Abstract. The growth rate of atmospheric carbon dioxide (CO₂) reflects the net effect of emissions and uptake resulting from anthropogenic and natural carbon sources and sinks. Annual mean CO₂ growth rates have been determined from satellite retrievals of column-average dry-air mole fractions of CO₂, i.e., XCO₂, for the years 2003 to 2016. The XCO₂ growth rates agree with National Oceanic and Atmospheric Administration (NOAA) growth rates from CO₂ surface observations within the uncertainty of the satellite-derived growth rates (mean difference ± standard deviation: 0.0±0.3 ppm/year; R: 0.82). This new and independent data set confirms record large growth rates around 3 ppm/year in 2015 and 2016, which are attributed to the 2015/2016 El Niño. Based on a comparison of the satellite-derived growth rates with human CO₂ emissions from fossil fuel combustion and with El Niño Southern Oscillation (ENSO) indices, we estimate by how much the impact of ENSO dominates the impact of fossil fuel burning related emissions in explaining the variance of the atmospheric CO₂ growth rate.
Introduction

Atmospheric carbon dioxide (CO$_2$) is an important greenhouse gas that causes global warming (IPCC 2013). Sources that emit CO$_2$ into the atmosphere include anthropogenic and natural sources at the surface, and the oxidation of carbon monoxide and hydrocarbons in the atmosphere. The sinks that remove CO$_2$ primarily at the surface include biological (photosynthesis) and physical (solubility) processes. Anthropogenic emissions of CO$_2$, primarily from fossil fuel combustion, have increased the atmospheric CO$_2$ mixing ratios at the surface by more than 40% since pre-industrial times, from less than 280 parts per million (ppm) to 402.8±0.1 ppm in 2016 (Dlugokencky and Tans, 2017a). A global increase of atmospheric CO$_2$ by 1 ppm in a one-year time period corresponds to an annual increase of 2.12 GtC/year (Ballantyne et al., 2012). However, this increase in mass does not directly correspond to the emissions. The reason is that only a fraction of the emitted CO$_2$ remains in the atmosphere as CO$_2$ is partitioned between the atmosphere and ocean and land carbon sinks. On average, somewhat less than half of the emitted CO$_2$ remains in the atmosphere but this “airborne fraction” varies substantially from year to year (Le Quéré et al., 2016, 2018). Variations of the airborne fraction are not well understood primarily because of an inadequate understanding of the terrestrial carbon sink, which introduces large uncertainties for climate prediction (e.g., IPCC 2013; Peylin et al., 2013; Wieder et al., 2015; Huntzinger et al., 2017). Identification of the origin of changes of the growth rate requires additional information for the attribution to particular sources or sinks (Peters et al., 2017). Atmospheric CO$_2$ growth rates inferred from in-situ CO$_2$ surface measurements are regularly determined and published, for example, by the National Oceanic and Atmospheric Administration (NOAA) (see https://www.esrl.noaa.gov/gmd/ccgg/trends/gr.html). In this study, we present and interpret atmospheric growth rates determined from the remote sensing of CO$_2$ vertical columns from space, which are described in the following section.

