part of the atmospheric equivalent  
110 refractive index structure parameter is related to turbulent transport and the spatial distribution  
111 characteristics of aerosols. Experiments also showed that there is a strong correlation between the  
112 imaginary part of the atmospheric equivalent refractive index and the mass concentration of aerosol  
113 particles (Yuan et al., 2016). Thus, similar to the temperature structure parameter reflecting the  
114 sensible heat flux, the structural parameter of the imaginary part of the atmospheric equivalent  
115 refractive index can reflect the mass flux of aerosol particles. This paper attempts to measure the  
116 aerosol mass flux in the BTH area.

117 To gain a deeper understanding of the interaction between atmospheric heavy pollution and  
118 weather in the BTH region, joint observations have been carried out in the BTH region since the  
119 winter of 2016 (Zhong et al., 2018b; Zhong et al., 2018a; Wang et al., 2018; Shen et al., 2018). The  
120 observations reveal the large-scale and mesoscale transport processes of aerosols between heavy  
121 pollution episodes (HPEs) in the BTH region in the winter of 2016. Most HPEs in the BTH region  
122 are due to horizontal transport and unfavourable meteorological conditions (Zhong et al., 2018a).  
123 However, during HPEs, no research has been conducted in the BTH area on quantifying the

124 contribution of surface emissions to the concentration of pollutants. In this study, we focus on HPEs  
125 through field observations of aerosol transport based on the light propagation theory and surface  
126 similarity in the Beijing urban district and Gucheng suburban area.

127 The second section of this paper introduces the theory of aerosol vertical transport flux  
128 measurements, the third section introduces the experiment, the fourth section gives the experimental  
129 results, and finally, the conclusion and discussion are presented in the fifth section.

## 130 2 Theory and methods

131 The theory for calculating the vertical flux of aerosol particles and the theory for calculating  
132 the friction velocity and characteristic temperature using the temperature and wind profiles is  
133 presented in the following subsections.

### 134 2.1 Calculation of the aerosol mass vertical flux

135 According to the micrometeorological principle (Stull, 1988), similar to the estimation method  
136 of the sensible heat flux, the aerosol flux  $F_a$  can be obtained as follows:

$$137 \quad F_a = u_* M_* \quad (1)$$

138 where  $u_*$  is the friction velocity, which can be obtained from the temperature and wind speed  
139 profiles or directly from three-dimensional wind speed measurements; see Sec. 2.2. Prior  
140 experiments have shown that the motion characteristics of aerosol particles in the atmosphere  
141 approximate the motion of general scalars (Martensson et al. 2006; Vogt et al. 2011b). Therefore,  
142 aerosol particles can be approximated as scalars, and characteristic parameters  $M_*$  similar to the  
143 scalars can be introduced, which can be regarded as the atmospheric aerosol mass concentration  
144 scale in the surface layer and deduced from surface layer similarity theory. This approximation is  
145 similar to the surface-layer temperature scale (Stull, 1988) as follows:

$$146 \quad \frac{C_M^2 (z-d)^{2/3}}{M_*^2} = \eta(\xi) \quad (2)$$

147 where  $z$  is the measurement height,  $d$  is the zero-displacement height (Evans and De Bruin,  
148 2011; Hartogensis et al., 2003),  $\xi = (z-d)/L$  is the nondimensional stability parameter,  $L$  is the Monin-  
149 Obukhov (M-O) length and defined as  $L = \frac{\bar{T} u_*^2}{\kappa g T_*}$  (Stull, 1988),  $\bar{T}$  is the average temperature,  $T_*$   
150 is the surface-layer characteristic temperature,  $\kappa$  is the von Karman constant, which is 0.4, and  $g$  is  
151 acceleration due to gravity. The stability function ( $\eta(\xi)$ ) can be expressed as follows depending

152 on the stability condition (DeBruin et al., 1995):

$$153 \quad \eta(\xi) = a_1[1 - a_2\xi]^{-2/3} \quad (3)$$

154 for unstable conditions ( $\xi < 0$ ), and the following:

$$155 \quad \eta(\xi) = b_1[1 + b_2(\xi)^{e_1}] \quad (4)$$

156 for stable conditions ( $\xi \geq 0$ ) (Wyngaard et al., 1971).

157 In Eqs. (3) and (4),  $a_1$ ,  $a_2$ ,  $b_1$ ,  $b_2$  and  $e_1$  are constants, and different experiments have provided  
 158 different values, although the differences between these results are small. Here, we take the  
 159 parameters  $a_1=4.9$ ,  $a_2=9$ ,  $b_1=5$ , and  $b_2=0$  (DeBruin et al., 1995).

160  $C_M^2$  in Eq. (2) is the aerosol mass concentration structure parameter. We assume that the  
 161 aerosol particles in the atmosphere follow the movement of the air and satisfy the turbulent motion  
 162 law. Previous studies have shown that the particle concentration fluctuation spectra follow a ‘-5/3’  
 163 power law under unstable stratification conditions (Martensson et al., 2006; Vogt et al., 2011b), and  
 164 the velocity-concentration co-spectra follows a ‘-4/3’ power law (Martensson et al., 2006; Vogt et  
 165 al., 2011a; Kaimal et al., 1972). Thus, the distribution of small particles can be considered as a  
 166 conservative passive quantity analogous to the temperature. Then, at a separation ( $r$ ) of the order in  
 167 the inertial subrange in a locally isotropic field, the aerosol mass concentration (denoted as  $M_a$ )  
 168 structure function ( $D_M(r)$ ) follows a “2/3 law” (Wyngaard, 2010) and can be expressed as  
 169  $D_M(r) = \overline{[M_a(\mathbf{x}) - M_a(\mathbf{x} + \mathbf{r})]^2} = C_M^2 r^{2/3}$ , where  $\mathbf{x}$  is the position vector,  $\mathbf{r}$  is the separation vector,  
 170 and the overbar indicates the spatial average.

