Abstract. Atmospheric aerosols scatter or absorb a fraction of the incoming solar radiation to cool or warm the atmosphere, decreasing surface temperature and altering atmospheric stability to further affect the dispersion of air pollutants in the planetary boundary layer (PBL). In the present study, simulations during a persistent and heavy haze pollution episode from 05 December 2015 to 04 January 2016 in the North China Plain (NCP) were performed using the WRF-Chem model to comprehensively quantify contributions of aerosol shortwave radiative feedback (ARF) to near-surface (around 15 m above the ground surface) PM_{2.5} mass concentrations. The WRF-Chem model generally performs well in simulating the temporal variations and spatial distributions of air pollutants concentrations compared to observations at ambient monitoring sites in the NCP, and the simulated diurnal variations of aerosol species are also consistent with the measurements in Beijing. Additionally, the model simulates well the aerosol radiative properties, the downward shortwave flux, and the PBL height against observations in the NCP. During the episode, ARF deteriorates the haze pollution, increasing the near-surface PM_{2.5} concentrations in the NCP by 10.2 $\mu\text{g m}^{-3}$ or with a contribution of 7.8% on average. Sensitivity studies have revealed that high loadings of PM_{2.5} attenuate the incoming solar radiation reaching the surface to cool the low-level atmosphere, suppressing development of PBL, decreasing the surface wind speed, further hindering the PM_{2.5} dispersion and consequently exacerbating the haze pollution in the NCP. Furthermore, when the near-surface PM_{2.5} mass concentration increases from around 50 to several hundred $\mu\text{g m}^{-3}$, ARF contributes to the near-surface PM_{2.5} by more than 20% during daytime in the NCP, substantially aggravating the heavy haze formation. However, when the near-surface PM_{2.5} concentration is less than around 50 $\mu\text{g m}^{-3}$, ARF generally reduces the

41 near-surface $PM_{2.5}$ concentration due to the consequent perturbation of atmospheric dynamic
42 fields.

48 1 Introduction

49 Atmospheric aerosols, produced both naturally and anthropogenically, influence the
50 radiative energy budget of the Earth's atmospheric system in many ways. They scatter or
51 absorb a fraction of the incoming solar radiation to cool or warm the atmosphere, decreasing
52 surface temperature and altering atmospheric stability (e.g., Ackerman, 1977; Jacobson, 1998,
53 2002). Also, they serve as cloud condensation nuclei (CCN) and ice nuclei (IN), thus
54 modifying cloud optical properties and lifetime (e.g., Zhang et al., 2007; Li et al., 2008;
55 2009). Among those impacts, the scattering and absorption of solar radiation by aerosols and
56 the associated feedbacks (hereafter referred to as aerosol-radiation feedback or ARF) not only
57 constitute one of the main uncertainties in climate prediction (IPCC, 2007), but also
58 substantially affect the atmospheric chemistry by perturbing the temperature profile and
59 moistures, winds, and planetary boundary layer (PBL) stability (Boucher et al., 2013).
60 Particularly, as a short-lived pollutant with uneven distribution and physical and chemical
61 heterogeneities in the atmosphere, ARF varies by more than a factor of ten with location or
62 time of emissions (Penner et al., 2010).

63 During wildfire with high loading absorbing aerosols, ARF has been reported to heat the
64 atmosphere and cool the surface, and thence enhance the PBL stability (e.g., Grell et al., 2011;
65 Fu et al., 2012; Wong et al., 2012). In addition, numerous studies have been performed to
66 evaluate impacts of ARF of dust on the regional meteorology and climate (e.g., Perez et al.,
67 2006; D. Zhang et al., 2009; Santese et al., 2010). Anthropogenic aerosols, dominated by
68 scattering components, such as organics and sulfate, primarily attenuate the incoming solar
69 radiation down to the surface, cooling the temperature of the low-level atmosphere to
70 suppress the development of PBL and hinder the aerosol dispersion in the vertical direction
71 (e.g., Fast et al., 2006; Vogel et al., 2009; Zhang et al., 2010). In addition, the temperature
72 profile perturbation caused by ARF also alters cloud formation and development, possibly

73 causing the precipitation delay or decrease (e.g., Zhao et al., 2005; Koch and Del Genio, 2010;
74 Ding et al., 2013).

75 Rapid industrialization and urbanization in China have significantly elevated the
76 concentrations of aerosols or fine particulate matters ($PM_{2.5}$), causing frequent occurrence of
77 haze pollution, particularly during wintertime in North China (e.g., Zhang et al., 2013; Pui et
78 al., 2014). Guo et al. (2014) have elucidated the haze formation mechanism in China,
79 highlighting the efficient aerosol nucleation and growth during haze episodes. Moreover,
80 high loading aerosols during heavy haze episodes induce efficient ARF, encumbering the
81 PBL development and further deteriorating the haze pollution. It is worth noting that ARF
82 increases precursors for the aerosol nucleation and growth in the PBL, such as sulfuric and
83 organic gases, causing efficient aerosol nucleation and growth (Zhang et al., 2004; Guo et al.,
84 2014). Based on field measurements, recent studies have proposed that the high level of
85 $PM_{2.5}$ increases the stability of PBL due to ARF and further decrease the PBL height (PBLH),
86 consequently enhancing $PM_{2.5}$ concentrations ($[PM_{2.5}]$) (Quan et al., 2013; Petaja et al., 2016;
87 Yang et al., 2016; Tie et al., 2017; Ding et al., 2017). Online-coupled meteorology and
88 chemistry models have also been used to verify the impact of ARF on the PBLH and
89 near-surface $[PM_{2.5}]$ during haze episodes in Europe, Eastern China and Northern China
90 (Forkel et al., 2012; Z. Wang et al., 2014; Wang et al., 2015; Zhang et al., 2015; Gao et al.,
91 2015). However, the ARF impact on near-surface $[PM_{2.5}]$ varies, depending on the evaluation
92 time and location (Table 1). For example, the two-way coupled WRF-CMAQ system has
93 been employed to evaluate the ARF contribution to the haze formation in January 2013 over
94 the North China Plain (NCP), showing that ARF reduces the PBLH by 100 m and enhances
95 near-surface $[PM_{2.5}]$ by up to $140 \mu g m^{-3}$ in Beijing (J. Wang et al., 2014). Therefore, it is
96 still imperative to comprehensively quantify the ARF contribution to near-surface $[PM_{2.5}]$
97 under various pollution levels to provide the underlying basis for supporting the design and

98 implementation of emission control strategies.

99 In this study, simulations are performed using the Weather Research and Forecasting
100 model with Chemistry (WRF-Chem) to interpret the relationship between the near-surface
101 [PM_{2.5}] and the PBLH and further quantify the ARF contribution to near-surface [PM_{2.5}]
102 under various pollution levels. The model and methodology are described in Section 2.
103 Analysis results and discussions are presented in Section 3, and summary and conclusions are
104 given in Section 4.

