20 **Abstract**

21

22 Highly-oxygenated Organic Molecules (HOM) are important contributors to Secondary Organic Aerosol  
23 (SOA) and New-Particle Formation (NPF) in the boreal atmosphere. This newly discovered class of molecules  
24 is efficiently formed from atmospheric oxidation of biogenic volatile organic compounds (VOC), such as  
25 monoterpenes, through a process called autoxidation. This process, in which peroxy-radical intermediates  
26 isomerize to allow addition of molecular oxygen, is expected to be highly temperature-dependent. Here, we

27 studied the dynamics of HOM formation during  $\alpha$ -pinene ozonolysis experiments performed at three different  
28 temperatures, 20 °C, 0 °C and -15 °C, in the Aarhus University Research on Aerosol (AURA) chamber. We  
29 found that the HOM formation, under our experimental conditions (50 ppb  $\alpha$ -pinene, 100 ppb ozone),  
30 decreased considerably as temperature decreased, with molar yields dropping by around a factor of 50 when  
31 experiments were performed at 0 °C, compared to 20 °C. At -15 °C, the HOM signals were already close to  
32 the detection limit of the nitrate-based Chemical Ionization Atmospheric Pressure interface Time Of Flight  
33 (CI-APi-TOF) mass spectrometer used for measuring gas-phase HOM. Surprisingly, very little difference was  
34 seen in the mass spectral distribution of the HOM molecules of interest at 0 °C and 20 °C, with e.g. the ratios  
35 between the typical HOM products  $C_{10}H_{14}O_7$ ,  $C_{10}H_{14}O_9$ , and  $C_{10}H_{14}O_{11}$  remaining fairly constant. The more  
36 oxidized species have undergone more isomerization steps, yet, at lower temperature, they did not decrease  
37 more than the less oxidized species. One possible explanation is be that the rate-limiting step forming these  
38 HOM occurs before the products become oxygenated enough to be detected by our CI-APi-TOF (i.e. typically  
39 seven or more oxygen atoms). The strong temperature dependence of HOM formation was observed under  
40 temperatures highly relevant for the boreal forest, but the exact magnitude of this effect in the atmosphere will  
41 be much more complex: the fate of peroxy-radicals is a competition between autoxidation (influenced by  
42 temperature and VOC type) and bimolecular termination pathways (influenced mainly by concentration of  
43 reaction partners). While the temperature influence is likely smaller in the boreal atmosphere than in our  
44 chamber, the magnitude and complexity of this effect clearly deserves more consideration in future studies in  
45 order to estimate the ultimate role of HOM on SOA and NPF under different atmospheric conditions.

## 50 1. Introduction

51

52 Aerosol particles impact Earth's climate by scattering and absorbing solar radiation, and by influencing cloud  
53 properties when they act as Cloud Condensation Nuclei (CCN) (IPCC, 2013). Organic compounds contribute

54 significantly to the chemical composition of aerosol, accounting from 20 % to 90 % of the total aerosol mass  
55 of sub-micrometer particles depending on their location in the globe (Jimenez et al., 2009). Submicron organic  
56 aerosol are dominantly secondary. Called Secondary Organic Aerosol (SOA), they originate from gas-to-  
57 particle conversion from condensable vapors (Hallquist et al., 2009; Zhang et al., 2007). These vapors are  
58 mainly oxidation products of Volatile Organic Compounds (VOC), having sufficiently low vapor pressure (i.e.  
59 volatility) to condense onto aerosol particles (Hallquist et al., 2009).

60

61 In order to interact efficiently with solar radiation or to activate cloud droplets, aerosol particles need to be  
62 around 100 nm in diameter or larger (Dusek et al., 2006). If particles have formed through nucleation processes  
63 in the atmosphere (e.g. Kulmala et al., 2013), their ability to grow to climate-relevant sizes before being  
64 scavenged through coagulation is critically impacted by the rate at which low-volatile vapors will condense  
65 onto them (Donahue et al., 2013). Extremely Low-Volatile Organic Compounds (ELVOC), introduced by  
66 Donahue et al. (2012), have the ability to condense irreversibly onto even the smallest aerosol particles and  
67 clusters and thus contribute to particle growth. Low-Volatile Organic Compounds (LVOC), typically more  
68 abundant in the atmosphere, are important for the growth of particles larger than a few nanometers (Tröstl et  
69 al., 2016).

70

71 Highly-oxygenated Organic Molecules (HOM, Ehn et al., 2014 & 2017) were recently identified as a large  
72 contributor to (E)LVOC and the growth of newly formed particles (Ehn et al., 2014; Tröstl et al., 2016). First  
73 observed in measurements of naturally charged ions in the boreal forest (Ehn et al., 2010 & 2012) using the  
74 Atmospheric Pressure interface Time Of Flight (APi-TOF) mass spectrometer (Junninen et al., 2010), HOM  
75 quantification only became possible through the application of nitrate ion chemical ionization (CI) mass  
76 spectrometry (Zhao et al., 2013; Ehn et al., 2014). Most studies have utilized the APi-TOF coupled to such a  
77 chemical ionization source (CI-APi-TOF, Jokinen et al., 2012), and detailed laboratory studies have been able  
78 to elucidate the primary formation pathways of HOM (Rissanen et al., 2014; Jokinen et al., 2014; Mentel et  
79 al., 2015). We also note that the HOM-related terminology has evolved over the last years, and here we define  
80 HOM as organic molecules formed through gas-phase autoxidation, containing six or more oxygen atoms.

81

82 The main process in HOM formation is peroxy-radical (RO<sub>2</sub>) autoxidation (Crouse et al., 2013), which  
83 involves an intramolecular H-abstraction by the peroxy-radical group to form a hydroperoxide and a carbon-  
84 centered radical to which molecular oxygen (O<sub>2</sub>) can rapidly add to form a new RO<sub>2</sub> with a higher level of  
85 oxygenation. The efficiency of this process is mainly determined by the availability of easily “abstractable”  
86 H-atoms, and such are often formed in the ozonolysis of endocyclic alkenes (Rissanen et al., 2014 & 2015;  
87 Berndt et al., 2015). This structural component can be found in many biogenic VOC, such as monoterpenes,  
88 enhancing their roles as SOA precursors through efficient autoxidation and HOM formation (Ehn et al., 2014;  
89 Jokinen et al., 2014; Berndt et al., 2016). Peroxy-radicals are important intermediates in nearly all atmospheric  
90 oxidation processes. The RO<sub>2</sub> that have undergone autoxidation will terminate to closed-shell species in similar  
91 ways as less oxidized RO<sub>2</sub>, taking place either by unimolecular processes leading to loss of OH or HO<sub>2</sub>, or  
92 bimolecular reactions with NO, HO<sub>2</sub> or other RO<sub>2</sub>. The termination pathway strongly influences the type of  
93 HOM that can be formed, with e.g. RO<sub>2</sub> + RO<sub>2</sub> reactions being able to form ROOR dimers and RO<sub>2</sub>+NO  
94 often forming organic nitrates (Ehn et al., 2014; Berndt et al., 2018). All these bimolecular reactions of peroxy-  
95 radicals, as well as the initial oxidant-VOC reaction, are temperature-dependent. For example, the reaction rate  
96 of ozone with α-pinene, a broadly studied SOA-forming system, is  $6.2 \cdot 10^{17} (\pm 1.3 \cdot 10^{17}) \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$  at 3  
97 °C, and  $8.3 \cdot 10^{17} (\pm 1.3 \cdot 10^{17}) \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$  at 22 °C (Atkinson et al., 1982). However, the intramolecular  
98 isomerization through H-shifts is likely to have a much stronger temperature dependence, due to the higher  
99 energy barrier for the H-shift (Seinfeld and Pandis, 2006; Otkjær et al., 2018). As an example (Praske et al.,  
100 2018) reported theoretical estimates of different H-shifts in hexane-derived RO<sub>2</sub> which increased roughly by  
101 a factor of 5 to 10 when the temperature increases by 22 °C (from 23 °C to 45 °C). Possible changes in HOM  
102 formation as a function of temperature are thus expected to derive mainly from changes in the autoxidation  
103 process. However, a detailed mechanistic understanding the various autoxidation steps, let alone their  
104 temperature dependencies, is still lacking for most atmospheric VOC-oxidant systems, owing partly to the  
105 plethora and the complexity of the possible reaction pathways.

