Abstract. The extreme El Niño of 2015 and 2016 coincided with record global warming and unprecedented strength of the Hadley circulation with significant impact on mean interhemispheric (IH) transport of CO\(_2\). The relative roles of eddy transport and mean advective transport on interannual differences in CO\(_2\) concentration between Mauna Loa and Cape Grim (C\(_{\text{mlo-cgo}}\)), from 1992 through to 2016, is explored. Eddy transport processes occur mainly in boreal winter-spring when C\(_{\text{mlo-cgo}}\) is large; an important component is due to Rossby wave generation by the Himalayas and propagation through the equatorial Pacific westerly duct generating and transmitting turbulent kinetic energy. Mean transport occurs mainly in boreal summer-autumn and varies with the strength of the Hadley circulation. The timing of annual changes in C\(_{\text{mlo-cgo}}\) is found to coincide well with dynamical indices that we introduce to characterize the transports. During the unrivalled 2009-2010 step in C\(_{\text{mlo-cgo}}\) the effects of the eddy and mean transport reinforce. In contrast for the 2015 to 2016 change in C\(_{\text{mlo-cgo}}\) the mean transport counteracts the eddy transport and the record strength of the Hadley circulation determines the annual IH CO\(_2\) difference. The interaction of increasing global warming and extreme El Niños may have important implications for altering the balance between eddy and mean IH CO\(_2\) transfer. The effects of interannual changes in mean and eddy transport on interhemispheric gradients in other trace gases are also examined.

1 Introduction

Interhemispheric (IH) exchange of CO\(_2\) occurs mainly by eddy transport in the boreal winter-spring and by mean convective and advective exchange in the boreal summer-autumn (Bowman and Cohen, 1997; Lintner et al., 2004; Miyazaki et al. 2008; and references therein).

On the basis of long-term (1949-2011) correlations of the upper-tropospheric zonal wind with the Southern Oscillation Index (SOI), Francey & Frederiksen (2016; hereafter FF16) defined an index for the Pacific westerly duct, \(u_{\text{duct}}\), as a measure of IH eddy transport of CO\(_2\). This index is the average zonal wind in the region 5°N to 5°S, 140°W to 170°W at 300hPa, as summarized in Table 1. In this article the period of interest is 1992 to 2016 and the corresponding correlation is shown in Fig. 1S of the Supplement. There the role of the changing Walker circulation with the cycle of the El Niño-Southern
Oscillation (ENSO) in determining the properties of the Pacific and Atlantic westerly ducts is also documented. The $u_{duct}$ index is an indicator of cross equatorial Rossby wave dispersion and associated increases in near equatorial upper tropospheric transient kinetic energy (Frederiksen and Webster, 1988), particularly between 300 and 100hPa (~9 km to ~16 km above sea level). The process normally occurs over the eastern Pacific Ocean during the boreal winter-spring and the Rossby waves (Webster and Holton, 1982; Stan et al., 2017), generated downwind of thermal anomalies and continental influences, in particular the massive Himalayan orography, propagate in a south-east direction through the Pacific westerly duct generating and transporting turbulent kinetic energy. The generation of turbulent kinetic energy occurs through Rossby wave breaking in the Pacific and Atlantic ducts and enhances turbulent mixing (Ortega et al. 2018 and references therein). FF16 also considered the relationship of $u_{duct}$ and other trace gases including CH$_4$. Indeed, recently Pandey et al. (2017) and Knol et al. (2017) also considered the implications of faster IH transfer of CH$_4$ during the La Niña of 2011 when the Pacific westerly wind duct is open and $u_{duct}$ is large.