171 The following describes the method to deduce the aerosol mass concentration structure  
 172 parameter  $C_M^2$ .

173 We assume that the aerosol particles are continuously dispersed in the air. The aerosol particles  
 174 and gases in the atmosphere can be considered as an equivalent medium, and an atmospheric  
 175 equivalent refractive index (AERI)  $n_{equ}$  is introduced that contains the real part  $n_{re}$  and the imaginary  
 176 part  $n_{im}$  of the equivalent refractive index. Thus,  $n_{equ} = n_{re} + i \cdot n_{im}$ . For visible light, the attenuation of  
 177 light by gases in the atmosphere is very weak; the cause of the attenuation is the absorption and  
 178 scattering due to aerosol particles. Therefore, the real part of the equivalent medium of aerosol  
 179 particles and gases is determined by the gas composition of the air. The fluctuation of the real part  
 180 is mainly determined by temperature fluctuations; the imaginary part is determined by the aerosol

181 particles, and the fluctuation of the imaginary part is determined by fluctuations in the aerosol  
 182 concentration.

183 For visible light, there is a strong linear relationship between the variation of the real part of

184 the AERI and the variation of the atmospheric temperature, i.e.,  $R_{TN} = \frac{\delta T}{\delta n_{Re}}$ ; thus, we have the

185 following:

$$186 \quad R_{TN} = -1.29 \times 10^4 \times \left(1 + \frac{7.52 \times 10^{-3}}{\lambda^2}\right)^{-1} \frac{\bar{T}^2}{\bar{P}} \quad (5)$$

187 which is based on the relationship between the real part of the AERI ( $n_{Re}$ ) and atmospheric  
 188 temperature (Tatarskii, 1961). Because the wavelength is deterministic, the ratio  $R_{TN}$  can be obtained  
 189 by measuring the atmospheric temperature. The imaginary part of the AERI has a close  
 190 correspondence with the extinction coefficient of the equivalent medium, and the extinction  
 191 coefficient is inversely proportional to the visibility. Higher concentrations of aerosols in the  
 192 atmosphere are related to lower visibility and vice versa; thus, the relationship between the  
 193 imaginary part of the AERI and the atmospheric aerosol mass concentration can be established. The  
 194 ratio of the atmospheric aerosol mass concentration to the imaginary part of the AERI  $R_{MN}$  can be  
 195 defined as follows:

$$196 \quad R_{MN} = \frac{M_a}{n_{Im}}. \quad (6)$$

197 Theoretical analysis has revealed that  $R_{MN}$  is associated with the aerosol particle size  
 198 distribution, mass density of the aerosol particles, and the aerosol particle refractive index. Because  
 199 of the relatively small variations in particle size and aerosol refractive index (Dubovik et al., 2002),  
 200  $R_{MN}$  can be treated as a constant for surface-layer aerosols at a given location.  $M_a$  approximates the  
 201  $PM_{10}$  value. The variable  $n_{Im}$  can be calculated as follows (Yuan et al., 2016):

$$202 \quad n_{Im} = \frac{0.55e-6}{4\pi} \cdot \frac{3.912}{L_V} \quad (7)$$

203 where the unit of visibility ( $L_V$ ) is m.

204 According to Eqs. (5) and (6), we have the following:

$$205 \quad C_T^2 = R_{TN}^2 C_{n,Re}^2 \quad (8)$$

$$206 \quad C_M^2 = R_{MN}^2 C_{n,Im}^2 \quad (9)$$

207 Thus, the temperature structure parameter  $C_T^2$  and the aerosol mass concentration fluctuation  
 208 structure parameter  $C_M^2$  are converted into the measurement of the real and imaginary structural

209 parameters of the AERI.

210 The measurement of relevant parameters is performed based on the light propagation theory.

211 When light is transmitted in an equivalent medium, the AERI fluctuation will cause fluctuations in

212 light intensity. Theoretical and experimental results have shown that the intensity fluctuation can be

213 decomposed into high-frequency and low-frequency fluctuations. The high-frequency fluctuations

214 are determined by fluctuations of the real part of the AERI, and the low-frequency fluctuations are

215 determined by fluctuations of the imaginary part of the AERI. Thus, the real and imaginary structure

216 parameters of the equivalent refractive index can be calculated by our developed LAS.