105 2 Model and methodology

106 2.1 WRF-Chem model and configurations

107 The WRF-Chem model (Grell et al., 2005) with modifications by Li et al. (2010, 2011a,
108 b, 2012) is applied to evaluate effects of ARF on the wintertime haze formation in the NCP.
109 The model includes a new flexible gas phase chemical module, which can be used with
110 different chemical mechanisms, such as CBIV, RADM2, and SAPRC. In the study, the
111 SAPRC99 chemical mechanism is used based on the available emission inventory. For the
112 aerosol simulations, the CMAQ/models3 aerosol module (AERO5) developed by US EPA
113 has been incorporated into the model (Binkowski and Roselle, 2003). The wet deposition is
114 based on the method in the CMAQ module and the dry deposition of chemical species
115 follows Wesely (1989). The photolysis rates are calculated using the FTUV (fast radiation
116 transfer model) with the aerosol and cloud effects on photolysis (Li et al., 2005, 2011a).

117 It is worth noting that the most recent extension of ISORROPIA, known as ISORROPIA
118 II, has incorporated a larger number aerosol species (Ca, Mn, K salts) and is designed to be a
119 superset of ISORROPIA (Fountoukis et al., 2009). However, the ISORROPIA Version II
120 uses the exact same routines as ISORROPIA to compute the equilibrium composition, which
121 produces identical results as ISORROPIA when crustal species are not considered. Therefore,
122 the inorganic aerosols in this study are predicted using ISORROPIA Version 1.7, calculating

123 the composition and phase state of an ammonium-sulfate-nitrate-water inorganic aerosol in
124 thermodynamic equilibrium with gas phase precursors (Nenes, 1998). In addition, a
125 parameterization of sulfate heterogeneous formation involving aerosol liquid water (ALW)
126 has been developed and implemented into the model, which has successfully reproduced the
127 observed rapid sulfate formation during haze days (Li et al., 2017a). The sulfate
128 heterogeneous formation from SO₂ is parameterized as a first order irreversible uptake by
129 ALW surfaces, with a reactive uptake coefficient of 0.5×10^{-4} assuming that there is enough
130 alkalinity to maintain the high iron-catalyzed reaction rate.

131 The OA module is based on the VBS approach with aging and detailed information can
132 be found in Li et al. (2011b). The POA components from traffic-related combustion and
133 biomass burning are represented by nine surrogate species with saturation concentrations (C*)
134 ranging from 10^{-2} to $10^6 \mu\text{g m}^{-3}$ at room temperature (Shrivastava et al., 2008), and assumed
135 to be semi-volatile and photochemically reactive (Robinson et al., 2007). The SOA formation
136 from each anthropogenic or biogenic precursor is calculated using four semi-volatile VOCs
137 with effective saturation concentrations of 1, 10, 100, and $1000 \mu\text{g m}^{-3}$ at 298 K. The SOA
138 formation via the heterogeneous reaction of glyoxal and methylglyoxal is parameterized as a
139 first-order irreversible uptake by aerosol particles with an uptake coefficient of 3.7×10^{-3}
140 (Liggio et al., 2005; Zhao et al., 2006; Volkamer et al., 2007).

141 A persistent air pollution episode from 05 December 2015 to 04 January 2016 in the
142 NCP is simulated using the WRF-Chem model. During the study episode, the average hourly
143 [PM_{2.5}] in the NCP are approximately $127.9 \mu\text{g m}^{-3}$, within the fourth grade of National
144 Ambient Air Quality Standards with [PM_{2.5}] between 115 and $150 \mu\text{g m}^{-3}$ (moderately
145 polluted, Feng et al., 2016). The persistent and widespread haze pollution episode with high
146 [PM_{2.5}] in the NCP provides a suitable case for observation analyses and model simulations
147 to investigate ARF effect on haze pollution. Figure 1a shows the model simulation domain,

148 and detailed model configurations can be found in Table 2.

149 2.2 Aerosol radiative module

150 In the present study, Goddard shortwave module developed by Chou and Suarez (1999,
151 2001) is employed to take into account the ARF effect on the haze formation. The aerosol
152 radiative module developed by Li et al. (2011b) has been incorporated into the **WRF-Chem**
153 model to calculate the aerosol optical depth (AOD or τ_a), single scattering albedo (SSA or
154 ω_a), and the asymmetry factor (g_a).

155 In the CMAQ aerosol module, aerosols are represented by a three-moment approach
156 with a lognormal size distribution:

$$157 \quad n(\ln D) = \frac{N}{\sqrt{2\pi} \ln \sigma_g} \exp\left[-\frac{1}{2} \left(\frac{\ln D - \ln D_g}{\ln \sigma_g}\right)^2\right] \quad (1)$$

158 Where D is the particle diameter, N is the number distribution of all particles in the
159 distribution, D_g is the geometric mean diameter, and σ_g is the geometric standard deviation.

160 To calculate the aerosol optical properties, the aerosol spectrum is first divided into 48 bins
161 from 0.002 to 2.5 μm , with radius r_i . The aerosols are classified into four types: (1)
162 internally mixed sulfate, nitrate, ammonium, hydrophilic organics and black carbon, and
163 water; (2) hydrophobic organics; (3) hydrophobic black carbon; and (4) other unidentified
164 aerosols. These four kinds of aerosols are assumed to be mixed externally. For the internally
165 mixed aerosols, the complex refractive index at a certain wavelength (λ) is calculated based
166 on the volume-weighted average of the individual refractive index. Given the particle size
167 and complex refractive index, the extinction efficiency (Q_e), ω_a and g_a are calculated
168 using the Mie theory at a certain wavelength (λ). The look-up tables of Q_e , ω_a and g_a are
169 established according to particle sizes and refractive indices to avoid multiple Mie scattering
170 calculation. The aerosol optical parameters are interpolated linearly from the look-up tables
171 with the calculated refractive index and particle size in the module.