106

107 Despite recent work in determining the impact of temperature on aerosol formation (Kristensen et al., 2017;  
108 Stolzenburg et al., 2018), literature on corresponding HOM effects are extremely limited. At room temperature

109 (i.e.  $20 \pm 5$  °C), HOM molar yields have been estimated to be some percent for most monoterpenes in reactions  
110 with ozone or OH (Ehn et al., 2014; Jokinen et al., 2015). Only very recently, studies were presented where  
111 HOM formation experiments have been conducted at varying temperatures. Stolzenburg et al. (2018) showed  
112 that at lower temperatures, the CI-API-TOF detects much lower HOM concentrations, though no quantitative  
113 values on the HOM yields were given. The impact of decreased HOM on new-particle growth rates was  
114 compensated by less oxidized species being able to condense at the lower temperatures. In another study, Frege  
115 et al. (2018) also concluded that HOM formation decreased at lower temperatures, but their study was based  
116 on observations of naturally charged ions using an API-TOF, complicating the interpretation of HOM  
117 formation rates.

118

119 In this study, we directly evaluate the impact of temperature on HOM yields in a laboratory chamber during  
120  $\alpha$ -pinene ozonolysis experiments at 20 °C, 0 °C and -15 °C. Relative changes in HOM formation are compared  
121 between temperatures both for total HOM yields as well as on a molecule-by-molecule basis. The more  
122 detailed impact of temperature on the molecular distribution of HOM is expected to provide new insights into  
123 critical steps in the formation pathways.

124

## 125 **2. Methods**

126

### 127 **2.1. The AURA Chamber**

128 A detailed description of the AURA chamber can be found in Kristensen et al. (2017). Essentially, it consists  
129 of a 5 m<sup>3</sup> Teflon® bag contained in a temperature-controlled enclosure. Configured in batch sampling mode,  
130 the chamber was initially cleaned by flushing at 20 °C with purified ambient air (i.e. filtered air exempt of  
131 particles, water vapor and VOC, and reduced NO<sub>x</sub> concentration), and subsequently set to the desired  
132 temperature and finally filled with the necessary reagents. Over the course of the experiment, it was  
133 progressively emptied due to sampling by the measuring instrumentation. In our experiments, we first added  
134 ozone to a concentration of 100 ppb, provided by an ozone generator (Model 610, Jelight Company, Inc.) after  
135 which the oxidation reaction started when the VOC was introduced by vaporization of a calculated volume of

136 liquid reagent ( $\alpha$ -pinene or  $\beta$ -pinene) into a hot stream of nitrogen, reaching the desired VOC concentration  
137 (10 or 50 ppb).

138

### 139 **2.2. The ACCHA Experiment**

140 The Aarhus Chamber Campaign on HOM and Aerosols (ACCHA) experiment aimed to explore oxidation  
141 processes and aerosol formation during dark monoterpene ozonolysis at different temperatures, from -15 °C  
142 to 20 °C. In practice, the experimental plan focused on  $\alpha$ -pinene oxidation at two different concentrations (10  
143 ppb and 50 ppb) for three different temperatures: -15 °C, 0 °C and 20 °C. Two additional experiments were  
144 conducted with temperatures ramped from the coldest to the warmest or reversely during experiments at 10  
145 ppb of  $\alpha$ -pinene. For comparison, fixed temperature runs were also performed using  $\beta$ -pinene, at a  
146 concentration of 50 ppb. Ozone (100 ppb) was used as the main oxidant, but hydroxyl radicals also took part  
147 in the oxidation reactions as OH-scavengers were not employed in the experiments discussed here. According  
148 to model simulations using the master chemical mechanism v3.3.1 (Jenkin et al., 1997 & 2015; Saunders et  
149 al., 2003), ozonolysis accounted for approximately 2/3 and OH-oxidation for 1/3 of the  $\alpha$ -pinene oxidation  
150 respectively. A table summarizing the experiments of the campaign can be found in the Appendix (Table A1).

151

### 152 **2.3. Instrumentation**

153 The ACCHA experiment involved a diverse set of instruments measuring both the gas phase and the particle  
154 phase. The gas phase instrumentation included a Proton Transfer Reaction Time Of Flight Mass Spectrometer  
155 (PTR-TOF-MS, Model 8000-783, IONICON Inc., Jordan et al., 2009) for measuring the concentrations of the  
156 injected VOCs and other volatile products, as well as a nitrate-based Chemical Ionization Atmospheric  
157 Pressure interface Time of Flight (CI-APi-TOF, TOFWERK A.G. & Aerodyne Research Inc., Jokinen et al.,  
158 2012) mass spectrometer, analyzing the highly oxidized organic products of lower volatility (e.g. HOM). The  
159 CI-APi-TOF is described in more detail in the following section. The aerosol phase measurement was done  
160 using (1) a nano-Condensation Nuclei Counter (nCNC), being a combination of a Particle Size Magnifier  
161 (PSM, Model A10, Airmodus Ltd.) and a Condensation Particle Counter (CPC, Model A20, Airmodus Ltd.),  
162 (2) a Scanning Mobility Particle Sizer (SMPS; Kr-85 neutralizer (Model 3077A, TSI), electrostatic classifier

163 (Model 3082, TSI), nano-water-based CPC (Model 3788, TSI)), counting the size resolved particles from 10  
164 nm to 400 nm, (3) a High Resolution Time-Of-Flight Aerosol Mass Spectrometer (HR-TOF-AMS, Aerodyne  
165 Research Inc., Jayne et al., 2000) determining the chemical composition of non-refractory aerosol particles  
166 larger than ~35 nm. The temperature and relative humidity inside the chamber were monitored using HC02-  
167 04 sensors (HygroFlex HF320, Rotronic AG), and the ozone concentration was measured with an ozone  
168 monitor (O<sub>3</sub>-42 Module, Environment S.A.).