Global satellite observations of atmospheric CO$_2$ columns

Satellites provide retrievals of CO$_2$ vertical columns in terms of the CO$_2$ column-average dry-air mole fraction, denoted XCO$_2$. Although a relatively new field, satellite-based XCO$_2$ data products have already been used to improve our knowledge of natural (e.g., Basu et al., 2013; Maksyutov et al., 2013; Chevallier et al., 2014; Reuter et al., 2014a; Schneising et al., 2014; Houweling et al., 2014; Parker et al., 2016; Heymann et al., 2017; Liu et al., 2017; Kaminski et al., 2017) and anthropogenic (e.g., Schneising et al., 2013; Reuter et al., 2014b; Kort et al., 2012; Hakkarainen et al., 2016; Nassar et al., 2017) CO$_2$ sources and sinks but only a few studies explicitly present and discuss CO$_2$ growth rates. Buchwitz et al., 2007, analyzed the first three years (2003-2005) of XCO$_2$ retrievals from SCIAMACHY/ENVISAT (Burrows et al., 1995; Bovensmann et al., 1999) generated using the WFM-DOAS retrieval algorithm (Buchwitz et al., 2006). They computed year-to-year CO$_2$ variations and compared the XCO$_2$ increase with the XCO$_2$ increase computed from the output of NOAA’s CO$_2$ assimilating system CarbonTracker (Peters et al., 2007) and found agreement within 1 ppm/year. Schneising et al., 2014, computed growth rates from the 2003-2011 SCIAMACHY XCO$_2$ record. They compared the derived annual growth rates with surface temperature and found that years having higher temperatures during the vegetation growing season are associated with larger growth rates in atmospheric CO$_2$ at northern mid-latitudes.
rates from GOSAT (Kuze et al., 2016) are published by the National Institute for Environmental Studies (NIES), Tsukuba, Japan (NIES 2017).

In this study, we analyze a new satellite XCO₂ data set covering 14 years (2003-2016) generated from SCIAMACHY/ENVISAT and TANSO-FTS/GOSAT. We use the XCO₂ data product Obs4MIPs (Observations for Model Intercomparisons Project) version 3 (O4Mv3), which is a gridded (Level 3) monthly data product at 5° latitude by 5° longitude spatial resolution in Obs4MIPs format (Buchwitz et al., 2017a). Obs4MIPs (https://www.earthsystemcog.org/projects/obs4mips/) is an activity to make observational products more accessible for climate model intercomparisons (e.g., Lauer et al., 2017). The O4Mv3 XCO₂ data product was generated by gridding (averaging) the XCO₂ Level 2 (i.e., individual soundings) product generated with the Ensemble Median Algorithm (EMMA, Reuter et al., 2013). EMMA uses as input an ensemble of XCO₂ Level 2 data products (Buchwitz et al., 2015, 2017a, 2017b; Reuter et al., 2013) from SCIAMACHY/ENVISAT and TANSO-FTS/GOSAT. To generate the O4Mv3 product, the EMMA version 3.0 (EMMAv3, Reuter et al., 2017e) product was used. The list of satellite products used for the generation of the EMMAv3 Level 2 product - and therefore also for the O4Mv3 Level 3 data product used in this study - is provided in Tab. 1. The quality of this product relative to Total Carbon Column Observing Network (TCCON) ground-based observations (Wunch et al., 2011, 2015) can be summarized as follows (Buchwitz et al., 2017c): +0.23 ppm overall (global) bias, relative accuracy 0.3 ppm (1-sigma), and very good stability in terms of linear bias trend (-0.02±0.04 ppm/year).

Figure 1 presents an overview of the O4Mv3 product in terms of time series and global XCO₂ maps. The maps show the typical coverage of XCO₂ from SCIAMACHY (until April 2012) and GOSAT (since mid 2009). As can be seen, the time series for the three latitude bands shown in Fig. 1 have very similar slopes. They mainly differ in the amplitude of the seasonal cycle, which reflects the latitudinal dependence of uptake and release of atmospheric CO₂ by the terrestrial biosphere (Schneising et al., 2014). These time series have been used to compute annual mean CO₂ growth rates as will be explained in the following section.

3 Atmospheric CO₂ growth rates from satellite observations

National Oceanic and Atmospheric Administration (NOAA) defines the annual mean CO₂ growth rate for a given year as the CO₂ concentration difference at the end of that year minus the CO₂ concentration at the beginning of that year (Thoning et al., 1989; see also additional explanations as given on the NOAA/ESRL website (https://www.esrl.noaa.gov/gmd/ccgg/about/global_means.html)). We adopt this definition. As described below, our method involves the following three steps: (i) Computation of an XCO₂ time series (at monthly resolution and sampling) by averaging the XCO₂ in the region of interest. (ii) Computation of monthly sampled XCO₂ annual growth rates by computing the difference of the XCO₂ value of month i minus the XCO₂ value of month i-12 and computation of the corresponding uncertainty estimate. (iii) Computation of annual mean growth rates and their corresponding uncertainties from the monthly sampled annual growth rates.