172 The aerosol optical depth (AOD or τ_a) at a certain wavelength (λ) in a given

173 atmospheric layer k is determined by the summation over all types of aerosols and all bins:

$$174 \quad \tau_a(\lambda, k) = \sum_{i=1}^{48} \sum_{j=1}^4 Q_e(\lambda, r_i, j, k) \pi r_i^2 n(r_i, j, k) \Delta Z_k \quad (2)$$

175 where $n(r_i, j, k)$ is the number concentration of j -th kind of aerosols in the i -th bin. ΔZ_k is
 176 the depth of an atmospheric layer. The weighted-mean values of σ and g are then
 177 calculated by (d'Almeida et al., 1991):

$$178 \quad \omega_a(\lambda, k) = \frac{\sum_{i=1}^{48} \sum_{j=1}^4 Q_e(\lambda, r_i, j, k) \pi r_i^2 n(r_i, j, k) \omega_a(r_i, j, k) \Delta Z_k}{\sum_{i=1}^{48} \sum_{j=1}^4 Q_e(\lambda, r_i, j, k) \pi r_i^2 n(r_i, j, k) \Delta Z_k} \quad (3)$$

$$179 \quad g_a(\lambda, k) = \frac{\sum_{i=1}^{48} \sum_{j=1}^4 Q_e(\lambda, r_i, j, k) \pi r_i^2 n(r_i, j, k) \omega_a(r_i, j, k) g_a(\lambda, r_i, j, k) \Delta Z_k}{\sum_{i=1}^{48} \sum_{j=1}^4 Q_e(\lambda, r_i, j, k) \pi r_i^2 n(r_i, j, k) \omega_a(r_i, j, k) \Delta Z_k} \quad (4)$$

180 When the wavelength-dependent τ_a , ω_a , and g_a are calculated, they can be used in the
 181 Goddard shortwave module to evaluate the ARF. Detailed information can be found in Li et
 182 al. (2011b).

183 2.3 Data and statistical methods for comparisons

184 The model performance is validated using the available measurements in the NCP,
 185 including AOD, SSA, PBLH, downward shortwave flux (SWDOWN), aerosol species, and
 186 air pollutants. The daily AOD is retrieved from Terra- and Aqua- Moderate Resolution
 187 Imaging Spectroradiometer (MODIS) level 2 products, with a resolution of $0.1^\circ \times 0.1^\circ$. The
 188 hourly SSA is calculated using the measurement of the turbidity meter at the National Center
 189 for Nanoscience and Technology (NCNST), Chinese Academy of Sciences (116.33°E ,
 190 39.99°N) in Beijing (Figure 1b). The daily PBLH at 12:00 Beijing time (BJT) is diagnosed
 191 from the radiosonde observation at a meteorological site (116.47°E , 39.81°N) in Beijing. The
 192 SWDOWN is measured by CM-11 pyranometers at four sites from Chinese Ecosystem
 193 Research Network (CERN) in the NCP (Liu et al., 2016). The hourly measurements of O_3 ,
 194 NO_2 , SO_2 , CO and $\text{PM}_{2.5}$ concentrations have been released by the China's Ministry of
 195 Ecology and Environment (China MEP) since 2013. The hourly submicron sulfate, nitrate,
 196 ammonium, and organic aerosols are measured by the Aerodyne Aerosol Chemical

197 Speciation Monitor (ACSM) at NCNST. The primary organic aerosol (POA) and SOA
198 concentrations are obtained from the ACSM measurement analyzed using the Positive Matrix
199 Factorization (PMF). In addition, we have also analyzed the relationship between
200 near-surface [PM_{2.5}] and the PBLH retrieved from the Lidar measurement at the Institute of
201 Remote Sensing and Digital Earth (IRSDE), Chinese Academy of Sciences (116.38°E,
202 40.00°N) in Beijing (Figure 1b).

203 In the present study, the mean bias (*MB*), root mean square error (*RMSE*) and the index
204 of agreement (*IOA*) are used to assess the performance of WRF-Chem model simulations
205 against measurements. The detailed description can be found in Supplementary Information
206 (SI).

207

208 3 Results and discussions

209 3.1 Model performance

210 We first define the base simulation in which ARF is considered (hereafter referred to as
211 f_{base}), and results from f_{base} are compared to observations in the NCP. Generally, the
212 model simulates well the horizontal distributions and temporal variations of PM_{2.5}, O₃, NO₂,
213 and SO₂ mass concentrations against measurements in the NCP. Additionally, the model also
214 reasonably well reproduces the temporal profiles of the aerosol species compared to
215 observations in Beijing. The detailed model validation of air pollutants in the NCP and the
216 aerosol species in Beijing can be found in SI.

217 3.1.1 Aerosol radiative properties simulations in NCP

218 Aerosol radiative forcing mainly depends on AOD, SSA, and asymmetry parameter (*g*).
219 The model validations of AOD and SSA are provided in this study to further evaluate the
220 aerosol radiative effect on the air pollution. The daily AOD at 550 nm, retrieved from Terra-
221 and Aqua- MODIS level 2 products, is compared with the simulation. Figure 2a shows the

222 scatter plot of the daily retrieved and simulated AOD averaged in the NCP from 05
223 December 2015 to 04 January 2016. The simulated daily average AOD correlates well with
224 the observation, with a correlation coefficient of 0.86. Generally, the retrieved and simulated
225 AOD increases with deterioration of the haze pollution, but the model considerably
226 underestimates the AOD against the observation. Figure 2b presents the Taylor diagram
227 (Taylor, 2001) to show the variance, bias and correlation of the simulated and retrieved AOD
228 from 05 December 2015 to 04 January 2016. There exists a good relationship between the
229 simulated and retrieved daily AOD during the study episode, with correlation coefficients
230 generally ranging from 0.5 to 0.9, and standard deviation mostly varying from 0.25 to 1.0.
231 Figure 3 shows the pattern comparison of the retrieved and simulated AOD averaged during
232 the simulation period. The model reasonably reproduces the AOD distribution compared to
233 the observations in the NCP, but considerably underestimates the AOD. The simulated and
234 retrieved AOD averaged in the NCP during the simulation period is 0.43 and 0.59,
235 respectively. It is worth noting that the simulated AOD is not only dependent on the column
236 aerosol content and constituent, but is also significantly influenced by the relative humidity
237 (RH) controlling the aerosol hygroscopic growth. Additionally, the satellite retrieved AOD is
238 subject to contamination by existence of clouds, and considering the high occurrence
239 frequency of clouds during haze days, the retrieved AOD is generally higher than the
240 simulation (Engstrom and Ekman, 2010; Chand et al., 2012; Grandey et al., 2013).

241 Aerosols are the mixture of absorbing and scattering constituents in the atmosphere.
242 Their radiative effect of cooling or warming the atmosphere relies on many parameters, and
243 SSA is one of the most important (Satheesh et al., 2010). Figure 4 depicts the comparison of
244 the measured and simulated diurnal profiles of SSA at NCNST in Beijing during the episodes.
245 The model performs reasonably in simulating the daily variation of SSA in Beijing, with an
246 *IOA* of 0.69 and a *MB* of 0.0, but the overestimation or underestimation is rather large. SSA

247 is the ratio of scattering to extinction, which is highly sensitive to the relative distribution of
248 scattering and absorbing aerosol constituents in the atmosphere, and the RH determining the
249 hygroscopic growth of aerosols. Therefore, the uncertainties of the simulated SSA probably
250 originated from the model biases of aerosol constituents and the RH.