217 So far, we have completed the estimation of the aerosol mass transport flux.

218 According to the previous derivation and analysis, there are two calculation schemes for

219 determining the aerosol mass flux as follows:

$$220 \quad F_{a1} = \left( \frac{C_{n,\text{Im}}^2}{C_{n,\text{Re}}^2} \right)^{1/2} \frac{R_{MN}}{R_{TN}} u_* |T_*| \quad (10)$$

$$221 \quad F_{a2} = u_* \sqrt{\frac{C_M^2 z^{2/3}}{\eta(\xi)}} = u_* R_{MN} \sqrt{\frac{C_{n,\text{Im}}^2 z^{2/3}}{\eta(\xi)}} \quad (11)$$

222 When the free convection approximation ( $-\xi \gg 1$ ) is assumed, based on the definition of the

223 M-O length, and the similarity theory (Wyngaard et al., 1971), the following can be obtained:

$$224 \quad F_{a3} = a \left( \frac{g}{T} \right)^{1/2} R_{TN}^{1/2} (C_{n,\text{Re}}^2)^{1/4} R_{MN} (C_{n,\text{Im}}^2)^{1/2} (z-d) \quad (12)$$

225 where the coefficient  $a = a_1^{-3/4} a_2^{1/2} K^{1/2}$  can be taken as 0.567 (DeBruin et al., 1995; Lagouarde et

226 al., 2006). Eqs. (10)-(12) are the theoretical basis for the aerosol mass flux measurements.

227 According to Eqs. (10)-(12), the vertical transport flux of aerosol particles is related to the  
 228 strength of turbulent fluctuations and aerosol mass concentration fluctuations.

## 229 2.2 Calculation of the friction velocity and surface-layer characteristic temperature

230 To calculate the aerosol vertical transport flux, according to Eq. (10), the values of the friction

231 velocity  $u_*$  and the characteristic temperature  $T_*$  are required. These can be obtained via wind speed

232 and temperature profile data. From the near-surface similarity theory, the temperature and wind

233 speed data measured at two heights of  $z_1$  and  $z_2$  can be used in the expressions of the friction velocity

234  $u_*$  and the characteristic temperature  $T_*$  (Stull, 1988) as follows:

$$235 \quad u_* = \frac{\kappa[U(z_2) - U(z_1)]}{\ln \frac{z_2}{z_1} - \Psi_U(\xi_2) + \Psi_U(\xi_1)} \quad (13)$$

$$T_* = \frac{\kappa[T(z_2) - T(z_1)]}{0.74 \left[ \ln \frac{z_2}{z_1} - \Psi_U(\xi_2) + \Psi_T(\xi_1) \right]} \quad (14)$$

where  $U(z_1)$  and  $U(z_2)$  are the measured velocities at heights  $z_1$  and  $z_2$ , respectively,  $T(z_1)$  and  $T(z_2)$  are the measured temperatures at heights  $z_1$  and  $z_2$ , respectively,  $\xi_1$  and  $\xi_2$  are the stabilities at heights  $z_1$  and  $z_2$ , respectively, and  $\Psi_U$  and  $\Psi_T$  are the correction terms for the velocity and temperature profiles under the condition of stability  $L$ . Under unstable conditions (Stull, 1988), we have the following:

$$\Psi_U(\xi) = \ln \left[ \left( \frac{1+x^2}{2} \right) \left( \frac{1+x}{2} \right)^2 \right] - 2 \arctan(x) + \frac{\pi}{2}, \quad x = (1-15\xi)^{1/4} \quad (15)$$

$$\Psi_T(\xi) = \ln \left[ \left( \frac{1+y}{2} \right)^2 \right], \quad y = (1-9\xi)^{1/2} \quad (16)$$

Under stable conditions (Cheng and Brutsaert, 2005), we have the following:

$$\Psi_U(\xi) = -a \ln[\xi + (1 + \xi^b)^{1/b}], \quad a=6.1, \quad b=2.5. \quad (17)$$

$$\Psi_T(\xi) = -c \ln[\xi + (1 + \xi^d)^{1/d}], \quad c=5.3, \quad d=1.1. \quad (18)$$

Based on Eqs. (13)-(18), the friction velocity  $u_*$  and characteristic temperature  $T_*$  can be determined.

### 3 Measurements and data processing

#### 3.1 Introduction of Experiments

Observations were collected at two locations (two rectangles in Fig. 1a) from December 2016 to March 2017: a rural site in Gucheng (GC site), Hebei Province and an urban site at the Chinese Academy of Meteorological Sciences (CAMS site) in Beijing. The distance between the two locations is approximately 100 km. According to the theoretical methods defined in the preceding section, to estimate the aerosol transport flux, the ratio of the aerosol mass to the imaginary part of the AERI, the ratio of the temperature to the real part of the AERI, the real and imaginary parts of the atmospheric equivalent refractive index structure parameter (AERISP), the friction speed, and the characteristic temperature must all be obtained. If the free convection condition is satisfied, fewer parameters are required, including the real and imaginary parts of the AERISP, the ratio of the aerosol mass to the imaginary part of the AERI, the ratio of the temperature to the real part of the AERI, and the atmospheric temperature.

Two sets of LASs developed by our research group were installed at the top of the building of the Beijing Institute of Meteorological Sciences (point A in Fig. 1b) and at the top of a two-story building in the farm of the Central Meteorological Bureau of Gucheng Town, Baoding City (point D in Fig. 1c). The light intensity sampling frequency of the receiving end was 500 Hz, and a file was recorded every 20 minutes. Then, the real and imaginary parts of the AERISP were calculated.