In the following, this method is described in detail using Fig. 2 for illustration. In Figure 2a monthly satellite XCO₂ (O4Mv3), as obtained by globally averaging all the individual (5°x5°) XCO₂ values, is plotted. To compute the spatially averaged XCO₂ time series (shown in Fig. 2a), we first longitudinally average the XCO₂ followed by
the computation of the area-weighted latitudinal average of XCO₂ by using the cosine of latitude as weight. We consider surface area because surface fluxes are linked to mass of CO₂ (or number of CO₂ molecules) rather than molecular mixing ratios or mole fractions. As can be seen, the computed time series does not start at the beginning of 2003 but in April 2003. As explained in Buchwitz et al., 2017d (see discussion of their Fig. 6.1.1.1) the underlying SCIAMACHY BESD v02.01.02 XCO₂ data product (see Tab. 1) apparently suffers from an approximately 1 ppm high bias in the first few months of 2003. The exact magnitude of this bias has not been quantified due to lack of TCCON validation data in this early time period. As this bias in early 2003 is critical for the year 2003 growth rate, we have omitted the first three months of 2003 for the computation of the growth rates shown in this publication.

Figure 2b shows monthly sampled annual growth rates as computed from the monthly XCO₂ values shown in Fig. 2a. Each value is the difference of two monthly XCO₂ values corresponding to the same month (e.g., January) but different years (e.g., 2004 and 2005). For example, the first data point (first diamond symbol) shown in Fig. 2b is the difference of the April 2004 XCO₂ value minus the April 2003 XCO₂ value. The second data point corresponds to May 2004 minus May 2003, etc. The time difference between the monthly XCO₂ pairs is always one year and the time assigned to each XCO₂ difference is the time in the middle of that year. Therefore, the time series shown in Fig. 2b starts six months later and ends six months earlier as compared to the time series shown in Fig. 2a. Each XCO₂ difference shown in Fig. 2b therefore corresponds to an estimate of the XCO₂ annual growth rate and the position on the time-axis corresponds to the middle of the corresponding one-year time period.

A 1-sigma uncertainty estimate has been computed for each of the monthly sampled annual growth rates shown in Fig. 2b (see grey vertical bars). They have been computed such that they reflect the following aspects: (i) the standard error of the O4Mv3 XCO₂ values as given in the O4Mv3 data product file for each of the 5°×5° grid cells, (ii) the spatial variability of the XCO₂ within the selected region, (iii) the temporal variability of the annual growth rates in the one year time interval, which corresponds to the annual growth rate, and (iv) the number of months (N) with data located in that one year time interval. The uncertainties have been computed as the mean value of three terms divided by the square root of N. The first term is the mean value of the standard error, the second term is the standard deviation of the XCO₂ values in the selected region and the third term is the standard deviation of the monthly sampled annual growth rates in the corresponding one-year time interval.

Figure 2c shows the final result, i.e., the annual mean XCO₂ growth rates and their estimated (1-sigma) uncertainties. The annual mean growth rates have been computed by averaging all the monthly sampled annual growth rates (shown in Fig. 2b), which are located in the year of interest (e.g., 2003). For most years, 12 annual growth rate values are available for averaging but there are some exceptions. For example, for the year 2003 only 3 values are present as can be seen from Fig. 2b and for the years 2014 and 2015 there are only 11 values as no data are available for January 2015 due to issues with the GOSAT satellite. The uncertainty of the annual mean growth rate has been computed by averaging the uncertainties assigned to each of the monthly sampled annual growth rates (shown as grey vertical bars in Fig. 2b) scaled with a factor, which depends on the number of months (N) available for averaging. This factor is the square root of 12/N. It ensures that the uncertainty is larger, the less data points are available for averaging. Overall, our uncertainty estimate is quite conservative, as we do
not assume that errors improve upon averaging. As a result of this procedure, the error bar of the year 2003 growth rate is quite large (0.76 ppm/year, see Tab. A1 in Annex A, where all numerical values are listed). This is because the monthly sampled annual growth rate varies significantly in 2003 (see Fig. 2b) and because only N=3 data points are available for averaging in 2003. In contrast, the year 2005 growth rate uncertainty is much smaller (0.28 ppm/year) because the growth rates vary less during 2005 and because N=12 data points are available for averaging.