251 3.1.2 Downward solar radiation simulations in North China Plain

252 Figure 5 presents the daily profiles of simulated and observed SWDOWN at ground
253 surfaces in Beijing, Jiaozhouwan, Luancheng, and Yuancheng from 05 December 2015 to 04
254 January 2016. The WRF-Chem model simulates well the daily variation of SWDOWN,
255 especially in Jiaozhouwan, Luancheng, and Yucheng, with *IOAs* around 0.90. The model is
256 subject to overestimating the SWDOWN against measurements, with *MBs* ranging from 6.3
257 to 86.2 W m⁻². The SWDOWN reaching the ground surface is very sensitive to the cloud
258 cover and optical thickness. However, the WRF-Chem model still has difficulties in
259 accurately predicting the cloud cover and optical thickness, which might constitute one of the
260 most important reasons for model biases of the SWDOWN. In addition, the horizontal
261 resolution used in simulations cannot adequately resolve the cumulus clouds, also causing
262 uncertainties in the simulations of the SWDOWN.

263 3.1.3 PBLH simulations in Beijing

264 Figure 6 shows the temporal variations of the observed and simulated PBLH at a
265 meteorological site in Beijing from 05 December 2015 to 04 January 2016. The average
266 PBLH at 12:00 BJT during the episode at the meteorological site is 465.2 m, with the
267 minimum of 101.8 m and the maximum of 1017.9 m, showing decreased PBLH during the
268 haze episode. In general, the WRF-Chem model tracks reasonably the daily variation of the
269 PBLH in Beijing, with an *IOA* of 0.70. However, the model has difficulties in reproducing
270 the observed very low PBLH, e.g., less than 200 m. The PBLH varies substantially with time
271 due to many factors including large-scale dynamics, cloudiness, convective mixing, and the

272 diurnal cycle of solar radiation (Sivaraman et al., 2013). Therefore, the simulation
273 uncertainties of meteorological conditions constitute the main reason for the simulation bias
274 of PBLH. For example, the overestimation of SWDOWN at 12:00 BJT (Figure 5a) probably
275 caused the overestimation of PBLH in Beijing.

276 In general, the simulated variations of SWDOWN, PBLH, aerosol radiative properties,
277 air pollutants ($\text{PM}_{2.5}$, O_3 , NO_2 , SO_2 , CO) and aerosol species are in good agreement with
278 observations, indicating that the simulations of meteorological conditions, chemical processes
279 and the emission inventory used in the WRF-Chem model are reasonable, providing a
280 reliable basis for the further investigation.

281 3.2 Relationship between near-surface $[\text{PM}_{2.5}]$ and PBLH

282 Figure 7 presents the scatter plot of the Lidar retrieved PBLH at IRSDE and
283 near-surface $[\text{PM}_{2.5}]$ at a monitoring site close to IRSDE during daytime (08:00 ~ 17:00 LT)
284 from 08 January to 20 February 2014. The wind speeds (WSPD) at a meteorological site
285 close to IRSDE are shown by the color of the filled circles in Figure 7. Additionally,
286 near-surface $[\text{PM}_{2.5}]$ during daytime are also subdivided into 20 bins with the interval of 25
287 $\mu\text{g m}^{-3}$. The PBLH as the bin of near-surface $[\text{PM}_{2.5}]$ is assembled, and an average of PBLH
288 in each bin is calculated (Nakajima et al., 2001; Kawamoto et al., 2006), which is represented
289 by the rectangle in Figure 7. Generally, on average, when the PBLH decreases from 1500 m
290 to around 400 m, the near-surface $[\text{PM}_{2.5}]$ increase from 10 to more than 200 $\mu\text{g m}^{-3}$. When
291 near-surface $[\text{PM}_{2.5}]$ exceed 200 $\mu\text{g m}^{-3}$, the PBLH remains 400~500 m. Previous studies
292 have also reported the nonlinear relationship between the PBLH and near-surface $[\text{PM}_{2.5}]$,
293 and proposed that increasing $[\text{PM}_{2.5}]$ reduce the PBLH or the ARF is attributed to the PBLH
294 decrease (e.g., Petaja et al., 2016; Tie et al., 2017; Liu et al., 2018).

295 The PBLH is primarily determined by the wind shear in the vertical direction and the
296 thermal condition of ground surfaces. The occurrence of low near-surface $[\text{PM}_{2.5}]$ generally

307 corresponds to efficient dispersions of $PM_{2.5}$ in horizontal and/or vertical directions. The
308 strong horizontal winds in the lower atmosphere not only disperse $PM_{2.5}$ emitted or formed
309 efficiently, but also intensify the wind shear in the vertical direction, increasing the PBLH
300 and facilitating the rapid vertical exchange of $PM_{2.5}$ in the PBL. When near-surface $[PM_{2.5}]$
301 are less than $50 \mu\text{g m}^{-3}$, the PBLH exceeding 1000 m is observed, which is chiefly
302 determined by strong horizontal winds and less influenced by the ground thermal condition
303 during wintertime, and the observed average WSPD is about 2.4 m s^{-1} . The occurrence of
304 high near-surface $[PM_{2.5}]$ indicates that the lower atmosphere is stable or stagnant, with weak
305 horizontal winds and inactive convections, hindering the dispersion of $PM_{2.5}$ in the horizontal
306 and vertical directions. Additionally, as the horizontal winds become weak or calm, the wind
307 shear in the vertical direction is diminished and the PBLH is dominated by the ground
308 thermal condition. When near-surface $[PM_{2.5}]$ increase from 50 to around $200 \mu\text{g m}^{-3}$, the
309 PBLH decreases from around 700 to 400 m, and the average WSPD decreases to 1.8 m s^{-1} .
310 However, the increased $PM_{2.5}$ reducing PBLH still cannot be fully attributed to ARF, which
311 is more likely caused by the decrease of winds or the formation of stagnant situations in the
312 low-level atmosphere. When near-surface $[PM_{2.5}]$ exceed $200 \mu\text{g m}^{-3}$, the observed PBLH
313 fluctuates between 400 and 500 m with the average WSPD of around 1.0 m s^{-1} , and does not
314 exhibit continuous decrease with the increasing near-surface $[PM_{2.5}]$.

315 Under the stagnant situation with weak winds, the PBLH is more sensitive to the ground
316 thermal condition. Increasing aerosols or $PM_{2.5}$ in the low-level atmosphere attenuate the
317 SWDOWN to the ground surface and decrease the surface temperature (TSFC) and
318 turbulence kinetic energy, suppressing the PBL development and further enhancing
319 near-surface $[PM_{2.5}]$. Therefore, with near-surface $[PM_{2.5}]$ exceeding $200 \mu\text{g m}^{-3}$, the inert
320 PBLH might be caused by the defect of the Lidar retrieved PBLH. The aerosol backscatter
321 signal received by Lidar is used to retrieve the PBLH. If the atmosphere is stable, the aerosols

322 near the maximal PBLH are subject to being confined in situ, and the retrieved PBLH is
323 generally the maximal one. Additionally, it is worth noting that the occurrence of the
324 wintertime severe haze pollution in the NCP is often accompanied with the high-level
325 convergence between 500 and 700 hPa, producing a persistent and strong sinking motion in
326 the mid-lower troposphere to reduce the PBLH and facilitate accumulation of air pollutants
327 (Wu et al. 2017; Ding et al., 2017). Therefore, a subsidence inversion appears in the lower
328 layer as a result of the air masses sinking in the middle-troposphere, restraining the PBL
329 development and determining the maximal PBLH. Hence, it is imperative to evaluate the
330 contribution of ARF to the PBLH and near-surface [PM_{2.5}].