In the CAMS site, the transmitter end of the LAS was placed on the roof of a building on the east side of the Institute of Meteorological Sciences, and the receiver end was placed at the top of the Chinese Academy of Meteorological Sciences. The propagation path was along an east-west direction. The distance between the two ends was 550 metres as shown in Fig. 1d. The light beam

271 passed over urban buildings, residential areas and urban roads. The beam height was 43 metres. The  
272 average height of the building below the beam was 24 metres; thus, the zero-displacement was 18  
273 metres ( $24 * 0.67 = 18$ ) (Leclerc and Foken, 2014), and the effective height of the beam was 25  
274 metres. At the Beijing observation point, the temperature and wind speed of the near-surface  
275 atmosphere were measured simultaneously, and the measurement heights were 1.5 m and 10 m,  
276 respectively. To calculate the aerosol flux, it is necessary to obtain the ratio of the aerosol mass to  
277 the imaginary part of AERI and to measure the aerosol mass concentration and visibility. In Haidian  
278 District, there is a site to measure the visibility of the near-surface layer (point B in Fig. 1b), and the  
279  $PM_{10}$  mass concentration measurements were collected at Guanyuan Station (see point C in Fig.  
280 1B). The sampling interval for the visibility and  $PM_{10}$  mass concentration measurements was 1 h.  
281 The measurement height of points B and C in Fig. 1b was approximately 20 metres. The ratio of the  
282 aerosol mass  $PM_{10}$  to the imaginary part of the AERI was calculated based on the data. The  
283 measurements were collected at the CAMS site from January 15, 2017 to March 20, 2017.

284 In the GC site (point D in Fig. 1c, namely, the LAS position) in Gucheng, Baoding, Hebei, the  
285 transmitter of the LAS was placed on the roof of a two-story building with a height of 8 m, and the  
286 receiving end was located in a room in a three-story building on the west side of National Highway  
287 107 at the same height as the transmitting end. The distance between the transmitting end and the  
288 receiving end was 1670 metres. The terrain between the transmitting end and the receiving end was  
289 flat, with farmland, a national road and sporadic trees below the beam, as seen in Fig. 1e. Near the  
290 light beam, there was a 30-metre-high meteorological observation tower, in which the temperature,  
291 relative humidity (RH), and wind speed were measured at 5 levels (1 m, 3 m, 8 m, 18 m, and 28 m).  
292 The friction speed and characteristic temperature were calculated according to the temperature wind  
293 speed profile. Visibility observations were made in Xushui District near the LAS position (see point  
294 E in Fig. 1c). The  $PM_{10}$  mass concentration was measured in Beishi District (see point F in Fig. 1c).  
295 From Fig. 1c, the three observation points (points D, E and F in Fig. 1c) formed a nearly straight  
296 line and were distributed in a northeast-southwest direction. During the experimental observation  
297 period, a northeast-southwest wind prevailed; thus, the Xushui District visibility data and Beishi  
298 District  $PM_{10}$  data can approximate the situation of the scintillometer position. The measurements  
299 were collected at the GC site from November 17, 2016 to March 30, 2017.

### 300 3.2 Data quality control

301 There are two types of variables, e.g., mean variables and fluctuation variables. Mean variables  
302 include temperature, wind speed, wind direction,  $PM_{10}$ , and visibility for averages of 30 minutes or  
303 60 minutes. Data quality control for the mean variables was conducted by comparing the measured  
304 data at different heights or from personal experience. All the measured mean data were determined  
305 to be adequate. Fluctuation variables include the high-frequency intensity fluctuation data measured  
306 by the LAS, the real and imaginary parts of the AERISP, and the calculated aerosol flux. Quality  
307 control mainly includes the elimination of spike and supplementing missing data.

308 Peaks in the light intensity fluctuation data appear because the received signal quickly increases  
309 when the light signal is blocked, such as due to birds along the transmission path. This situation is  
310 automatically determined by the data processing program. When this happens, the current 20-minute  
311 period is rejected. For the real and imaginary parts of the AERISP and the aerosol flux data, (a) 3  
312 times the standard deviation (SD) of the anomaly and (b) 3 times the SD of the adjacent difference

313 were determined. The method for judging 3 times the SD of the anomaly was applied to obtain a  
314 trend of two-hour averages. Then, the difference between the measured value and the trend at each  
315 moment was calculated, and the mean and SD of the difference were also calculated. The data with  
316 differences from the trend exceeding 3 times the SD were considered as spikes. The method for  
317 judging the difference of 3 times the SD of the adjacent differences was to first calculate the  
318 difference between adjacent observations and then calculate the mean and SD of the difference. Any  
319 data whose adjacent difference deviated from the mean of the adjacent difference by more than 3  
320 the SD was considered an error. Less than 5% of the data were considered to contain spikes or errors.

321 The data determined to be errors were supplemented by the average of the nearby observations.  
322 Of course, if data were missing over a long period, the missing gap could not be filled. For this  
323 situation, further supplementation was not considered.

324 Other errors in the measurements using a LAS due to specific reasons (Moene et al., 2009); for  
325 example, the impact of the uncertainty in the exact shape of the turbulence spectrum and the  
326 intermittent variations in the characteristics of that spectrum on the LAS signal were not considered  
327 in this study.

## 328 4 Results

329 First, the visibility and PM<sub>10</sub> aerosol mass concentration results at the CAMS site and the GC  
330 site are given and compared. Then, the characteristics of aerosol transport in typical weather  
331 conditions at the CAMS site and the GC site are discussed. Finally, the aerosol flux characteristics  
332 under heavy pollution weather conditions are analysed.