169

#### 170 **2.4. Measuring highly oxygenated organic molecules in the gas phase**

171 HOM present in the gas phase were measured using a CI-API-TOF mass spectrometer. The instrument is  
172 described by Jokinen et al. (2012), but also briefly presented here. Strong acids and highly oxygenated organic  
173 molecules have been shown to cluster efficiently with nitrate ion (Ehn et al., 2014; Hyttinen et al., 2015).  
174 Nitrate ions (i.e. NO<sub>3</sub><sup>-</sup>, HNO<sub>3</sub>NO<sub>3</sub><sup>-</sup> and (HNO<sub>3</sub>)<sub>2</sub>NO<sub>3</sub><sup>-</sup>), produced by exposure of nitric acid vapors to soft X-  
175 ray radiation, were electrostatically introduced into the sample flow of 10 LPM with a reaction time of roughly  
176 200 ms at atmospheric pressure. The ions, clusters with NO<sub>3</sub><sup>-</sup>, were sampled through a 300 μm critical orifice  
177 into the API, where ions were guided and focused by two segmented quadrupoles through chambers with  
178 gradually decreasing pressures (~2 mbar and ~10<sup>-2</sup> mbar, respectively). Finally, an ion lens assembly, at ~10<sup>-5</sup>  
179 mbar, guided the ions into the TOF chamber (~10<sup>-6</sup> mbar) where they were orthogonally extracted and their  
180 mass-to-charge ratios determined. The detected signal of each ion is then expressed as counts per second (cps)  
181 or counts per second normalized by the sum of reagent (nitrate) ions (norm. cps). More detail about the API-  
182 TOF itself can be found in Junninen et al. (2010). Quantification of HOM remains challenging, and, in this  
183 work, we aim at explaining the relative changes of HOM measured at different temperature rather than  
184 focusing on their absolute concentration. However, in some instances, we also estimate absolute quantities by  
185 applying a calibration factor  $C = 1.65 \cdot 10^9$  molecules cm<sup>-3</sup>, (cf. Jokinen et al., 2012, for details on C). As no  
186 calibrations were performed during the ACCHA experiments, the value was taken from a sulfuric acid  
187 calibration (methodology according to Kürten et al., 2012) performed during an earlier measurement  
188 campaign. While associated with a large uncertainty (estimated to be at least -50 % / +100 %), using this value  
189 we obtained HOM molar yields (as described in later sections) of a similar range as earlier studies (Jokinen et  
190 al., 2012; Ehn et al., 2014).

191 **2.5. HOM dynamics in a batch mode chamber**

192 Being configured in batch mode, without active mixing, the AURA chamber is a dynamic reactor where  
193 concentrations of products are a function of cumulative sources and cumulative sinks from the start of the  
194 experiment. In the case of HOM, their lifetime in the gas phase must be short due to their low vapor pressure  
195 and, thus, their fast condensation. This means that the measured HOM concentrations are mainly the result of  
196 production and loss having occurred within the previous minutes, as described in more detail in the following  
197 section.

198

199 The temporal change in HOM concentrations (i.e.  $\frac{d[HOM]}{dt}$ ) can be expressed as the sum of the production  
200 terms and loss terms. The HOM formation is governed by the VOC reaction rate while the loss is dominated  
201 by condensation onto particles or walls. For the yield estimation analysis, we focus mainly on the high  
202 concentration experiments (i.e.  $[\alpha\text{-pinene}] = 50$  ppb), where the high condensation sink (CS, on the order of  
203  $0.1 \text{ s}^{-1}$ ) will dominate over the wall loss rate. In a smaller chamber with active mixing, the wall loss rate for  
204 low-volatile species has been estimated to be around  $10^{-2} \text{ s}^{-1}$  (Ehn et al., 2014), and in the AURA chamber we  
205 expect it to be much slower, likely on the order of  $10^{-3} \text{ s}^{-1}$ . Therefore, we can formulate simplified expression  
206 as in the following equations:

207

208 
$$\frac{d[HOM]}{dt} = \gamma_{HOM} \cdot k \cdot [VOC] \cdot [O_3] - CS \cdot [HOM] \quad (Eq. 1)$$

209

210 
$$\gamma_{HOM} = \frac{\frac{d[HOM]}{dt} + CS \cdot [HOM]}{k \cdot [VOC] \cdot [O_3]} \quad (Eq. 2)$$

211

212 Herein,  $\gamma_{HOM}$  corresponds to the HOM yield. The temperature-dependent rate constant of  $\alpha$ -pinene ozonolysis,  
213  $k$ , was taken to be  $8.05 \cdot 10^{-16} e^{-640/(273.15+T)} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ , where  $T$  is the temperature in degrees Celsius,  
214 (Atkinson, 2000; Calvert et al., 2002). Since the majority of HOM are irreversibly lost upon contact with a  
215 surface (Ehn et al., 2014), the CS represents the total sink at a time  $t$ . The CS was estimated for an “average  
216 HOM”, in this case  $C_{10}H_{16}O_7$  (being one of the most abundant HOM), using the measured particle number size

217 distributions from the SMPS. The molecular properties that govern the CS are the mass accommodation  
218 coefficient, the molecular diffusion coefficient and the mean molecular speed. Based on the work by Julin et  
219 al. (2014), the mass accommodation coefficient was set to unity. The molecular diffusion coefficient was  
220 calculated using Fuller's method (Tang et al., 2015) and the mean molecular speed was calculated using kinetic  
221 theory. Both the molecular diffusion and speed depend on the absolute temperature during the experiments.  
222 With the aforementioned assumptions, a distinct yield for each identified HOM of interest can be derived based  
223 on Eq. 2, as the slope of a linear fit to the data during an experiment, with  $k \cdot [VOC] \cdot [O_3]$  on the x-axis and  
224  $\frac{d[HOM]}{dt} + CS \cdot [HOM]$  on the y-axis.