331 3.3 Sensitivity studies

332 The conceptual model about the ARF contribution to the heavy haze formation has been
333 established in previous studies (e.g., Tie et al., 2017; Liu et al., 2018). During wintertime,
334 under stagnant meteorological situations with weak winds and humid air, air pollutants are
335 subject to accumulation in the PBL, facilitating the formation of PM_{2.5}. Increasing PM_{2.5} in
336 the PBL absorbs or scatters the incoming solar radiation to decrease the TSFC and facilitate
337 anomalous temperature inversion, subsequently suppressing the vertical turbulent diffusion
338 and decreasing the PBLH to further trap more air pollutants and water vapor to increase the
339 RH in the PBL. Increasing RH enhances aerosol hygroscopic growth and multiphase
340 reactions and augments the particle size and mass, causing further dimming and decrease of
341 the TSFC and PBLH. The whole process constitutes a positive feedback induced by the
342 aerosol radiation effect to enhance near-surface [PM_{2.5}], which has been proposed in many
343 studies (Quan et al., 2013; Petaja et al., 2016; Yang et al., 2016; Tie et al., 2017; Ding et al.,
344 2017; Liu et al., 2018). The noted positive meteorological condition feedback has also been
345 considered as the main reason for the near-surface PM_{2.5} explosive growth (Zhong et al., 2018;
346 X. Y. Zhang et al., 2018).

347 To comprehensively evaluate the influence of ARF on near-surface [PM_{2.5}] during the
348 haze episode, a sensitivity study has been conducted, in which ARF is turned off (hereafter
349 referred as f_{rad0}). Therefore, the contribution of ARF to near-surface [PM_{2.5}] can be
350 determined by the difference between f_{base} and f_{rad0} ($f_{base} - f_{rad0}$). The most polluted
351 area in the NCP is first selected to verify the conceptual model of the ARF contribution to the
352 heavy haze formation, with the average near-surface [PM_{2.5}] during the haze episode
353 exceeding 150 $\mu\text{g m}^{-3}$. Figure 8 provides the temporal variation of near-surface [PM_{2.5}],
354 SWDOWN, TSFC, PBLH, and RH averaged in the selected area during the episode in f_{base}
355 and f_{rad0} . Apparently, ARF considerably decreases the solar radiation reaching the ground
356 surface and correspondingly lowers the TSFC (Figures 8b and 8c). Subsequently, the PBLH
357 is decreased and the surface RH is increased due to decreasing TSFC during daytime (Figures
358 8d and 8e). However, the variation trend of near-surface [PM_{2.5}], PBLH, TSFC and RH due
359 to ARF is not similar to that proposed in the conceptual model. During the haze development
360 stage, whether ARF is considered or not, the TSFC and RH exhibit an increasing trend,
361 showing the air mass originated from the south, and the PBLH does not consistently decrease
362 with increasing near-surface [PM_{2.5}]. Additionally, the ARF contribution to near-surface
363 [PM_{2.5}] is generally marginal during the haze development stage. During the haze maturation
364 stage, ARF commences to elevate near-surface [PM_{2.5}] appreciably. It is worth noting that,
365 even if ARF is not considered in f_{rad0} , the heavy haze pollution still occurs during the
366 episode. For example, from 17 to 20 December 2015, without ARF, near-surface [PM_{2.5}] still
367 continue to increase from around 30 to 300 $\mu\text{g m}^{-3}$, and fluctuate between 150 to 300 $\mu\text{g m}^{-3}$
368 until the occurrence of favorable meteorological conditions on 25 December. Hence,
369 according to the variation trend of near-surface [PM_{2.5}] with and without the ARF
370 contribution, the continuous accumulation of PM_{2.5} during the haze episode is not primarily
371 caused by ARF, but predominantly induced by the stagnant meteorological conditions as well

372 as the massive air pollutants emissions in the NCP. Figure 9 presents the temporal variation
373 of AOD at 550nm averaged in the selected area during the episode in f_{base} and f_{rad0} to
374 evaluate the impact of ARF on AOD. Apparently, except from 8 to 11 December, the ARF
375 contribution to AOD is generally marginal, indicating that ARF does not play an important
376 role in the column-integrated aerosol abundance. Additionally, the considerable AOD
377 enhancement from 8 to 11 December is more likely caused by the substantial increase in RH
378 due to ARF, which facilitates aerosol hygroscopic growth to augment particle size and further
379 increases AOD. It is worth noting that the extinction of haze aerosols in the PBL also
380 decreases the photolysis to suppress the photochemistry, further hindering the secondary
381 aerosol formation to offset effects of ARF on near-surface $[PM_{2.5}]$.

382 In order to quantitatively evaluate effects of ARF on near-surface $[PM_{2.5}]$, which cannot
383 be reflected by the temporal variation of near-surface $[PM_{2.5}]$, TSFC, PBLH and RH, an
384 ensemble method is used in this study. The daytime near-surface $[PM_{2.5}]$ in the NCP during
385 the episode in f_{base} are first subdivided into 30 bins with an interval of $20 \mu\text{g m}^{-3}$. The
386 SWDOWN, TSFC, PBLH, the near-surface WSPD, RH, and $[PM_{2.5}]$ in f_{base} and f_{rad0} in
387 the same grid cell are assembled as the bin $[PM_{2.5}]$, respectively, and an average of these
388 variables in each bin is calculated. Figure 10 shows the decrease of SWDOWN (%), TSFC
389 ($^{\circ}\text{C}$), PBLH (%), WSPD (m s^{-2}), and the increase of RH (%), not percentage change) and
390 near-surface $[PM_{2.5}]$ contribution (%) caused by ARF as a function of bin $[PM_{2.5}]$. The
391 SWDOWN reaching the ground surface almost decreases linearly with the enhancement of
392 near-surface $[PM_{2.5}]$. When ARF is considered, aerosols in the atmosphere absorb or scatter
393 the incoming solar radiation, directly attenuating the radiation reaching the ground surface.
394 When near-surface $[PM_{2.5}]$ exceed $200 \mu\text{g m}^{-3}$, the SWDOWN at ground surfaces decreases
395 by more than 20% (Figure 10a). Moreover, the decrease of the SWDOWN correspondingly
396 lowers the TSFC and the decrease of the TSFC is generally proportional to near-surface

397 [PM_{2.5}], about 0.35 °C per 100 μg m⁻³ PM_{2.5} (Figure 10b). Interestingly, ARF also decreases
398 near-surface WSPD by about 0.1~0.2 m s⁻¹ with near-surface [PM_{2.5}] exceeding 80 μg m⁻³
399 (Figure 10c). When severe air pollution occurs in the NCP during wintertime, atmospheric
400 convergence occurs in the PBL (Liao et al., 2015; Ding et al., 2017). However, the ARF
401 induced cooling in the low-level air generates a divergence in NCP, causing the decrease of
402 near-surface WSPD.