In Fig. 2c also the NOAA global growth rates (Dlugokencky and Tans, 2017b) are shown. As can be seen, the satellite-derived growth rates agree well with the NOAA growth rates obtained from CO₂ surface observations. For the time period 2003-2016 the linear correlation coefficient $R$ is 0.82 and the difference is -0.02±0.28 ppm/year (mean difference ± standard deviation). Perfect agreement is not to be expected as these two growth rate time series have been obtained from CO₂ observations, which represent very different vertical sampling of the atmosphere (surface (NOAA) versus entire vertical column (satellite)).

As can also be seen from Fig. 2c, the largest growth rates are approximately 3 ppm/year during 2015 and 2016. These record large growth rates (Peters et al., 2017) are attributed to the consequences of the strong 2015/2016 El Niño event, which produced large CO₂ emissions from fires and enhanced net biospheric respiration in the tropics relative to normal conditions (Heymann et al., 2017; Liu et al., 2017). Many of these fires are initiated by humans, for example, to clear tropical forests. In this study, human emissions of CO₂ are defined as emissions from fossil fuel combustion and industry (Le Quéré et al., 2016, 2018) but do not include, for example, CO₂ emissions originating from slash and burn agriculture.

4 Correlation of CO₂ growth rates with fossil CO₂ emissions and ENSO indices

It is well known that changes of the growth rate of atmospheric CO₂ have anthropogenic and natural causes (e.g., Jones et al., 2001; Betts et al., 2016; Kim et al., 2016; Liu et al., 2017; Chylek et al., 2018). In this section we are aiming at answering the following question: “Assuming that the variability of the CO₂ growth rate is dominated by ENSO and by human emissions, which of the two considered causes dominates the growth rate variability given the satellite-derived growth rates and their uncertainty?”. To answer this question we are using a simple linear statistical model and time series of human emissions and two ENSO indices assuming that these indices are appropriate proxies for ENSO related effects in the context of providing a reliable answer.

Figure 3 shows a comparison of the CO₂ annual mean growth rates (Fig. 3a) with annual global CO₂ emissions from fossil fuel combustion and industry (Fig. 3b) (Le Quéré et al., 2018; GCP 2017) (correlation of growth rate and human emissions: $R^2 = 31\%$). As can be seen, the growth rates vary significantly in recent years despite nearly constant human emissions. Figure 3d shows two ENSO indices: the Southern Oscillation Index (SOI, blue lines) (NOAA 2017a; Ropelewski and Jones, 1987) and the Oceanic Niño Index (ONI, green lines) (NOAA 2017b). Whereas SOI is defined as the normalized pressure difference between Tahiti and Darwin (values less than -1 indicate the presence of a strong El Niño), ONI is based on Sea Surface Temperature (SST) differences (positive values correspond to El Niño). The dotted lines correspond to the original (i.e., unshifted) annual mean indices and the solid lines correspond to time shifted ENSO indices. Time shifts have been investigated to
consider the delay in atmospheric response to ENSO-induced changes. As shown in Fig. 3c, the growth rate response as quantified by $R^2$ is largest after 4 months for ONI ($R^2 = 35\%$) and after 7 months for SOI ($R^2 = 30\%$). These maxima have been adopted for the solid (shifted) lines in Fig. 3d. This finding is consistent with results from other studies, where lags in the range 3-9 months have been reported (Jones et al., 2001; Kim et al., 2016; Chylek et al., 2018).