225

## 226 3. Results & Discussion

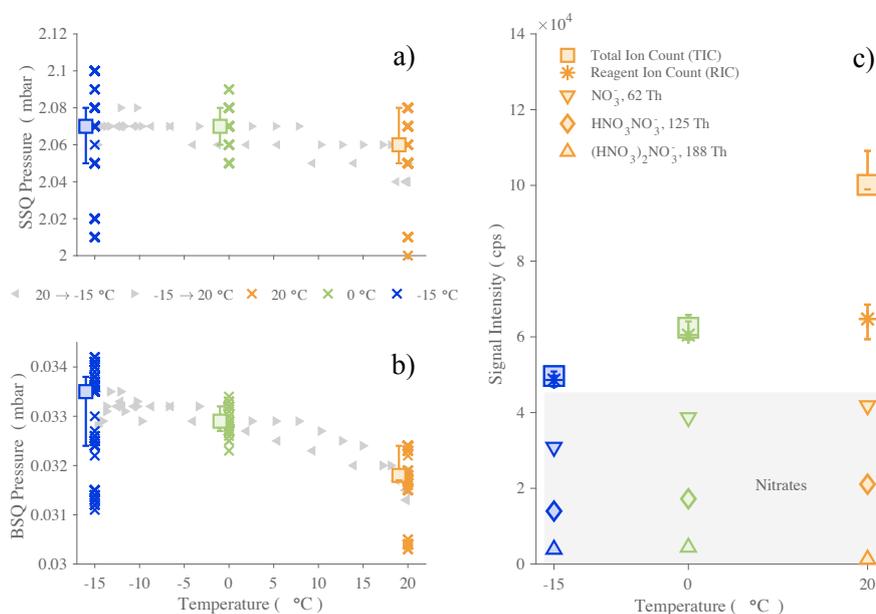

227

### 228 3.1. Effect of the temperature on the CI-API-TOF

229 Since this work targets the variation of HOM in relation to temperature, it is necessary to assess the reliability  
230 of the CI-API-TOF measurement towards temperature variations. The sensitivity towards a certain molecule  
231 depends to first approximation on the charging efficiency in the CI inlet and the transmission efficiency of the  
232 sampled ion in the API-TOF. The charging efficiency of a HOM is primarily determined by the stability of the  
233  $HOM \cdot NO_3^-$  cluster relative to the  $HNO_3 \cdot NO_3^-$  cluster (Hyttinen et al., 2015), and we do not expect  
234 temperature to cause a large difference in this relative behavior. However, the transmission can be sensitive to  
235 small changes, and especially pressures inside the instrument are important to monitor, as the optimal voltages  
236 guiding the sampled ions through the instrument have been tuned for specific pressures. The pressures of the  
237 two quadrupole chambers (named “SSQ” and “BSQ”, respectively, where the pressure dependence is the  
238 largest) as well the Total Ion Count (TIC, i.e. sum of all signals), the Reagent Ion Count (RIC, i.e. sum of  
239 nitrate ion signals) and the contributions of each nitrate ion signals are presented in Figure 1. The SSQ  
240 pressures (Fig. 1a) were found relatively stable (average:  $\sim 2.07$  mbar) and the BSQ averaged pressure (Fig.  
241 1b) was  $\sim 3.3 \cdot 10^{-2}$  mbar, which are typical values for this instrument. Unfortunately, the other instrumental  
242 pressures (i.e. ion lens assembly chamber or TOF chamber pressures) were not recorded due to sensor failures.  
243 However, as these chambers are at low enough pressures that ion-gas collisions are very rare, any possible

244 small variations in the pressures are unlikely to affect our results. When going from the coldest temperature (-  
245 15 °C) to the highest (20 °C), in a continuous temperature ramp, the SSQ pressure decreased by ~0.01 mbar,  
246 corresponding to a relative change of 0.5 % (Fig. 1a). Over the same temperature range, the pressure within  
247 the second chamber (BSQ) decreased by  $\sim 1.5 \cdot 10^{-3}$  mbar ( $\sim 4.5$  %) when the temperature varied by 35 °C (Fig.  
248 1a). The same characteristics were observed when comparing across experiments performed at constant  
249 temperatures and for the continuous temperature ramping experiments. The SSQ pressure values below 2.02  
250 mbar at -15 °C and 20 °C, corresponding also to the lowest BSQ pressures measured, were related to  
251 particularly low ambient pressures ( $\sim 981.8$  mbar). Thus, the effect of temperature within the AURA chamber  
252 caused smaller variability of the internal pressures than ambient pressure changes.  
253

254

255

256 Figure 1: Evolution of the CI-API-TOF pressures in the first (a) and second (b) quadrupole chambers (SSQ and BSQ, respectively) and  
257 signal counts (c) as a function of temperature in the AURA chamber. The API pressures (panels a & b) are represented by crosses,  
258 depicting 10-minute averaged data points for all  $\alpha$ -pinene ozonolysis experiments, colored by temperature (blue for -15 °C, green for  
259 0 °C and orange for 20 °C). The squares are the median values for each temperature with their 75th and 25th percentiles. Additionally,  
260 the gray triangles relate the data (10-minute averages) of two temperature ramp experiments, from -15 °C to 20 °C (right-pointing

261 triangles) or from 20 °C to -15 °C (left-pointing triangles). Panel c) shows averages of the sum of all ion signals (TIC, square-markers)  
262 and the sum of all reagent ion signal (RIC, asterisks-markers). RIC markers also include 25th and 75th percentiles. Nitrate signal  
263 contributions are also included separately (markers in gray-shaded area: down pointing triangle for  $\text{NO}_3^-$ , diamond marker for  
264  $\text{HNO}_3\text{NO}_3^-$  and triangle pointing upward for  $(\text{HNO}_3)_2\text{NO}_3^-$ ).

265

266 The RIC signal (Fig. 1c) stayed within the range  $5\text{-}7 \cdot 10^4$  cps, with its lowest values observed at -15 °C. The  
267 comparatively larger increase in TIC at the highest temperature is mainly explained by the fact that much  
268 higher HOM concentrations were formed at 20 °C compared to lower temperature experiments, and the  
269 transmission at these masses is generally higher than in the region of the reagent ions (Junninen et al., 2010;  
270 Ehn et al., 2011; Heinritzi et al., 2016). We conclude from the above investigations that changes on the order  
271 of tens of percent occurred in our instrument as the AURA chamber temperature was varied, and that only  
272 signal changes larger than this should be attributed to actual perturbations in the chemistry taking place in the  
273 chamber.