403 The PBLH is primarily determined by the atmospheric dynamic and thermal condition of
404 ground surfaces. Therefore, the decrease of WSPD and TSFC due to ARF subsequently
405 suppresses the PBL development and diminishes the PBLH (Figure 10d). When near-surface
406 [PM_{2.5}] are less than 250 μg m⁻³, the PBLH decreases rapidly with increasing [PM_{2.5}]. When
407 the near-surface [PM_{2.5}] are between 250 μg m⁻³ and 350 μg m⁻³, the decrease of PBLH is
408 around 28%. With near-surface [PM_{2.5}] more than 350 μg m⁻³, the decrease of PBLH exceeds
409 30%. As for ARF effect on water vapor in the PBL, the conceptual model has proposed that
410 the decreased PBL induced by ARF weakens the vertical exchange of water vapor or the
411 dispersion of water vapor is constrained by the shallow PBL (Tie et al., 2017; Liu et al.,
412 2018). However, Figure 11a shows that ARF decreases the near-surface water vapor content
413 slightly, by more than 0.1 g kg⁻¹ with near-surface [PM_{2.5}] exceeding 100 μg m⁻³. During the
414 haze episode in the NCP, the abundant moisture in the PBL is mainly transported from the
415 south. The divergence due to cooling caused by ARF weakens the prevailing southerly wind
416 and decreases the moisture transport from the south, reducing the water vapor content in the
417 NCP. Considering that the RH is sensitive to the temperature with a constant water vapor
418 content, the ARF induced cooling still increases the near-surface RH (Figure 10e). When
419 near-surface [PM_{2.5}] exceed 300 μg m⁻³, the RH is increased by more than 5%, so the heavy
420 haze generally causes the air to be more humid.

421 More PM_{2.5} emitted or formed are trapped by a shallow PBL caused by ARF, and

422 increased RH promotes the aerosol hygroscopic growth and further multiphase reactions,
423 progressively enhancing near-surface $[PM_{2.5}]$ (Figure 10f). When near-surface $[PM_{2.5}]$ are
424 more than $50 \mu\text{g m}^{-3}$, the contribution of ARF to near-surface $[PM_{2.5}]$ consistently increases
425 with the haze deterioration. When the severe haze occurs, i.e., near-surface $[PM_{2.5}]$ exceed
426 $250 \mu\text{g m}^{-3}$, more than 12% or $30 \mu\text{g m}^{-3}$ $PM_{2.5}$ is contributed by ARF. The simulated ARF
427 effects on near-surface $[PM_{2.5}]$ are generally comparable to those reported by previous
428 studies. Z. Wang et al. (2014) have shown that ARF increases the monthly $PM_{2.5}$
429 concentration by 10%-30% in Beijing-Tianjin-Hebei in January 2013. Using the WRF-Chem
430 model, Gao et al. (2015) have indicated that ARF increases the $PM_{2.5}$ concentration by 10-50
431 $\mu\text{g m}^{-3}$ (2%-30%) over Beijing, Tianjin, and south Hebei from 10 to 15 January 2013, a
432 period with the simulated maximum hourly surface $PM_{2.5}$ concentration of more than $600 \mu\text{g}$
433 m^{-3} . X. Zhang et al. (2018) have also quantified the aerosol-meteorology interaction effect on
434 $PM_{2.5}$ concentrations in China in 2014 using the WRF-Chem model, showing that the
435 increase of $PM_{2.5}$ concentrations associated with ARF is up to 16% in China. Other previous
436 studies have also confirmed ARF effect during the heavy haze pollution episode (Wang et al.,
437 2015; Zhang et al., 2015; Gao et al., 2016). However, when near-surface $[PM_{2.5}]$ are less than
438 $50 \mu\text{g m}^{-3}$, the contribution of ARF to near-surface $[PM_{2.5}]$ is negative, although ARF
439 decreases PBLH and increases RH. One of the possible reasons for the negative contribution
440 of ARF is perturbations of wind fields caused by the ARF induced cooling. Figure 11b
441 presents the average vertical velocity (the net velocity by combining updrafts and downdrafts)
442 below about 400 m in f_{rad0} as a function of near-surface $[PM_{2.5}]$. Apparently, when ARF
443 is not considered, the area with near-surface $[PM_{2.5}]$ less than $100 \mu\text{g m}^{-3}$ is generally
444 controlled by downward airflow, and vice versa for the area with near-surface $[PM_{2.5}]$ more
445 than $100 \mu\text{g m}^{-3}$. The ARF induced cooling generally cause a downward motion in the PBL
446 (Figure 11c), which suppresses the upward motion in the area with near-surface $[PM_{2.5}]$ more

447 than $100 \mu\text{g m}^{-3}$ to enhance near-surface $[\text{PM}_{2.5}]$, but accelerates the downward motion in the
448 area with near-surface $[\text{PM}_{2.5}]$ less than $100 \mu\text{g m}^{-3}$ to strengthen the divergence intensity,
449 further decreasing near-surface $[\text{PM}_{2.5}]$. Countered by the decrease of PBLH and increase of
450 RH, the ARF contribution becomes positive with near-surface $[\text{PM}_{2.5}]$ exceeding $50 \mu\text{g m}^{-3}$.

451 Figure 12 presents spatial distributions of the average near-surface $\text{PM}_{2.5}$ contribution
452 due to ARF during the episode. The average near-surface $\text{PM}_{2.5}$ contribution caused by ARF
453 in the NCP is $10.2 \mu\text{g m}^{-3}$ or 7.8%, with the maximum exceeding $40 \mu\text{g m}^{-3}$ in the south of
454 Hebei. On average, the ARF contribution to near-surface $[\text{PM}_{2.5}]$ is the most significant in
455 Tianjin, about $17.6 \mu\text{g m}^{-3}$ or 10.3%, followed by Hebei ($11.6 \mu\text{g m}^{-3}$ or 9.3%), Shandong
456 ($11.5 \mu\text{g m}^{-3}$ or 7.3%), Henan ($11.2 \mu\text{g m}^{-3}$ or 7.7%), Anhui ($7.7 \mu\text{g m}^{-3}$ or 7.4%), Beijing
457 ($7.3 \mu\text{g m}^{-3}$ or 6.9%), and Jiangsu ($7.0 \mu\text{g m}^{-3}$ or 6.2%). It is noteworthy that the ARF
458 contribution during the episode in North China is generally positive, but in its surrounding
459 area the contribution becomes negative. At a large scale, when the air pollution occurs during
460 wintertime in North China, the vertical motion over the polluted area generally shows an
461 ascending-descending-ascending distribution from the surface to the middle level of the
462 troposphere, and wind directions present a structure of convergence-divergence-convergence
463 accordingly (Liao et al., 2015; Wu et al., 2017; Ding et al., 2017). ARF cools the low-level
464 atmosphere and induces a downward motion, which suppresses the upward motion in the
465 convergence area in North China to increase near-surface $[\text{PM}_{2.5}]$, but accelerates the
466 downward motion in the divergence area to decrease $[\text{PM}_{2.5}]$.