### 333 4.1 Relationship between $n_{im}$ and PM<sub>10</sub>

334 To obtain the ratio of the atmospheric aerosol mass concentration to the imaginary part of the  
335 AERI ( $n_{im}$ )  $R_{MN}$ , PM<sub>10</sub> and visibility were measured.

336 The maximum PM<sub>10</sub> concentration in the Baoding area appeared at 1:00 on January 28, 2017  
337 (up to 1071  $\mu\text{g m}^{-3}$ ), and the maximum PM<sub>10</sub> concentration in the Beijing area appeared at 2:00 on  
338 January 28, 2017 (up to 917  $\mu\text{g m}^{-3}$ ). This heavy pollution event swept through Beijing and the  
339 surrounding areas, reaching a maximum at almost the same time. The visibility at the corresponding  
340 time was less than 500 metres. The imaginary part of the AERI can be calculated from the visibility  
341 (Yuan et al., 2016). Fig. 2a shows a scatter diagram of the imaginary parts of the AERI and PM<sub>10</sub>  
342 data measured in the Beijing area; there is a strong correlation between the AERI and aerosol particle  
343 mass concentration, with a linear correlation coefficient of 0.96. The fitted linear in Fig. 2a has a  
344 slope of 3845  $\text{kgm}^{-3}$ . Therefore,  $R_{MN}$  was taken as 3845  $\text{kgm}^{-3}$  for the Beijing area to estimate the  
345 aerosol vertical transportation flux. Similarly, Fig. 2b shows the results for the Baoding area, and  
346  $R_{MN}$  was set to 3711  $\text{kgm}^{-3}$  for the Baoding area to estimate the aerosol vertical transportation flux.  
347 The two ratio coefficients are relatively close. Figs. 2a and 2b also show that in the case of light  
348 pollution, Beijing's  $R_{MN}$  is slightly larger.

349 Furthermore, Figs. 2a and 2b show that although there is a large scattering between PM<sub>10</sub> and  
350  $n_{IM}$  that may be attributed to a large separation between the two measurement locations for visibility  
351 and PM<sub>10</sub>, there is a strong linear correlation between the imaginary part of the AERI and PM<sub>10</sub>. The  
352 imaginary part of the AERI has a slightly stronger correlation with the PM<sub>10</sub> data obtained in the  
353 Baoding area than in the Beijing area.

354 The following provides the results of the aerosol transport flux under typical weather  
355 conditions in Beijing and Baoding for the period from March 10, 2017 to March 17, 2017.

#### 356 4.2 Characteristics of aerosol flux in the Beijing region

357 To analyse the aerosol transport flux characteristics, we present the time series of the  
358 conventional meteorological parameters. The measurement site is the Beijing Meteorological  
359 Observatory, which is 20 metres above the ground. The time series of temperature, RH, wind speed,  
360 wind direction,  $PM_{10}$ ,  $C_{n,Re^2}$ ,  $C_{n,lm^2}$  and aerosol flux are shown in Figs. 3a-3h, respectively. The  
361 temperature has an obvious diurnal variation, indicating that this period had primarily sunny weather.  
362 The RH from March 10, 2017 to March 17, 2017, was less than 60%, and the RH for most of the  
363 time period was less than 30%. The wind speed was low; only during the period from March 11 to  
364 March 14 was the wind strong. At 6:00 on March 12, the maximum wind speed was  $4.2 \text{ m s}^{-1}$ . At  
365 that time, there was no dominant wind direction. Moreover, two light pollution events occurred  
366 (MEP, 2012) on March 11 and March 16, with  $PM_{10}$  concentrations approaching  $200 \mu\text{g m}^{-3}$ . From  
367 the data of  $C_{n,Re^2}$  and  $C_{n,lm^2}$  in Figs. 3f and 3g, the real part of the AERISP  $C_{n,Re^2}$  has obvious diurnal  
368 variations, i.e., smaller in the morning and at night and larger at noon. The imaginary part of the  
369 AERISP  $C_{n,lm^2}$  had no obvious diurnal variation. According to Fig. 3g, there are some peak values,  
370 i.e., some sudden increases and decreases, which may be related to sudden changes in wind direction,  
371 as shown in Fig. 3d.

372 Aerosol fluxes in Beijing are calculated using the assumption of free convection. Because there  
373 was no measurement of wind speed and temperature profiles near the LAS measurement location,  
374 the friction velocity and characteristic temperature could not be calculated. Because the height of  
375 the LAS instrument at the CAMS site was 43 m, the conditions assumed for free convection were  
376 easily satisfied. During the day, the surface layer is usually unstable. At night, for the city, even if  
377 there is an inversion at a higher altitude, due to the existence of the urban heat island, the surface  
378 layer is often weakly unstable. The stable stratification situation is rare (Li et al., 2007).

379 From the aerosol flux time series given in Fig. 3h, the aerosol flux is large at noon and small  
380 in the morning and at night, which is mainly because of the strong convection at noon. However,  
381 large aerosol fluxes also occurred on the nights of March 11 and March 12, which were related to  
382 high wind speeds. The mean aerosol flux measured at this observation point during this period was  
383  $0.0039 \text{ mg m}^{-2} \text{ s}^{-1}$ .