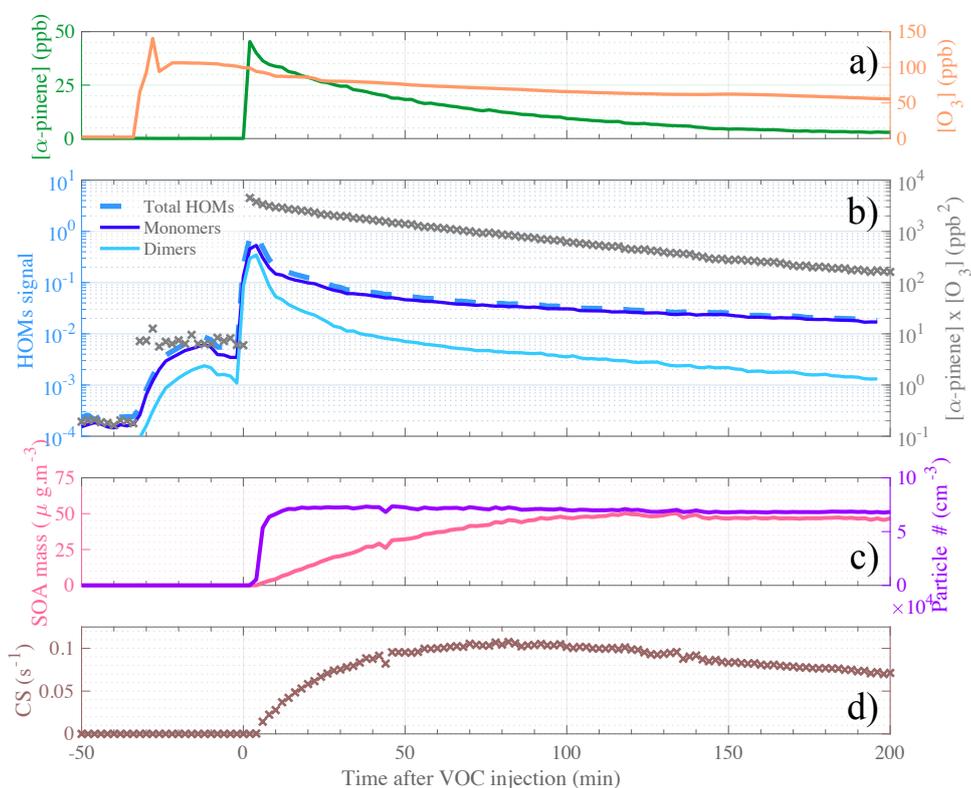

274

### 275 3.2. Ozonolysis reaction in the AURA chamber: a typical $\alpha$ -pinene experiment at 20 °C

276 Selected gas phase precursors and products, including aerosols, for a high-load (i.e. 50 ppb, during 12-Jan-  
277 2017)  $\alpha$ -pinene oxidation experiment at 20 °C are shown in Figure 2. The steep increase in  $\alpha$ -pinene  
278 concentration, measured by PTR-TOF-MS, indicates the start (defined as time 0) of the oxidation reaction  
279 experiment (Fig. 2a). The formed aerosol product, i.e. particle number and aerosol mass, are presented in Fig.  
280 2c. Herein, we observe an increase of the aerosol mass over the first two hours of the experiment whereas the  
281 particle number concentration plateaued in the first ten minutes after VOC injection. On the other hand, the  
282 HOM signals (Fig. 2b) show a large increase immediately as the VOC was injected. A smaller increase was  
283 also observed when the ozone was introduced, most likely due to residual volatiles reacting with ozone inside  
284 the chamber. After the first 10 min, HOM signals start to decrease as the CS (Fig. 2d) rapidly increases under  
285 these high aerosol loads. After the first half hour, the CS only changes by some tens of percent, while the  
286 VOC oxidation rate (gray crosses in Fig. 2b) decreases around one order of magnitude over the following  
287 hours of the experiment. Therefore, concentrations of low-volatile HOM should largely track the decay rate of  
288 the VOC oxidation rate, which is also observed. We observe a slower decay of HOM monomers than dimers,

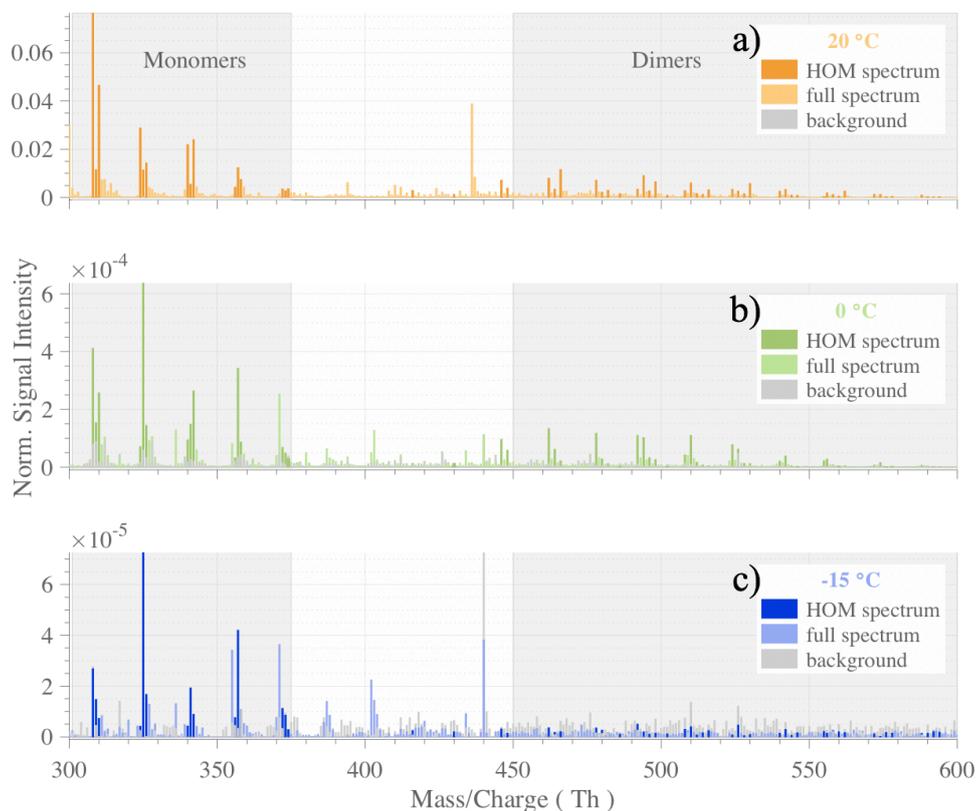

289 suggesting that some of the monomers may be semi-volatile enough to not condense irreversibly upon every  
290 collision with a surface, and/or that the VOC oxidation rate also influences the formation chemistry, as  
291 discussed in more detail in later sections.  
292

293  
294 **Figure 2:** Temporal evolution of the main parameters during a typical  $\alpha$ -pinene ozonolysis experiment (initial conditions:  $[\alpha$ -pinene]  
295 = 50 ppb,  $[O_3] = 100$  ppb,  $T = 20$  °C). Reactant concentrations are shown in Panel a, with  $\alpha$ -pinene concentration in dark green and  
296 ozone concentration in orange. HOM signals are plotted in Panel b, with a distinction between Total HOM (dashed medium-blue line),  
297 HOM monomers ( $C_{10}H_{14-16}O_{7-11}$ , dark blue line) and HOM dimers ( $C_{19-20}H_{28-32}O_{10-18}$  light blue line), as well as the product  $[\alpha$ -pinene]  
298  $\cdot [O_3]$  represented by gray cross markers. Panel c depicts the SOA mass (pink line) and the particle concentration (purple line). Panel  
299 d shows the evolution of the condensation sink. The time span (in x-axis) is expressed as minutes after  $\alpha$ -pinene injection, thus the  
300 time zero represents the start of the experiment.  
301

302 For a more detailed investigation at the HOM formation upon the reaction between ozone and  $\alpha$ -pinene, we  
303 compare compounds observed in the range between 300 – 600 Thomson (Th) in the CI-API-TOF, during a  
304 background measurement before and 10 min after  $\alpha$ -pinene injection for each temperature (Figure 3). The  
305 largest HOM signals, highlighted in darker colors, are primarily observed at the highest temperature, but also  
306 in the monomer area (300 – 375 Th). The dimer signals (between 450 – 600 Th) are smaller, but still contribute  
307 significantly to the total HOM concentration. With the exception of the -15 °C experiment where HOM dimers  
308 already reach the background level after 10 min, all molecules selected as representative HOM are present in  
309 all the spectra. The detailed peak list of HOM compounds, selected for their high signal intensity, including  
310 exact masses and elemental composition is provided in the Appendix (Table A2).  
311

312

313 **Figure 3:** Typical HOM mass spectra observed during  $\alpha$ -pinene ozonolysis experiments (initial conditions: [ $\alpha$ -pinene] = 50 ppb, [ $O_3$ ]

314 = 100 ppb), at T = 20 °C (panel a) in orange, T = 0 °C (panel b) in green, T = -15 °C (panel c) in blue. The normalized signals were

315 averaged over 2 minutes during background measurement before VOC injection (gray bars), and 10 min after  $\alpha$ -pinene injection  
316 (colored bars). Specific masses, selected for representing high-intensity HOM, are highlighted in darker colors. Gray-shaded areas  
317 show HOM sub-ranges of monomers and dimers.