467 Furthermore, when ARF is considered, near-surface $[\text{PM}_{2.5}]$ over the East and South
468 China Sea are also increased, with an enhancement less than $5 \mu\text{g m}^{-3}$ (about 3% to more than
469 15%). Considering the low near-surface $[\text{PM}_{2.5}]$ over sea, the $[\text{PM}_{2.5}]$ enhancement might be
470 caused by the $\text{PM}_{2.5}$ transport from the continent. Figure 13 shows the spatial distribution of
471 the TSFC and wind field variation caused by ARF averaged during the episode. Apparently,

472 ARF causes a widespread cooling effect in East China, and the cooling is the most significant
473 in the NCP, with the maximum TSFC decrease exceeding 1.5°C. The cooling effect in the
474 NCP induces a weak northerly wind, decreasing the prevailing southerly wind during the
475 haze episode (Figure 13). Additionally, the cooling effect over the continent also intensifies
476 the temperature contrast between land and sea, producing a secondary circulation to transport
477 the PM_{2.5} from the continent to the East and South China Sea.

478

479 **4 Conclusions**

480 In the study, a persistent haze pollution episode in the NCP from 05 December 2015 to
481 04 January 2016 is simulated using the WRF-Chem model to verify the ARF contribution to
482 the haze formation. Generally, the model reproduces well the spatial distributions and
483 temporal variations of PM_{2.5}, O₃, NO₂, SO₂, and CO mass concentrations against observations
484 in the NCP. The calculated temporal variations of aerosol species are also consistent with the
485 ACSM measurement in Beijing, particularly with regard to the simulation of sulfate, nitrate,
486 and ammonium. Moreover, the model simulates reasonably well the variation of SWDOWN,
487 PBLH, and aerosol radiative properties during the episode, compared to the measurement.

488 Previous studies have established that a positive feedback induced by ARF causes the
489 heavy haze formation by modulating the PBL and RH. However, model results demonstrate
490 that during the haze development stage in the NCP, ARF does not dominate accumulation of
491 near-surface [PM_{2.5}], while ARF considerably enhances near-surface [PM_{2.5}] during the haze
492 mature stage.

493 Ensemble analyses of model results show that, during daytime, ARF attenuates
494 SWDOWN reaching ground surfaces efficiently, and correspondingly the TSFC
495 progressively decreases with increasing near-surface [PM_{2.5}] in the NCP. The ARF induced
496 cooling generates a divergence in the low-level atmosphere in the NCP, lowering the

497 near-surface WSPD and decreasing the water vapor transport from the south. The decreased
498 WSPD and TSFC caused by ARF hinder the PBL development and the PBLH decreases
499 rapidly with increasing near-surface $[PM_{2.5}]$. Although the water content in the NCP is
500 decreased slightly, the RH is still increased due to the ARF induced cooling. A shallow PBL
501 and more humid air caused by ARF accelerate the $PM_{2.5}$ accumulation and secondary
502 pollutant formation, facilitating heavy haze formation. The contribution of ARF to
503 near-surface $[PM_{2.5}]$ increases from 12% to 20% when near-surface $[PM_{2.5}]$ increase from
504 250 to 500 $\mu\text{g m}^{-3}$. However, ARF decreases the $PM_{2.5}$ level with near-surface $[PM_{2.5}]$ less
505 than 50 $\mu\text{g m}^{-3}$.

506 The average near-surface $PM_{2.5}$ contribution of ARF during the episode in the NCP is
507 10.2 $\mu\text{g m}^{-3}$ or 7.8%. ARF aggravates the heavy haze formation in North China, but in its
508 surrounding area ARF slightly mitigates the haze pollution. Generally, there is a structure of
509 convergence-divergence-convergence over the polluted area of North China from the surface
510 to the middle level of the troposphere. A downward motion is induced due to the widespread
511 cooling effect of the low-level atmosphere caused by ARF, impeding the upward motion in
512 the convergence area in North China to increase near-surface $[PM_{2.5}]$, but accelerating the
513 downward motion in the divergence area to decrease $[PM_{2.5}]$.

514 Although the model performs generally well in simulating air pollutants, aerosol species
515 and radiative properties, SWDOWN, and PBLH, the uncertainties from meteorological fields
516 and emission inventory still have potentials to influence ARF evaluation. Particularly, further
517 studies need to be conducted to improve the AOD simulations. In this study, ARF only
518 considers the aerosol effect on the solar radiation, and the influence of longwave radiation
519 also needs to be included. It is worth noting that modification of photolysis by aerosol
520 scattering or absorbing solar radiation ultimately alters the atmospheric oxidizing capacity to
521 influence the secondary aerosol formation, which potentially offsets ARF effect on the haze

522 pollution. Hence, further studies need to be performed to evaluate the effect of aerosol
523 photolysis interaction on the haze pollution. In addition, aerosols play an important role in the
524 cloud process serving as cloud condensation nuclei (CCN) and ice nuclei (IN). Therefore,
525 aerosol-cloud interactions (aerosol indirect effect) modify temperature and moisture profiles
526 and further influence precipitation, leading to potential effects on the atmospheric chemistry
527 (Wang et al., 2011). Future studies should be performed to investigate the feedbacks of the
528 aerosol indirect effect on the air pollutants.

530

531

532 *Author contribution.* Guohui Li, as the contact author, provided the ideas and financial
533 support, developed the model code, verified the conclusions, and revised the paper. Jiarui Wu
534 conducted a research, designed the experiments, carried the methodology out, performed the
535 simulation, processed the data, prepared the data visualization, and prepared the manuscript
536 with contributions from all authors. Naifang Bei provided the treatment of meteorological
537 data, analyzed the study data, validated the model performance, and reviewed the manuscript.
538 Bo Hu provided the observation data used in the study, synthesized the observation, and
539 reviewed the paper. Suixin Liu, Meng Zhou, Qiyuan Wang, Zirui Liu, and Yichen Wang
540 provided the data and the primary data process, and reviewed the manuscript. Xia Li, Lang
541 Liu, and Tian Feng analyzed the initial simulation data, visualized the model results and
542 reviewed the paper. Junji Cao, Xuexi Tie, Jun Wang provided critical reviews pre-publication
543 stage. Luisa T. Molina provided a critical preview and financial support, and revised the
544 manuscript.