#### 384 4.3 Characteristics of aerosol flux at the GC site

385 Similarly, Figs. 4a-4d provide the time series of temperature, RH, wind speed and wind  
386 direction at 3 metres and 18 metres for the GC site, and Figs. 4e-4h show the  $PM_{10}$ ,  $C_{n,Re^2}$ ,  $C_{n,lm^2}$   
387 and aerosol flux curves over time. According to Fig. 4a, the temperatures at both heights show  
388 obvious diurnal variations. The daytime is characterized by unstable stratification, and at night,  
389 stable stratification prevails. Moreover, in the morning and evening, there is a transition period  
390 between the stable and unstable stratification. Here,  $u^*$ ,  $T^*$  and MO length  $L$  were calculated from  
391 the wind speed and temperature measured at 3 m and 18 m on a meteorological tower. Fig. 4b shows  
392 a plot of the two levels of RH over time, again with obvious diurnal variations. The RH of the GC  
393 site was lower at the CAMS site. Figs. 4c and 4d provide the time series of wind speeds and wind

394 directions at two levels. At 6:00 on March 12, the wind speed was relatively high, and the maximum  
395 at 18 metres was  $6.5 \text{ m s}^{-1}$ . At the same time, the maximum wind speed was reached in the Beijing  
396 area, although the speed was lower in Beijing. The overall trend of wind direction at the GC site  
397 was more consistent with the results of the CAMS site.

398 Figure 4e shows the  $\text{PM}_{10}$  trend of over time. There were two light pollution events on March  
399 11 and March 16. The overall trend is the same as in Fig. 3(e) except that there is a slight difference.  
400 Figs. 4f and 4g show the time series of the imaginary and real parts of the AERISP for the GC site.  
401 The real part of the AERISP is large at noon, and the optical turbulence is strong. The real part of  
402 the AERISP is small during the morning and evening, and the corresponding turbulence is weak.  
403 The imaginary part of the AERISP given in Fig. 4g does not show an obvious diurnal variation, and  
404 there may be some sharp peaks.

405 Figure 4h shows the aerosol mass vertical flux changes over time. The aerosol flux has a  
406 significant diurnal variation characteristic associated with turbulent transport near the surface. The  
407 mean aerosol flux measured at the GC site during this period was  $0.0016 \text{ mgm}^{-2}\text{s}^{-1}$ . This value is  
408 much smaller than the results for the CAMS site. Human activities contribute to increased water  
409 vapor releases in urban areas compared to rural areas, as observed by Dou et al.(2014), and  
410 especially for the night-time SBL in winter. During our observation period, the RH of the city was  
411 lower than the rural area. However, human activities cause more aerosol particles in urban areas  
412 than in rural areas.

#### 413 4.4 Aerosol flux during heavy pollution periods

414 In the winter of 2016, there were several heavy pollution events. Generally, based on the  $\text{PM}_{2.5}$   
415 daily mean mass concentration limit in the primary standard of China's national environmental  
416 quality standards (EPD, 2012), a pollution episode is referred to as the period during which the  
417  $\text{PM}_{2.5}$  concentration exceeds  $80 \mu\text{g m}^{-3}$  for 3 consecutive days between two clean periods, while a  
418 period when the  $\text{PM}_{2.5}$  level is less than  $35 \mu\text{g m}^{-3}$  is defined as a clean period. Pollution episodes  
419 with peak  $\text{PM}_{2.5}$  values of more than  $400 \mu\text{g m}^{-3}$  or less than  $300 \mu\text{g m}^{-3}$  are termed heavy-pollution  
420 episodes (HPEs) or light-pollution episodes (LPEs), respectively (Zhong et al., 2017).

421 A heavy pollution event began on December 1, 2016 and ended on January 10, 2017. Relevant  
422 observational experiments were performed in the Beijing and Baoding areas, including observations  
423 of meteorological parameters and aerosol parameters, to understand the causes of the heavy  
424 pollution. The observations show that the beginning of the HPE was characterized by pollutant  
425 transport under southerly conditions, i.e., the formation of heavy pollution was mainly caused by  
426 the pollutants transported from southern Beijing, which we call the transport stage (TS). Usually,  
427 after the TS stage, the explosive growth of  $\text{PM}_{10}$  and the rapid accumulation of pollutants occur,  
428 which is called the accumulative stage (AS). During the other period within the HPEs, aerosol  
429 particles are usually removed from the atmosphere, which is called the removal stage (RS). During  
430 heavy pollution events, there is a lower boundary layer depth, low wind speeds and high RH, and  
431 the  $\text{PM}_{10}$  concentration increases rapidly and reaches a very high value (Zhong et al., 2017). There  
432 were 7 TS stages in the 2016 winter heavy pollution event, and the AS stage appeared immediately  
433 after 4 TS stages. These included 00:00 on December 1 to 03:20 on December 4, 18:40 on December  
434 15 to 00:00 on December 22, 00:00 on December 29 to January 2, and 00:00 and 8:40 on January 2  
435 to 00:00 on January 5.