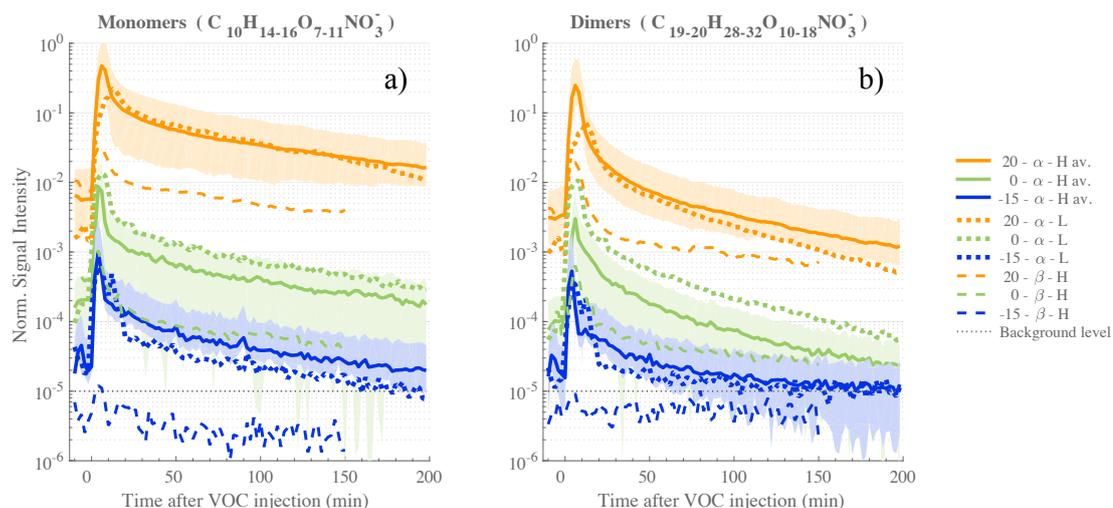

318

319

### 320 3.3. Effect of the temperature on measured HOM

321 We performed a total of twelve  $\alpha$ -pinene ozonolysis experiments with seven at high loading (i.e. [ $\alpha$ -pinene] =  
322 50 ppb), out of which two were conducted at 20 °C, two at 0 °C and three at -15 °C. Three experiments were  
323 performed with [ $\alpha$ -pinene] = 10 ppb – one for each aforementioned temperature. Experiments with 50 ppb of  
324  $\beta$ -pinene were also performed at the same three temperatures (see Table A2). An overview of HOM  
325 measurements for the different experiments is shown in Figure 4, with distinction between HOM monomers  
326 (Fig. 4a) and dimers (Fig. 4. b) as defined earlier.

327

328

329 **Figure 4:** Time series of HOM measured during the ACCHA campaign. HOM monomer (a) and dimer (b) traces include compounds  
330 with a chemical composition of C<sub>10</sub>H<sub>14-16</sub>O<sub>7-11</sub> and C<sub>19-20</sub>H<sub>28-32</sub>O<sub>10-18</sub>, respectively. The series are colored based on temperature, orange  
331 for 20 °C experiments, green for 0 °C and blue for -15 °C. Statistics over  $\alpha$ -pinene (“ $\alpha$ ” in the legend) high load (50 ppb, “H”)  
332 experiments are shown, with averaged values (“av.” in continuous line) and the maximum and minimum values of the measured HOM

333 signal (bounded shaded area).  $\alpha$ -pinene low load (L) experiments are symbolized with colored dotted lines and the  $\beta$ -pinene (“ $\beta$ ”)  
334 experiments by dashed lines. The gray dotted line depicts the estimated background level of the CI-API-TOF.

335

336 For a similar experiment type (i.e. same initial VOC concentrations), it can be seen that the resulting HOM  
337 concentrations were considerably impacted by the temperature at which the oxidation reaction occurred. The  
338 signal intensity for HOM monomers from  $\alpha$ -pinene measured 30 minutes after the VOC injection was roughly  
339 two orders of magnitudes higher at 20 °C compared to 0 °C, and about three orders of magnitude higher  
340 compared to the -15 °C experiment. Very similar behavior is observed with respect to temperature for the  
341 dimer species as well, but with the differences that (1) less dimers are found in comparison to the HOM  
342 monomers and (2) HOM dimer concentrations are found to decrease at a faster rate during the experiment. The  
343 faster decrease of dimers compared to monomers results either from a lower production or a higher loss for  
344 dimers towards the end of the experiments. We expect that the reduced [ $\alpha$ -pinene] and [ $O_3$ ], leading to slower  
345 oxidation rates and consequently lower [ $RO_2$ ] will have a greater impact on the dimers than the monomers, as  
346 the formation rate of dimers is proportional to [ $RO_2$ ]<sup>2</sup>, while monomers can still be formed efficiently via other  
347  $RO_2$  termination pathways, as discussed earlier.

348

349 When comparing the high (50 ppb) and low (10 ppb) loading  $\alpha$ -pinene experiments, HOM signals were within  
350 the same range of concentration, and even higher at 0 °C the HOM were even more abundant in the low initial  
351 VOC concentration. Although this result may seem surprising at first, it only verifies our assumptions in Eq.  
352 1 that the HOM concentration is a relatively simple function of formation and loss rates. Despite the fact that  
353 the low-concentration experiments had five times lower [VOC] (and consequently five times lower HOM  
354 formation rate), the condensation sink, being the primary loss for HOM, was ~8 times due to reduced aerosol  
355 formation. In other words, the loss rates decreased more than the formation rate when the precursor  
356 concentration was lowered, resulting in an increase of [HOM].

357

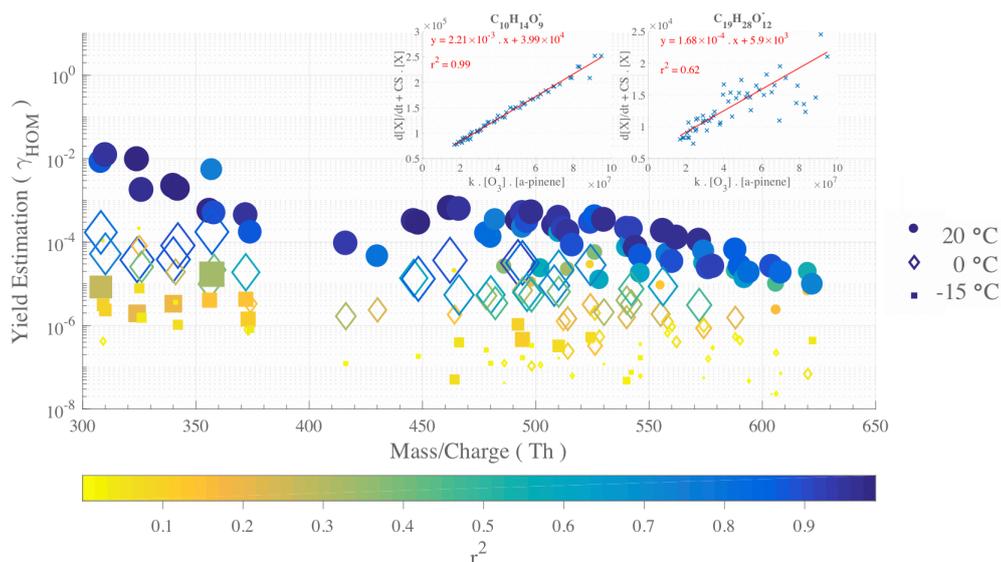

358 Finally, the use of  $\beta$ -pinene as HOM precursor produced significantly less HOM, with concentrations being  
359 more than a factor of 10 lower compared to experiments performed with  $\alpha$ -pinene at the same conditions. This