FF16 explained the exceptional step in CO$_2$ IH difference between 2009 and 2010 as due to a contribution from the large anomaly in $u_{duct}$ observed at the time. Recently results from the National Aeronautics and Space Administration (NASA) Orbiting Carbon Observatory-2 (OCO-2) during the 2015-2016 El Niño have been published (Chatterjee et al., 2017; and references therein) In particular release by NASA (2016) of data in a movie ‘Following Carbon Dioxide through the Atmosphere’ provides further direct evidence of the Pacific duct hypothesis. The NASA OCO-2 CO$_2$ concentration in Fig. 1(a) is for 17 Feb 2015 and shows Rossby wave trains over the eastern Pacific and across South America associated with IH exchange as a typical example of OCO-2 images that coincide with the shaded 2015 period in Fig. 1(b). The dynamical properties of these Rossby waves are further explored in the Supplement including Figs. 3S and 4S. Figure 1(b) uses the covariance between CO$_2$ and $u_{duct}$ in early 2015, indicated by shading, to predict IH CO$_2$ exchange through the Pacific duct. The atmospheric circulation data and indices used throughout this article are obtained from the National Centers for Environmental Prediction (NCEP) and National Center for Atmospheric Research (NCAR) reanalysis (NNR) data (Kalnay et al., 1996); in Section 6 we briefly consider the robustness of our results using another reanalysis data set. The results in Figs. 1(a) and (b) are also consistent with upper-tropospheric ($u,v$) wind vectors. Between 5 and 23 February 2015 NNR wind vectors show that a strong Pacific North American height anomaly caused a split in the Pacific upper tropospheric winds, the Pacific westerly duct was open, and there were south-east cross equatorial winds from the Northern to Southern Hemispheres. This is illustrated in Fig. 1(c) for 300 hPa wind vectors on 17 Feb 2015.

The focus here is on IH CO$_2$ difference, anomalies in the mean convective and advective mode of IH CO$_2$ exchange and changes in the relative importance of the mean and eddy transport modes.

### 2 Changes in CO$_2$ interhemispheric difference

To represent CO$_2$ interhemispheric difference we define $C_{\text{mlo-cgo}}$ as the difference in Commonwealth Scientific and Industrial Research Organisation (CSIRO) analysed CO$_2$ concentrations in baseline air sampled from Mauna Loa (mlo, 20°N, 156°W)
2.1 The influences of terrestrial fluxes and transport on interhemispheric CO₂ differences

The growth rate and concentration of atmospheric CO₂ depend on many mechanisms including fossil fuel emissions, surface fluxes, such as associated with the growth and decay of vegetation, and atmospheric mean and eddy transport. The CO₂ growth rate and IH gradients in CO₂ vary on daily, monthly, yearly and multi-year time scales where there is a quasi-periodic variability associated with the influence of ENSO (e.g. Thoning et al. 1989). This reflects the response of tropical vegetation to rainfall variations and both hemispheres are also affected through dynamical coupling.

A number of recent inversion studies have largely attributed growth anomalies in atmospheric CO₂ concentrations to anomalous responses of the terrestrial biosphere. However, the variability in the responses within Dynamic Global Vegetation Models (DGVMs) is significant. Le Quéré et al. (2017) for example note that the “standard deviation of the annual CO₂ sink across the DGVMs averages to ± 0.8 GtC yr⁻¹ for the period 1959 to 2016”. This is significantly larger than the reported extratropical sink anomalies during for example the major 2009-2010 step in CO₂ concentrations (Poulter et al., 2014; Trudinger et al., 2016). Francey and Frederiksen (2015) presented reasons supporting a dynamical contribution to the cause of the 2009-2010 Cmlo-cgo step.

For the 2015-2016 period of particular relevance here there are two studies that stand out. Keenan et al. (2016) interpret slowing CO₂ growth in 2016 as strong uptake by Northern Hemisphere terrestrial forests. Yue et al. (2018) examine the reasons for the strong positive anomalies in atmospheric CO₂ growth rates during 2015. They present evidence of the Northern Hemisphere terrestrial response to El Niño events by way of satellite observations of vegetation greenness. To reconcile increased greenness with increased CO₂ growth their inversion modelling requires the “largest ever observed” transition from sink to source in the tropical biosphere at the peak of the El Niño, “but the detailed mechanisms underlying such an extreme transition remain to be elucidated”.

In this study, we find that the 2015-2016 El Niño also corresponds to unprecedented anomalies in both mean and eddy IH CO₂ transport characterized by indices of these transfers that we introduce. As for the anomalies in CO₂ IH gradient during
the 2009-2010 El Niño, studied in FF16, this again suggests a contributing role for anomalous IH transport during the 2015-2016 event. We examine this possibility in detail and study the relationships between the extremes in IH CO₂ differences and transport anomalies for 1992 to 2016 and associated correlations between \( C_{\text{mlo-cgo}} \) (and other trace gases) and dynamical indices of transport.