436 During this period, we used a LAS to conduct an observational study of the aerosol vertical  
437 flux in the GC site, which was from 00:00 on December 1, 2016, to 00:00 on December 22, 2016.  
438 No corresponding observations were made at the Beijing site during this period. Here, we first  
439 discuss the observation results of the GC site, Baoding City, as shown in Fig. 5. Fig. 5a shows the  
440 time series of the aerosol vertical transport flux. Figs. 5b-5g show the time series for the real and  
441 imaginary parts of the AERISP, the temperature and RH at 18 metres, and the wind speed and  
442 direction. Purple curves indicate the TS stages, red curves indicate the AS stages, and grey curves  
443 indicate the RS stages.

444 According to Fig. 5a, in the TS stages and the RS stages, the aerosol flux exhibited diurnal  
445 variations, while the AS stage did not show a diurnal variation. There were some peaks in the TS  
446 stage. The average aerosol flux of the TS stages was  $0.00065 \text{ mgm}^{-2}\text{s}^{-1}$ , the average value of the AS  
447 stages was  $0.00025 \text{ mgm}^{-2}\text{s}^{-1}$ , and the average value of the RS stages was  $0.00063 \text{ mgm}^{-2}\text{s}^{-1}$ . The  
448 aerosol transport fluxes in the TS and RS stages were similar, while the aerosol transport flux in the  
449 AS stage was much smaller than the TS and RS stages.

450 According to Fig. 5b-5c, the imaginary structure parameters and the real structure parameters  
451 of the refractive index in the TS and RS stages exhibited diurnal variations, while the AS stage did  
452 not exhibit a diurnal variation. Fig. 5d shows that except for the second AS event (22:00 on  
453 December 19, 2016 to 00:00, December 22, 2016), the temperature showed a diurnal variation.  
454 During the AS stage, the RH (see Fig. 5e) was close to 100%, while the RH during the TS and RS  
455 stages was lower. Moreover, Fig. 5f shows that during this time, the wind speed was relatively weak,  
456 although the wind speed was slightly stronger on December 5. As shown in Fig. 5g, during the TS  
457 and AS stages, southerly winds prevailed, while during the RS period, northerly winds prevailed.  
458 The high wind speed and convection in the TS and RS stages contributed to the upward transport of  
459 aerosol particles, whereas the low wind speed and stable stratification in the AS stage were not  
460 conducive to the upward transport of aerosol particles.

461 During the heavy pollution period from December 1, 2016 to January 10, 2017, we did not  
462 conduct surface aerosol flux observations at the CAMS site. From January 25 to January 31, the  
463 pollution in the Beijing area also reached the level of heavy pollution. During this heavy pollution  
464 period, a measurement of surface aerosol fluxes at the CAMS site was conducted. Figure 6 shows  
465 the results of the meteorological and pollutant observations for 6 days from 00:00 on January 25,  
466 2017 to 00:00 on January 31, 2017. According to Fig. 6, northerly winds prevailed after 12:00 on  
467 January 26, when the concentration of  $\text{PM}_{10}$  dropped rapidly from  $254 \mu\text{gm}^{-3}$  at 12:00 to  $5 \mu\text{gm}^{-3}$  at  
468 15:00. During the period 12:00-24:00 on January 26, the average wind speed was  $2.6 \text{ ms}^{-1}$ . On  
469 January 27, southerly winds prevailed, the average wind speed was only  $0.8 \text{ ms}^{-1}$ , and the aerosol  
470 concentration ( $\text{PM}_{10}$ ) increased slowly; the increase began at 6:30 before increasing rapidly at 17:50,  
471 reaching more than  $300 \mu\text{gm}^{-3}$  at 23:00 and  $917 \mu\text{gm}^{-3}$  at 2:00 am on January 28, which was the  
472 maximum aerosol concentration over the 6 day period. Then, the aerosol concentration decreased  
473 gradually. The average wind speed on January 27 was  $0.6 \text{ ms}^{-1}$ , southerly winds prevailed, and the  
474 mean  $\text{PM}_{10}$  concentration was  $440 \mu\text{gm}^{-3}$ , which constitutes a serious pollution level. The average  
475  $\text{PM}_{10}$  concentration during the period from 00:00 on January 25 to 00:00 on January 31 was  $170$   
476  $\mu\text{gm}^{-3}$ .

477 According to the previous characteristics for the TS and AS stages, a period of southerly winds  
478 can be determined as the TS stage. Thus, January 27 can be designated as the TS stage, January 28  
479 can be determined as the AS stage, and January 29 can be determined as the RS stage. During

480 Beijing's heavy pollution event in January 2017 (20170125-20170131), the mean aerosol vertical  
481 flux in the TS stage was  $0.0024 \text{ mgm}^{-2}\text{s}^{-1}$ , the average value during the AS stage was  $0.00087 \text{ mgm}^{-2}\text{s}^{-1}$   
482  $^2\text{s}^{-1}$  and the RS stage was  $0.0049 \text{ mgm}^{-2}\text{s}^{-1}$ . The overall average value was  $0.0032 \text{ mg m}^{-2}\text{s}^{-1}$ .

483 Even during heavy pollution events, the RH in Beijing was lower than in the outer suburbs.  
484 According to Fig. 6e, the RH exceeded 60% in the period from 3:00 to 6:00 on January 26, where  
485 the maximum value was 63%, and the RH was less than 60% in the remaining periods. In urban  
486 areas, when the RH is low, heavy pollution incidents can occur. In Beijing, during the AS stage, the  
487 vertical flux of aerosol was less than during the TS and RS stages.