360 agrees with earlier studies (Jokinen et al., 2014; Ehn et al., 2014) which have shown clearly lower HOM yields  
361 for  $\beta$ -pinene compared to  $\alpha$ -pinene ozonolysis. The difference is primarily attributed to the exocyclic double  
362 bond in  $\beta$ -pinene. Note that, the  $\beta$ -pinene HOM concentrations at the lowest temperature,  $-15\text{ }^{\circ}\text{C}$ , were below  
363 the instrumental limit of detection.

364

### 365 3.4. Yield estimation and temperature influence for molecule-specific HOM

366

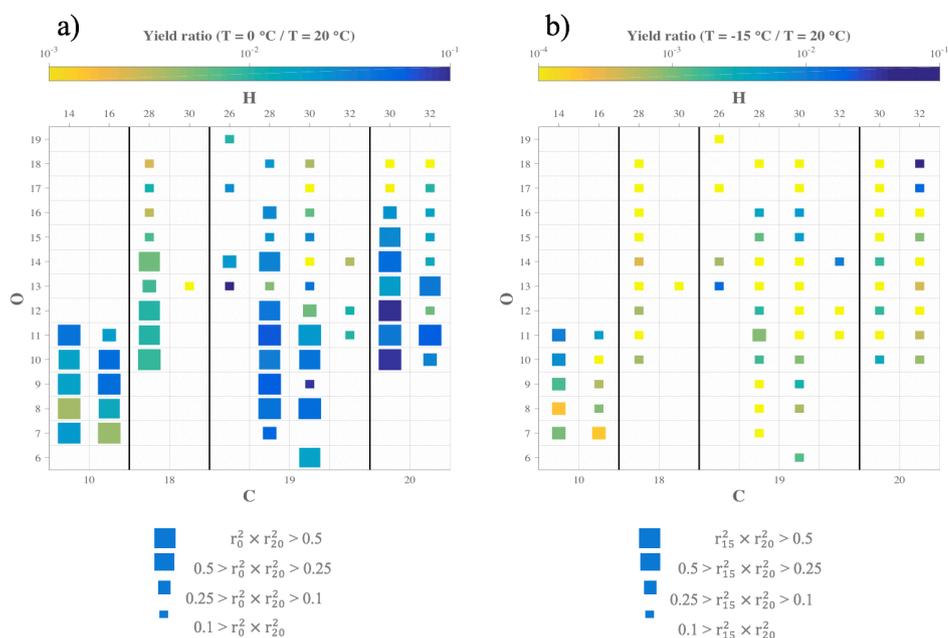

367 **Figure 5:** Yield estimations for individual  $\alpha$ -pinene HOM from linear fits at  $20\text{ }^{\circ}\text{C}$ ,  $0\text{ }^{\circ}\text{C}$  and  $-15\text{ }^{\circ}\text{C}$ . Filled circles symbolize data from  
368 a  $20\text{ }^{\circ}\text{C}$  experiment (12-Jan-2017), diamond symbols illustrate  $0\text{ }^{\circ}\text{C}$  data (16-Jan-2017), and the filled squares represents  $-15\text{ }^{\circ}\text{C}$  data  
369 (13-Jan-2017). The markers are colored and sized by  $r^2$  values, coefficient of determination, evaluating the goodness of the linear fit  
370 used to derive the yields. The top-right insets show two examples (for  $\text{C}_{10}\text{H}_{14}\text{O}_9$  and  $\text{C}_{19}\text{H}_{28}\text{O}_{12}$ ) of the yield determination by robust  
371 linear fits to the variables described in the methods section.

372

373 We determined yield estimates, individually for each HOM of interest, from the results of a robust linear fit as  
374 described in the methods section and Eq. 2. The yield results are shown in Figure 5, with fit examples shown  
375 for  $\text{C}_{10}\text{H}_{14}\text{O}_9$  and  $\text{C}_{19}\text{H}_{28}\text{O}_{12}$  in the insets. As expected, based on Figure 4, the retrieved yield values ( $\gamma_{\text{HOM}}$ )

376 decrease considerably with colder reaction conditions, with a total HOM yield (i.e. sum of the individual yields  
 377 for each temperature) found to be 5.2 % at 20 °C, 0.10 % at 0 °C and  $6.3 \cdot 10^{-3}$  % at -15 °C.  
 378 We again emphasize the large uncertainties in these absolute estimates, but the HOM yield estimated for T =  
 379 20 °C does agree well with earlier reported values (e.g. Ehn et al. (2014), Jokinen et al. (2014), Sarnela et al.  
 380 (2018)). As the largest contribution to the HOM yield comes from the least oxidized monomers (e.g. high  
 381 signal intensity at 308 Th and 310 Th for  $C_{10}H_{14}O_7$  and  $C_{10}H_{16}O_7$  respectively), the molar yield may be slightly  
 382 over-estimated, especially at 20 °C, due to the loss rates possibly being lower than assumed if these HOM are  
 383 not condensing irreversibly onto the aerosol.  $\gamma_{HOM}$  values are on average higher for HOM monomers than for  
 384 dimers, with the overall shape of the distribution closely resembling the mass spectrum in Figure 3. We  
 385 performed the same calculation for the experiment were  $[\alpha\text{-pinene}] = 10$  ppb and found total HOM-yields in  
 386 the same range, as the numbers found at 50 ppb, considering our estimated uncertainty: 8.8 % at 20 °C, 0.25  
 387 % at 0 °C and  $5.5 \cdot 10^{-3}$  % at -15 °C. The slightly higher values may indicate that at the higher loadings,  
 388 bimolecular RO<sub>2</sub> termination reactions are already occurring so fast that autoxidation is hampered. The total  
 389 HOM yield decrease when going from 20 °C to 0 °C decreased by a factor 50 at the higher loadings, while the  
 390 corresponding value at lower loadings was 35.

392 **Figure 6:** Comparison of yields for specific HOM compositions at different temperatures. Each square symbolizes a specific HOM  
393 measured by the CI-APi-TOF. The elemental composition can be read by taking the number of C atoms from the bottom axis, the  
394 number of H atoms from the top axis, and the number of O atoms from the left axis. The size of the square depicts the goodness of fit  
395 ( $r^2$ ) used to derive the yields, and color shows the ratio of the yield at 0 °C (Panel a) or -15 °C (Panel b) compared to the yield measured  
396 at 20 °C.