2.2 Dynamical influences on IH exchange

Figure 2(b) confirms that much of the year-to-year variability in \( C_{\text{mlo-cgo}} \), particularly preceding 2010, occurs in the boreal winter-spring (Dec-May) when eddy transport is expected to be the more active contribution to IH exchange (FF16). The step jump in annual values between 2009 and 2010 that was the focus of FF16, is the most prominent feature. A similar relationship with \( u_{\text{d duct}} \) is supported prior to 2010 as indicated here by vertical dashed gridlines aligned with the beginning of the calendar years when \( u_{\text{d duct}} \) is unusually low \( (u_{\text{d duct}} \leq 3 \text{ ms}^{-1}) \). At these times \( u_{\text{d duct}} \) generally corresponds to above-average \( C_{\text{mlo-cgo}} \) consistent with an accumulation of CO₂ in the Northern Hemisphere at a time when the Pacific duct transfer is small.

A notable exception occurs in 2015-2016 and this is a particular focus of this study that we address in the context of the unusual \( C_{\text{mlo-cgo}} \) behaviour since 2010. For example, since 2010 the annual average \( C_{\text{mlo-cgo}} \) in Fig. 2(a) shows reduced scatter and a slight decrease at a time when fossil fuel emissions continue to grow. As shown in Fig. 2(b), this \( C_{\text{mlo-cgo}} \) decrease is more marked in the boreal summer-autumn (Jun-Nov) than in boreal winter-spring (Dec-May) when it is relatively stable (and even recovers in the last 3 years).

The steadily decreasing \( u_{\text{d duct}} \) since 2012 occurs all year round in Fig. 2(c). Similar but more marked decreases occur in indices \( \omega_H \) and \( \nu_H \) in Fig. 2(d), which measure the strength and location of the Hadley circulation. Here, \( \omega_H \) is the 300 hPa vertical velocity in pressure coordinates \( (\omega = dp/dt \text{ where } p \text{ is pressure}) \) averaged zonally \( (0-360^\circ) \) and between 10°N and 15°N (Table 1). Also, \( \nu_H \) is the 200 hPa south-to-north meridional wind averaged zonally and between 5°N and 10°N (Table 1). Both \( \omega_H \) and \( \nu_H \) become more negative and the mean transport from the Northern to Southern Hemispheres increases with a strengthening of the Hadley circulation. As noted by Freitas et al. (2017; and references therein) the Hadley circulation strengthens during El Niños, and particularly for strong events such as during 2015-2016 (L’Heureux et al., 2017). There are subtle relationships between the latitudinal width of the equatorial heating during El Niño and global warming (Freitas et al., 2017) and the Hadley circulation. However, it is expected that there will be an increasing frequency of extreme El Niño events with increasing global warming (Cai et al., 2014; Yeh et al., 2018).

Before examining the Hadley component further, we clarify factors associated with the eddy transfer through the Pacific duct.
3 The role of the Pacific westerly duct in IH CO$_2$ eddy transport

We examine here the concept of relatively rapid interhemispheric CO$_2$ exchange through a spatially restricted Pacific duct and discuss issues of the uniqueness of the duct and the transport of both turbulent kinetic energy and CO$_2$ to and through the Pacific duct region.

3.1 Eddy generation in the equatorial zone

The $u_{duct}$ zonal wind based on the peak climatological correlation with SOI (140°W -170°W) is also largely representative of near equatorial (5°N to 5°S) zonal winds and their variability in the larger region between 90°W and 180°. Pattern correlations between the two vary from $r \sim 0.9$ for November to April to $r \sim 0.7$ for May to October.

In Fig. 3, Hovmoller diagrams for the Western Hemisphere (180° to 0°W) between 2008 and 2016 show the time-longitude of daily 300hPa zonal winds between 5°N and 5°S. The cool blue background represents easterly winds (negative $u$) while warm colours, green to yellow through to red, depict westerlies (positive $u$). Frederiksen and and Webster (1988) found that near equatorial upper tropospheric transient kinetic energy generation is approximately linearly related to zonal wind strength (their Fig. 6) and is strongest for westerlies when the winds oppose the earth’s rotation. The longitudinal limits of $u_{duct}$ determined from the SOI correlation are enclosed by solid white rounded rectangles in Fig. 3, while the time period (rectangle height) represents those months when $C_{mlo-cgo}$ is at a seasonal maximum and winds in the Pacific duct are normally westerly (Feb-Apr).