In order to separate and quantify the contributions of the human CO$_2$ emissions and of ENSO, as described by the two indices SOI and ONI, to the growth rate variations, we employ the method of “variation partitioning” (Peres-Neto et al., 2006). To achieve this, we have fitted three basis functions to the 2003-2016 growth rate time series via linear least-squares minimization (we explain the method in this paragraph using SOI but the method does not depend on which ENSO index is used): (i) a constant offset (variance zero), (ii) the human CO$_2$ emissions (Fig. 3b) and (iii) SOI shifted by 7 months (blue solid line in Fig. 3d). The variance of the scaled emission, i.e., of the human emission scaled with the corresponding fit parameter, is 0.0758 ppm$^2$/year$^2$ (note that in this section we report numerical values with four digital places but this shall not imply that all decimal places are significant). The variance of the scaled SOI is 0.1070 ppm$^2$/year$^2$ and the variance of the fit residual is 0.0728 ppm$^2$/year$^2$. The sum of the three individual variances is 0.2557 ppm$^2$/year$^2$ whereas the variance of the annual mean growth rate is 0.2307 ppm$^2$/year$^2$. This shows that the sum of the variances is 10.8\% larger than the variance of the growth rate, i.e., the sum of the variances is not exactly equal to the variance of the sum. The reason for this is that the CO$_2$ emission and the SOI time series are not uncorrelated ($R = 0.14$). To account for correlations, we subtract the variance of the residual from the variance of the growth rate. The result is the part of the variance to be explained by the emissions and by the SOI. The ratio of this to be explained variance (0.1579 ppm$^2$/year$^2$) and the sum of the variances of the emissions and SOI ((0.0758 + 0.1070) ppm$^2$/year$^2$ = 0.1828 ppm$^2$/year$^2$) is 0.8638. The latter is then used as a scaling factor applied to the variances of the emissions and of the SOI. The scaled variances are 0.0655 ppm$^2$/year$^2$ for the emissions and 0.0924 ppm$^2$/year$^2$ for SOI (note that the sum of these scaled variances and the variance of the residual is equal to the variance of the growth rate). From this we conclude that the human emissions explain 28\% ($= 0.0655/0.2307$) of the variance of the growth rate and that ENSO as quantified by the SOI explains 40\% ($= 0.0924/0.2307$). We computed (1-sigma) uncertainties of these estimates by numerically perturbing the satellite-derived annual mean growth rates taking into account their uncertainty (see Figs. 2c and 3) and by subsequently repeating the computations as explained above 10,000 times. The perturbations correspond to random perturbations of the annual mean growth rates assuming normal distributions for each year and no correlation between the different years. This analysis yields that 40±13\% of the growth rate variation results from the impact of ENSO and that 28±14\% is due to the human emissions of CO$_2$. Using these simulations, we also computed the fraction of cases where the ENSO impact dominates over the human emissions. This fraction is 63\% in this case, i.e., when using SOI and when the analysis is applied to the entire time period 2003-2016. This fraction is interpreted as the probability that ENSO-induced impacts on the variation of the growth rate dominates that of human emissions.

When using ONI instead of SOI, ENSO explains 37±14\% of the growth rate variance during 2003-2016, human emissions explain 24±14\% and the fraction where ENSO dominates is again 63\%. When restricting the time period to 2010-2016, which is dominated by strong 2010/2012 La Niña events (Boening et al., 2012; Rodrigues et al., 2014) and by the strong 2015/2016 El Niño, the results are the following: Using the SOI analysis, we find that
ENSO explains 58±19% of the variance, human emissions explain 2±9% and the probability that ENSO dominates is 94%. For the ONI analysis, we find that ENSO explains 59±20% of the variance, human emissions explain 3±9% and the probability that ENSO dominates is 94%. This analysis shows that the ENSO impact on CO₂ growth rate variations dominates over that of human emissions throughout the period 2003-2016 but in particular in the second half of this period, i.e., during 2010-2016.

5 Conclusions

We presented a method for the computation of atmospheric CO₂ column annual mean growth rates from satellite XCO₂ retrievals. The satellite XCO₂ data product used is the Obs4MIPs version 3 (O4Mv3) XCO₂ data product based on SCIAMACHY/ENVISAT and TANSO-FTS/GOSAT satellite data. This product covers the time period 2003-2016 and has monthly time and 5°x5° spatial resolution.