397

398 While Figure 5 showed the estimated yields for every HOM at every temperature probed, specific chemical  
399 composition cannot be read from the plot. In order to assess the impact of temperature of the yield of HOM  
400 based on each elemental composition, Figure 6 depicts for each compound the ratio of the yield at 0 °C (Fig.  
401 6a) or -15 °C (Fig. 6b) compared to the yield at 20 °C for a high load experiment of  $\alpha$ -pinene ozonolysis. In  
402 Fig. 6a, many larger squares are observable, indicating a good reliability of our comparison analysis, but in  
403 Fig. 6b, it is clear that the HOM concentrations at the lowest temperature were too low to provide much reliable  
404 compound-specific information. From Fig. 6a we see no clear trend in the yield change for any column (i.e.  
405 changing oxygen content HOM with a given amount of C and H). The HOM yields yield ratios between the  
406 two temperatures are primarily within  $10^{-2} - 10^{-1}$ , meaning that the molecule-specific yields dropped to  
407 between 1-10% when temperature decreased from 20 °C to 0 °C. If autoxidation of RO<sub>2</sub> decreased this  
408 considerably, one could have expected the more oxygenated HOM to decrease more than the less oxygenated  
409 ones. However, this did not seem to be the case, as e.g. some of the most abundant HOM C<sub>10</sub>H<sub>14</sub>O<sub>7</sub>, C<sub>10</sub>H<sub>14</sub>O<sub>9</sub>,  
410 and C<sub>10</sub>H<sub>14</sub>O<sub>11</sub> seemingly decreased the same amounts. One possible interpretation of this is that the rate-  
411 limiting step in the autoxidation chain takes place in RO<sub>2</sub> radicals with 6 or less O atoms, which are not detected  
412 with our CI-APi-TOF, while the later H-shift reactions are fast enough that other reactions still do not become  
413 competitive. These “non-HOM” RO<sub>2</sub> radicals may then also be key molecules for determining the final  
414 branching leading to the different observed HOM with 7 or more O atoms. This may shed light on one of the  
415 main open challenges (Ehn et al., 2017) in understanding HOM formation, namely how RO<sub>2</sub> radicals with e.g.  
416 6, 8 and 10 O atoms can form within a second, yet the relative distribution of these three does not change if  
417 the reaction time is allowed to increase (Berndt et al., 2015). Since the O<sub>10</sub>-RO<sub>2</sub> (or its closed shell products)  
418 are not seen to accumulate over time, our results here provide support for a pathway where the O<sub>6</sub>- and O<sub>8</sub>-  
419 RO<sub>2</sub> are to some extent “terminal” products incapable of further fast H-shift reactions, while the O<sub>10</sub>-RO<sub>2</sub> has

420 been formed via another branch of the reaction where the autoxidation is able to proceed further. In this branch,  
421 the O<sub>6</sub>- and O<sub>8</sub>-RO<sub>2</sub> are likely only short-lived intermediates. While in no way conclusive, this highlights the  
422 need for fast measurements of HOM formation as well as improved techniques for observing less oxidized  
423 RO<sub>2</sub> radicals.

424

425 The only compound group where a slight decrease can be seen as a function of O-atom content is the  
426 C<sub>20</sub>H<sub>30</sub>O<sub>n</sub> dimers. Interestingly, these also show some of the smallest yield ratios of all compounds. At the  
427 same time, the level of C<sub>18</sub> dimers appears to drop most of all compound groups, potentially suggesting that  
428 the mechanism through which carbon atoms were lost on the way to the C<sub>18</sub> dimers was sensitive to  
429 temperature, and at 0 °C the fragmentation was less prominent. It is conceivable that the different branching  
430 at 0 °C caused some of the C<sub>18</sub> dimer precursors to form C<sub>20</sub> dimers instead. However, this issue would need  
431 more detailed experiments in order to verify.

432

433 The decrease in HOM yield due to slower RO<sub>2</sub> H-shift rates at lower temperatures was found to be very  
434 dramatic under our conditions. However, the exact magnitude of this decrease in HOM yield is determined by  
435 the processes competing with the H-shifts. Under our conditions, the RO<sub>2</sub> lifetime is kept quite short, both due  
436 to bimolecular (RO<sub>2</sub> + RO<sub>2</sub> or RO<sub>2</sub> + HO<sub>2</sub>) reactions and collisions with particles, and therefore any reduction  
437 in H-shift rates can strongly reduce the HOM yield. Inversely, under very low loadings, the RO<sub>2</sub> lifetime may  
438 be long enough that the temperature decreases from 20 °C to 0 °C may cause much smaller changes in the  
439 HOM yields. If the lifetime of RO<sub>2</sub> radicals is clearly longer than the time needed for multiple consecutive H-  
440 shifts to take place, HOM yields would decrease only marginally with temperature. In the atmosphere, RO<sub>2</sub>  
441 lifetime will often be governed by NO, which means that there can exist an intricate dependence of HOM  
442 yields as a function of temperature, VOC type, VOC oxidation rate, and NO<sub>x</sub>.

443

#### 444 4. Conclusion

445

446 We present laboratory studies of HOM formation from monoterpene ozonolysis at different temperatures (20  
447 °C, 0 °C, and -15 °C). Our main insight is that temperature considerably impacted the HOM formation,  
448 decreasing the observed HOM yield by around 50-fold upon a decrease by 20 °C. The exact temperature  
449 dependence of HOM formation in general is likely both VOC- and loading-dependent, due to the competition  
450 between autoxidation and termination reactions, and will likely be smaller at lower loadings. While  
451 autoxidation is expected to decrease with temperature, our result is still striking as it takes place over a  
452 temperature range which is atmospherically relevant for areas where monoterpene emissions are abundant, e.g.  
453 the boreal forest. One important observation was that HOM were present at all measured temperatures with  
454 roughly similar spectral distributions. This suggested that the total HOM yield as well as the final HOM  
455 distribution are mainly determined by the first H-shift steps, i.e. in the region where the CI-API-TOF is unable  
456 to measure. This highlights the need for more comprehensive observations of autoxidation, allowing direct  
457 observations of the critical steps determining the HOM yields and, subsequently, the production rate of low-  
458 volatile organic compounds able to form secondary organic aerosol.

459

## 460 **Authors Contribution**

461

462 M. Ehn, M. Bilde, and M. Glausius supervised the ACCHA campaign. L.L.J Quéléver, K. Kristensen, M. Bilde  
463 and M. Ehn designed the experiments. K. Kristensen and L. N. Jensen initialized the chamber for experiments.  
464 L.L.J. Quéléver performed the measurement and analyzed the gas-phase HOM. K. Kristensen and L. N. Jensen  
465 measured and analyzed the aerosol phase. K. Kristensen, B. Rosati and R. Teiwes measured and analyzed the  
466 VOCs and their semi-volatile oxidation production. M. Ehn, K. Daellenbach, O. Peräkylä and P. Roldin guided  
467 and helped the analysis of HOM yield performed by L.L.J. Quéléver. L. L. J. Quéléver prepared the manuscript  
468 with the contribution from all co-authors.