In most years, $u_{duct}$ is positive in boreal winter-spring and Rossby waves generated by, for example, the Himalayas (height of 8.8 km) can propagate through the downstream Pacific duct region (140°W -170°W, 5°N-5°S) producing and transporting turbulent kinetic energy southwards. In some years, such as the boreal winter-spring of 2009-2010 and 2015-2016, $u_{duct}$ is anomalously weak and the peak equatorial 300 hPa zonal winds are over the Atlantic ocean, particularly in the Atlantic duct region defined as 10°W-40°W, 5°N-5°S. The Atlantic duct region, most conspicuously, is downstream of the Rockies (height of 4.4 km). Figure 1S of our Supplement and Fig. 4(a) of FF16 show that the SOI and Atlantic duct zonal winds are strongly anti-correlated in contrast to the strong correlation with $u_{duct}$; as well, in the Eastern Hemisphere the correlation between the SOI and equatorial zonal winds is quite weak. We note that $u_{duct}$ and the Atlantic duct winds are anti-correlated with $r = -0.66$. Further while $u_{duct}$ is anti-correlated with $C_{mlo-cgo}$ the Atlantic duct winds are correlated with a similar magnitude. This indicates that changes in $u_{duct}$ are the primary determinant of interhemispheric CO$_2$ duct transfer via eddy processes and $C_{mlo-cgo}$ and the opening of the Atlantic duct is mainly important through the associated closing of the Pacific duct. This is consistent with the idea that Rossby wave dispersion from the smaller topographic features of the Rockies is less important than from the more massive Himalayas, as further discussed in the Supplement.
3.2 Transport of surface CO$_2$ emissions to the upper troposphere

Transport of CO$_2$ emissions from the surface to the upper troposphere is explored next. We find that when the Pacific duct is open there is also large scale uplift slightly downstream of Asia so that in a given winter-spring season the substantial regional emissions are effectively transported directly through the duct via Rossby wave dispersion, including by the Himalayan wave train. Figure 4 shows the Feb-Apr correlation between the 500hPa $\omega$ (the vertical wind in pressure coordinates with negative values corresponding to uplift in height coordinates) and the SOI from 1948 to 2016. The most prominent correlations occur within ±30° of the equator at longitudes 120°E to 170°W, upstream and at the longitudes of the Pacific duct and this is in fact the case at all levels between the surface and 100 hPa (not shown). Broadly similar correlations are obtained between the 500 hPa $\omega$ and $u_{duct}$ for Feb-Apr (and for 500 hPa $\omega$ and SOI for Jan-Dec). At other times, for example in 2010 and 2015-2016, when there have been persisting easterlies in the Pacific duct region there has been descent slightly downstream of the Asian region. Thus the recent record Asian emissions may play a significant role in direct episodic IH CO$_2$ transfer through the Pacific duct. To the extent that Asian emissions might be preferentially represented in direct IH CO$_2$ transfer, it is relevant that uncertainty and possibly variability in Asian emissions are greater than the reported uncertainty and variability in the global totals (Andres et al., 2014).

4 The role of the Hadley circulation in mean IH CO$_2$ transport

As noted in Section 2, the years 2010 and 2016 exhibit a similar anomalous eddy transport index, $u_{duct}$, but have different $C_{mol-cgo}$ responses relative to previous years (Fig. 2(a)). Since the CO$_2$ emitted in the Northern Hemisphere and tropics is also transported into the Southern Hemisphere by the mean divergent flow associated with the Hadley circulation, particularly during boreal summer (Miyazaki et al., 2008), this is now explored in more detail. The Pacific duct transfer in boreal winter-spring, with peaks in Feb-Apr, occurs when the CO$_2$ IH partial pressure difference is near maximum due to forest respiration. Likewise the mean IH transport related to the Hadley circulation occurs in boreal summer-autumn, with peaks in Jun-Aug, when the CO$_2$ IH partial pressure difference has a proportionally larger contribution due to the accumulated fossil fuel CO$_2$ from NH industrial emissions.