The estimated uncertainty of the satellite-derived annual mean growth rates is typically 0.3 ppm/year (1-sigma) with the exception of the first year 2003, where the uncertainty is 0.76 ppm/year, and of the last year 2016, where the uncertainty is 0.50 ppm/year. The growth rates agree with NOAA within the uncertainty of the satellite-derived growth rates (mean difference ± standard deviation: 0.0±0.3 ppm/year; R: 0.82). In agreement with NOAA, we find that the growth rates are largest in the years 2015 and 2016. These growth rates are around 3 ppm/year and are attributed to the 2015/2016 El Niño resulting in large CO₂ emissions from fires and enhanced net biospheric respiration in the tropics relative to normal conditions (Heymann et al., 2017; Liu et al., 2017). Our analysis also shows that the ENSO impact on CO₂ growth rate variations dominates over that of human emissions throughout the period 2003-2016 (14 years) but in particular during the period 2010-2016 (second half of the investigated time period) due to strong La Niña and El Niño events. We estimate the probability that the impact of ENSO on the variability is larger than the impact of human emissions to be 63% for the time period 2003-2016. If the time period is restricted to 2010-2016 this probability increases to 94%.

In the future, we plan to regularly update the satellite-derived XCO₂ growth rates to monitor this important quantity. This will also include satellite XCO₂ retrievals from other satellite instruments such as XCO₂ from NASA’s OCO-2 mission (e.g., Eldering et al., 2017; Reuter et al., 2017c, 2017d).

Annex A

Growth rate time series have also been computed for several latitude bands as shown in Fig. A1. As can be seen, the growth rates agree within their 1-sigma uncertainty range in all latitude bands including the global results (for numerical values see Tab. A1).

The reason for this is that atmospheric CO$_2$ is long-lived and therefore well-mixed. Because of this we expect similar annual mean CO$_2$ growth rates, i.e., agreement within measurement error, for the different latitude bands and globally. Identical growth rates are not expected due to differences in the sources and sinks and the time needed for transport and mixing. The expectation of similar growth rates is corroborated by Fig. A2, which shows a comparison of the uncertainty of the satellite-derived growth rates (red bars) with the difference of two annual mean CO$_2$ growth rate time series from NOAA, namely the time series from Mauna Loa, Hawaii, and the global time series obtained from globally averaged marine surface data (both obtained from https://www.esrl.noaa.gov/gmd/ccgg/trends/gr.html). As shown in Fig. A2, the uncertainty of the satellite data is similar (mean value: 0.34 ppm/year) as the difference between the two NOAA time series (standard deviation: 0.21 ppm/year). We acknowledge that the maximum difference between any two latitude bands may be somewhat larger than the difference between the two NOAA time series shown in Fig. A2, but it is assumed that the difference shown in Fig. A2 is at least a reasonable approximation.

The agreement shown in Fig. A1 is interpreted as an indication of the good quality of the satellite XCO$_2$ data product and of the adequacy of the method used to compute the annual mean CO$_2$ growth rates because we do not find “strange values” in certain latitude bands or certain years, which would be an indication for a potential problem.
Figure A1. Satellite-derived annual mean XCO₂ growth rates: Global (black), Northern Hemisphere (NH) mid latitudes (“NHmidlat” (30°N - 60°N), red), Tropics (30°S - 30°N, green), and Southern Hemisphere mid latitudes (“SHmidlat” (60°S - 30°S), blue). The corresponding numerical values are listed in Tab. A1.
Figure A2. Comparison of the 1-sigma uncertainty range of the satellite-derived growth rates (red bars) with the difference of two annual mean growth rate time series obtained from NOAA, namely the time series from Mauna Loa (MLO), Hawaii, and the global time series obtained from globally averaged marine surface data (black line and symbols).
Table A1. Satellite-derived annual mean XCO₂ growth rates in ppm/year including 1-sigma uncertainty (in brackets). Abbreviations: NH is Northern Hemisphere and SH is Southern Hemisphere.