840 Table 1 Impact of ARF on near-surface [PM_{2.5}] in China
841

Reference	Time	Location	Impact on [PM _{2.5}]
Z. Wang et al. (2014)	January 2013	Beijing-Tianjin-Hebei	+10~30%
J. Wang et al. (2014)	January 2013	North China Plain	Up to +140 µg m ⁻³
Gao et al. (2015)	10-15 January 2013	Beijing, Tianjin, and south Hebei	+10-50 µg m ⁻³ (2-30%)
Wang et al. (2015)	7-11 July 2008	Beijing, Tianjin, Hebei, East Shanxi, West Shandong, and North Henan	+14%
Zhang et al. (2015)	January 2013	Henan, Hubei, Guangxi, and Sichuan	Maximum +69.3 µg m ⁻³
Ding et al. (2016)	December 2013	Eastern China and the Sichuan Basin	Up to +100 µg m ⁻³
Gao et al. (2016)	January 2010	Shijiazhuang	More than +20 µg m ⁻³
X. Y. Zhang et al. (2018)	December 2016	Beijing	around +84% of [PM _{2.5}] during cumulative explosive growth
Liu et al. (2018)	15-21 December 2016	North China Plain	+56 µg m ⁻³
X. Zhang et al. (2018)	2014	China	over +16% for the daily maximum [PM _{2.5}]
Zhong et al. (2018)	January 2013, February 2014, December 2015, and December 2016 to 10 January 2017	Beijing	Over +70% of [PM _{2.5}] during cumulative explosive growth

846

847 Table 2 WRF-Chem model configurations.

848

Region	East Asia
Simulation period	05 December 2015 to 04 January 2016
Domain size	400 × 400
Domain center	35°N, 114°E
Horizontal resolution	12 km × 12 km
Vertical resolution	35 vertical levels with a stretched vertical grid with spacing ranging from 30 m near the surface, to 500 m at 2.5 km and 1 km above 14 km
Microphysics scheme	WSM 6-class graupel scheme (Hong and Lim, 2006)
Cumulus scheme	Grell-Devenyi ensemble scheme (Grell and Devenyi, 2002)
Boundary layer scheme	MYJ TKE scheme (Janjić, 2002)
Surface layer scheme	MYJ surface scheme (Janjić, 2002)
Land-surface scheme	Unified Noah land-surface model (Chen and Dudhia, 2001)
Longwave radiation scheme	Goddard longwave scheme (Chou and Suarez, 2001)
Shortwave radiation scheme	Goddard shortwave scheme (Chou and Suarez, 1999)
Meteorological boundary and initial conditions	NCEP 1°×1° reanalysis data
Chemical initial and boundary conditions	MOZART 6-hour output (Horowitz et al., 2003)
Anthropogenic emission inventory	Developed by Zhang et al. (2009) and Li et al. (2017), 2012 base year, and SAPRC-99 chemical mechanism
Biogenic emission inventory	Online MEGAN model developed by Guenther et al. (2006)

Figure Captions

855 Figure 1 (a) WRF-Chem simulation domain with topography and (b) Beijing-Tianjin-Hebei
856 area. In (a), the blue circles represent centers of cities with ambient monitoring sites
857 in, and the size of blue circles denotes the number of ambient monitoring sites of
858 cities. In (b), the blue and red filled circles denote the NCNST and IRSDE site,
859 respectively, the red filled rectangle denotes the meteorological site. The red numbers
860 denote the CERN sites with the solar radiation measurement. 1: Beijing urban; 2:
861 Jiaozhouwan; 3: Yucheng; 4: Luancheng.

862 Figure 2 (a) Scatter plot of the MODIS retrieved and simulated daily AOD, (b) Taylor
863 diagram (Taylor, 2001) to present the variance, bias and correlation of the retrieved
864 and simulated daily AOD averaged in the NCP from 05 December 2015 to 04 January
865 2016.

866 Figure 3 Spatial distribution of (a) retrieved and (b) simulated AOD averaged from 05
867 December 2015 to 04 January 2016 in the NCP.

868 Figure 4 Comparison of measured (black dots) and predicted (red line) diurnal profiles of
869 SSA in Beijing from 05 December 2015 to 04 January 2016.

870 Figure 5 Comparison of measured (black dots) and predicted (red line) diurnal profiles of the
871 SWDOWN reaching the ground surface in (a) Beijing, (b) Jiaozhouwan, (c)
872 Luancheng, and (d) Yucheng from 05 December 2015 to 04 January 2016.

873 Figure 6 Comparison of predicted diurnal profile (red line) of PBLH from 05 December 2015
874 to 04 January 2016 with observations at 12:00 BJT in Beijing.

875 Figure 7 Scatter plot of the PBLH and near-surface $[PM_{2.5}]$ at IRSDE site from 12 January to
876 20 February 2014. The black rectangle shows the bin average of PBLH. The color of
877 the filled circles denotes the WSPD at the meteorological site close to IRSDE in
878 Figure 1b.

879 Figure 8 Temporal variations of the average (a) near-surface $[PM_{2.5}]$, (b) SWDOWN at the
880 ground surface, (c) TSFC, (d) PBLH, and (e) RH in the most polluted area in the NCP
881 with $[PM_{2.5}]$ of more than $150 \mu\text{g m}^{-3}$ in f_{base} (red solid line) and f_{rad0} (blue solid
882 line) from 05 December 2015 to 04 January 2016.

883 Figure 9 Temporal variations of the average AOD at 550nm in the most polluted area in the
884 NCP with $[PM_{2.5}]$ of more than $150 \mu\text{g m}^{-3}$ in f_{base} (red solid line) and f_{rad0} (blue
885 solid line) from 05 December 2015 to 04 January 2016.

886 Figure 10 Average (a) percentage decrease of SWDOWN at the ground surface, (b) decrease
887 of TSFC, (c) decrease of WSPD, (d) percentage decrease of PBLH, (e) increase of RH,
888 and (f) percentage contribution of near-surface $[PM_{2.5}]$ caused by ARF, as a function
889 of the near-surface $[PM_{2.5}]$ in the NCP during daytime from 05 December 2015 to 04
890 January 2016.

891 Figure 11 Average decrease of (a) near-surface water vapor content and (c) vertical velocity
892 below 400 m caused by ARF, and (b) average vertical velocity below 400 m in f_{rad0}
893 as a function of the near-surface $[PM_{2.5}]$ in the NCP during daytime from 05
894 December 2015 to 04 January 2016.

895 Figure 12 Near-surface $[PM_{2.5}]$ contribution caused by ARF, averaged from 05 December
896 2015 to 04 January 2016 in NCP.

897 Figure 13 TSFC and wind filed variations caused by ARF, averaged from 05 December 2015
898 to 04 January 2016 in NCP.