Figure 5 shows latitude-height cross sections, over the Pacific, averaged between 120°E-240°E, of June to August vertical wind in pressure coordinates, $\omega$, while Fig. 6 shows the corresponding results for the meridional wind, $v$. Recall that negative $\omega$ corresponds to positive vertical velocity in height coordinates and negative $v$ is north-to-south meridional wind. In the boreal summer-spring average values for 1979 to 2016 show the uplift (negative $\omega$) at low northern latitudes (Fig. 5(a)) while the advective Hadley Cell meridional transfer (negative $v$) to the Southern Hemisphere at high altitude can be seen in Fig. 6(a).
By subtracting the 1979-2016 average from the 2016 $\omega$ values and $\nu$ values, the nature of the extreme 2016 anomaly becomes visible, with strong uplift including between 10°N and 15°N shown in Figs. 5(b) and extensive meridional wind penetration into the Southern Hemisphere, particularly between 500hPa and 300hPa, shown in Fig. 6(b). Figures 5(c) and 6(c) depict the difference between the anomaly years 2016 and 2010. Both the uplift between 10°N and 15°N and penetration of the meridional wind into the Southern Hemisphere is stronger in the upper troposphere and mean transport through convection and advection into the Southern Hemisphere more extensive in 2016.

On the basis of these figures, and similar figures for the corresponding zonally averaged quantities, we have chosen four indices to characterize the mean circulation by the Hadley Cell (Table 1). These are $\omega_p$ the vertical velocity in pressure coordinates over the Pacific ocean at 300 hPa averaged between 120°E-240°E and 10°N-15°N, $\nu_p$ the meridional wind at 200hPa averaged between 120°E-240°E and 5°N-10°N as well as the corresponding zonally averaged indices $\omega_H$ and $\nu_H$ introduced in Section 2.

5 Quantifying the $C_{\text{mlo-cgo}}$ relationships with eddy and mean transport indices

The timing of a majority of short term variations in the 25-year baseline $C_{\text{mlo-cgo}}$ corresponds to atmospheric transport changes that influence the interhemispheric exchange. To quantify relationships between $C_{\text{mlo-cgo}}$ and the eddy and mean transport indices involved we first suppress the $C_{\text{mlo-cgo}}$ changes expected from reported anthropogenic emissions. The global annual average anthropogenic emissions (Le Quere et al., 2017) are converted to ppm using the coefficient 0.36 ppm/PgCyr$^{-1}$ derived in Section 2 from Fig. 2 and subtracted from the observed $C_{\text{mlo-cgo}}$. In Fig. 6 we compare the FF-adjusted $C_{\text{mlo-cgo}}$, which we denote $C^*_{\text{mlo-cgo}}$, for two periods when $C_{\text{mlo-cgo}}$ is positive; the first is Feb-Apr that best captures the eddy IH exchange, and the second is Jun-Aug when mean transfer related to the Hadley circulation is captured.

We focus first on the FF-adjusted $C^*_{\text{mlo-cgo}}$ plots in Figs. 7(a) and (b). The mean and year-to-year variation is very much larger in (a) compared to (b) and is also larger in (a) compared to the annual averaged values in Fig. 2(a). The contrasting behaviour between the two periods after 2012 is also more marked.