## 488 5 Discussions and conclusions

489 During the winter of 2016 and the spring of 2017, HPEs occurred frequently in the BTH area.  
490 This study investigated the aerosol vertical mass flux and compared its magnitude during different  
491 stages of HPEs, including RSs, TSs, and ASs, in two representative urban and rural sites, including  
492 the CAMS site in Beijing and the GC site in Hebei Province. Based on the light propagation theory  
493 and surface-layer similarity theory, the aerosol vertical mass flux was obtained by combining LAS  
494 observations, surface  $\text{PM}_{2.5}$  and  $\text{PM}_{10}$  mass concentrations, and meteorological observations,  
495 including air temperature and RH. We found that under favourable meteorological conditions for  
496 pollution dispersion, i.e., from March 10, 2017 to March 17, 2017, the vertical aerosol mass flux  
497 exhibited striking diurnal variations, with the mass fluxes reaching peak values at noon and lowering  
498 in the morning and evening. During the HPEs from January 25, 2017 to January 31, 2017 in Beijing,  
499 the vertical aerosol mass flux varied substantially during the different stages. Specifically, the mean  
500 mass flux decreased by 51% from  $0.0049 \text{ mg m}^{-2}\text{s}^{-1}$  in the RSs to  $0.0024 \text{ mg m}^{-2}\text{s}^{-1}$  in the TSs, which  
501 was partly due to the wind speed reduction from strong northerly winds in the RSs to southerly  
502 winds in the TSs. During the ASs, the mean mass flux decreased further to  $0.00087 \text{ mg m}^{-2}\text{s}^{-1}$ , which  
503 accounted for approximately 1/3 of the flux during the TSs. Due to the cooling effect of elevated  
504 aerosols in the ASs, the near-ground temperature decreased and caused or reinforced the inversion,  
505 which suppressed the turbulence diffusion. The weakened mass flux would further facilitate aerosol  
506 accumulation. During the HPE from December 01, 2016, to December 22, 2016, in Gucheng, the  
507 mean mass flux was similar in the RSs and TSs, ranging from  $0.00063 \text{ mg m}^{-2}\text{s}^{-1}$  to  $0.00065 \text{ mg m}^{-2}\text{s}^{-1}$ .  
508 This is partly because Gucheng was less affected by strong northerly winds than Beijing. Thus,  
509 the wind speed varied slightly from the RSs to TSs. However, the mass flux decreased substantially  
510 to  $0.00025 \text{ mg m}^{-2}\text{s}^{-1}$  in the ASs, which was merely 1/3 of the mean flux in the TSs.

511 In this study, the aerosol emission flux was also estimated in these two rural and urban sites.  
512 Generally, compared with the emissions in spring, we found that in winter, the near-ground  
513 emissions were weaker in suburban areas and were similar in urban areas. In suburban areas,  
514 although the aerosol concentrations were relatively high (Shen et al., 2018), the upward emitted  
515 aerosol flux was smaller than in urban areas. During the ASs of the HPEs, the aerosol emission flux  
516 from the ground was weaker than for the RSs and TSs at both the CAMS and GC sites, which  
517 indicates that surface pollutant emissions are not the major cause of explosive  $\text{PM}_{2.5}$  growth. During  
518 the ASs with weak solar radiation, the factors most associated with aerosol concentration changes  
519 were horizontal transport and BL height variations, which might be the main causes of increased  
520  $\text{PM}_{2.5}$  (Zhong et al., 2018b; Zhong et al., 2018a; Zhang et al., 2018).

521 Due to the lack of necessary experimental conditions, such as meteorological towers and EC  
522 systems, current experimental results cannot be compared with EC methods. According to the

523 literature data, the two methods have been compared indirectly, and the estimated aerosol flux under  
524 different measurement conditions is consistent in magnitude (Yuan et al., 2016). However, a direct  
525 comparison of the two methods is in development.

526 Compared with the EC method, the aerosol flux has high spatial representativeness based on  
527 the principle of light propagation, and there is no need to install a high tower. However, the  
528 estimation of aerosol fluxes using the LAS method still has theoretical and practical deficiencies.  
529 At present, the LAS method for the aerosol flux regards the aerosol particles as ordinary scalar  
530 molecules. At the same time, based on the assumption of the equivalent medium, the imaginary part  
531 of the AERI is taken for granted as proportional to the aerosol mass concentration. This is often not  
532 the case. The actual turbulence spectrum shape often deviates from the "-5/3" law, and turbulence  
533 intermittent and scintillation saturation can also occur (Moene et al., 2009). The applicability of the  
534 near-surface layer similarity theory to the aerosol particle motion under stable layer conditions also  
535 has many problems. The formation of new particles and changes in aerosol particle size distribution  
536 also affect the scintillation in light propagation. There are also practical problems such as untimely  
537 maintenance, rainfall and low visibility, and platform vibrations required for observation. All these  
538 problems will cause errors in final estimates, so more theoretical and experimental research is  
539 needed.

540

541 **Author contributions.** Renmin Yuan and Xiaoye Zhang designed experiments and wrote the manuscript;  
542 Renmin Yuan, Hao Liu, Yu Gui, Bohao Shao, Yaqiang Wang, Junting Zhong and Xiaoping Tao  
543 carried out experiments; Renmin Yuan analyzed experimental results. Yubin Li and Zhiqiu Gao  
544 designed experiments and discussed the results.

545