To emphasize the similarities between $C^*_{\text{mlo-cgo}}$ and Pacific duct winds we plot $-u_{\text{duct}}$ in Fig. 7(a), so that easterlies are shown as positive and the more frequent westerlies as negative; the timings of peaks in both panels then correspond. When winds in the Pacific duct are easterly or near zero, FF-adjusted $C^*_{\text{mlo-cgo}}$ peak or are above average; this is now more obvious in 2016 compared with the corresponding results for $C_{\text{mlo-cgo}}$ in Dec-May shown in Figs. 2(b) and 2(c). In fact the FF-adjusted $C^*_{\text{mlo-cgo}}$ has very similar behaviour to the detrended $C_{\text{mlo-cgo}}$, with pattern correlations of anomalies of $r = 0.931$, $r = 0.954$ and $r = 0.981$ for Jan-Dec, Jun-Aug and Feb-Apr respectively. The similarity can also be seen by comparing the top panel of Fig. 7(b) with that of Fig. 8. Despite persistent agreement in timing, the magnitude of the $C_{\text{mlo-cgo}}$ response to the $u_{\text{duct}}$ anomaly is more variable. This is reflected in the correlation between the detrended $C_{\text{mlo-cgo}}$ anomalies and the detrended $u_{\text{duct}}$ anomalies which is $r = -0.500$ for Feb-Apr and $r = -0.228$ for Dec-May. These results confirm the preferential Pacific duct transfer in late boreal winter and early spring (Feb-Apr). They also indicate that although there is an
important relationship between \( C_{\text{mlo-cgo}} \) and the zonal wind in the Pacific duct, other processes detailed in Section 2, such as changes in direct advective transport by the mean winds and emissions, also play roles in year-to-year IH variations. This is also confirmed by a regression analysis of \( C_{\text{mlo-cgo}} \) anomalies onto \( u_{\text{duct}} \) anomalies (not shown) where there is significant scatter about the regression line.

In particular, during 2009-2010 there were a number of complicating factors that most likely contributed. The unusually low \( C_{\text{mlo-cgo}} \) in 2008, 2009 coincide with the Global Financial Crisis when global emissions dipped (and recent British Petroleum, 2018, estimates of emissions suggest an even larger 2008-2009 anomaly than in data used here). Terrestrial Net Biosphere Production south of 30°S was also anomalously low in 2009 and anomalously high in 2010 (FF16; Trudinger et al. 2016; though by amounts not sufficient to impact on the Cape Grim baseline CO\(_2\) records). The low \( C_{\text{mlo-cgo}} \) also align with near-record strong westerlies in the Pacific duct, and associated larger eddy transport, in 2008; both potentially contribute to increasing the magnitude of the subsequent CO\(_2\) step.

In Fig. 7(b) the post-2010 decrease in Jun-Aug FF-adjusted \( C^*_{\text{mlo-cgo}} \) is clearly mirrored in the decreasing \( \omega \) and \( \nu \) indices (indicating strengthened Hadley circulation), particularly in the 120°E-240°E Pacific sector (\( \omega_p \) and \( \nu_p \)) compared to the zonal average (\( \omega_H \) and \( \nu_H \)). The considerably weaker strength of the Hadley circulation in 2010 compared with 2016 is shown quite distinctly. The correlations between the detrended \( C_{\text{mlo-cgo}} \) anomalies and indices of mean transport are shown in Table 2.

Generally Jun-Aug correlations are stronger than the Jun-Nov correlations and correlations over the Pacific sector 120°E-240°E are generally larger than for the zonally averaged quantities. This is clearly the case for \( \omega \) while \( \nu_H \) is an exception being larger for the longer time period. The \( C_{\text{mlo-cgo}} \) correlations for Jun-Aug involving \( \omega_p \) and \( \nu_p \) have roughly similar magnitudes to those for Feb-Apr involving \( u_{\text{duct}} \) and \( \omega_p \) and \( \nu_p \) provide similar predictability of the role of the Hadley circulation in mean IH CO\(_2\) transport as \( u_{\text{duct}} \) does for eddy transport. Interestingly, during 2009-2010 the effects of \( u_{\text{duct}} \) and \( \omega_p \) and \( \nu_p \) reinforce to make the step in \( C_{\text{mlo-cgo}} \) large, while for 2015-2016 \( \omega_p \) and \( \nu_p \) counteract \( u_{\text{duct}} \) and the exceptionally strong Hadley circulation becomes the dominant feature in determining the annual \( C_{\text{mlo-cgo}} \) (Fig. 1a). These results show that there is an important connection between the \( C_{\text{mlo-cgo}} \) and the indices that characterize the strength of the Hadley circulation and mean transport. Again, as also suggested by regression analysis (not shown), other processes, detailed in Section 2 and above, also play important roles.

The somewhat different behaviours of \( C_{\text{mlo-cgo}} \) and the dynamical indices, particularly during the El Niños of 2009-2010 and 2015-2016 and of 1997-1998, may partly reflect the diversity of El Niños and whether the heating is focussed in the Eastern Pacific or in the Central Pacific (Capotondi et al. 2015; L’Heureux et al. 2017 and references therein). The strong 1997-1998 event like, the 1982-1983 event, was a classic Eastern Pacific El Niño with maximum temperature anomalies there of nearly +4°C (L’Heureux et al. 2017). The 2009-2010 event in contrast was a Central Pacific El Niño with record-breaking warming in the central Pacific (Kim et al. 2011). The 2015-2016 El Niño fell between these two canonical cases with less warming in the eastern Pacific Ocean than the 1997-1998 event but similar warming to the 2009-2010 event in the central Pacific (L’Heureux et al. 2017).
The broadly increasing magnitude of the negative $\omega$ and $\nu$ indices since 2012 is associated with both increasing global temperatures, breaking the record in 2016, and the large El Niño of 2015 and 2016. This has resulted in the increasing importance of the mean convective and advective CO$_2$ transport by the Hadley circulation relative to the eddy transport including through the Pacific duct. It will be interesting to see whether this favouring of the mean over the eddy IH CO$_2$ transport will become increasingly important with further global warming and the extent to which it depends on extreme El Niños (Cai et al., 2014; Freitas et al., 2017; Yeh et al., 2018).

The dynamical indices that we have used for this study are based on the NCEP-NCAR reanalysis (NNR) data (Kalnay et al. 1996). There is generally close correspondence between the major global atmospheric circulation data sets that, like the NNR data, use full data assimilation throughout the atmosphere (Frederiksen & Frederiksen 2007; Frederiksen et al. 2017a; Rikus 2018). We have confirmed this by recalculating our dynamical indices and main correlations with $C_{\text{mlo-cgo}}$ based on the NASA Modern Era Retrospective-analysis for Research and Applications (MERRA) data (Rienecker et al. 2011). For example, the 1992 to 2016 correlation between MERRA and NNR data for $u_{\text{duct}}$ in Feb-Apr is $r = 0.974$, for $\omega_p$ in Jun-Aug is $r = 0.899$ and for $\nu_p$ in Jun-Aug is $r = 0.931$. The corresponding correlations between detrended anomalies of $C_{\text{mlo-cgo}}$ and the MERRA based dynamical indices are also very similar. The correlations are $r = -0.512$ with $u_{\text{duct}}$ for Feb-Apr (compared with $r = -0.500$ for the NNR index), $r = 0.504$ with $\omega_p$ for Jun-Aug (compared with $r = 0.522$ based on NNR) and $r = 0.538$ with $\nu_p$ for Jun-Aug (compared with $r = 0.539$ based on NNR).

6 Interhemispheric exchange of other trace gases

Next, we consider the eddy and mean IH exchange of other trace gas species and their correlations with CO$_2$ and dynamical indices of transport. We focus on Feb-Apr for eddy transport and Jun-Aug for mean transport since these periods were the peaks for correlations of CO$_2$ IH difference with eddy and mean transport indices respectively. However, there are differences in the seasonal variability of interhemispheric gradient in the different trace gas species that are reflected in their transport and for that reason we also briefly mention the results for other time periods. We begin by further examining Mauna Loa minus Cape Grim (mlo–cgo) differences, between 1992-2016, in the routinely monitored CSIRO species CH$_4$, CO and H$_2$ in addition to CO$_2$ that were briefly considered by Francey and Frederiksen (FF16), as well as N$_2$O (for 1993-2016). Thereafter we discuss mlo–cgo differences in SF$_6$ data sourced from the NOAA Halocarbons and other Atmospheric Trace Species Group (HATS) program from 1998 (NOAA, 2018).

6.1 Pacific westerly duct and eddy IH transport of CSIRO monitored trace gases

The IH exchange of the trace gas species, CH$_4$, CO and H$_2$, in addition to CO$_2$, and the role of the Pacific westerly wind duct were also considered in FF16. In particular, the covariance, of the mlo–cgo difference in these routinely monitored CSIRO species with $u_{\text{duct}}$, is shown in Fig. 5 of FF16. We recall that the $u_{\text{duct}}$ index is the average zonal wind in the region 5°N to 5°S, 140°W to 170°W at 300hPa. As noted in FF16, the extreme cases of Pacific westerly duct closure in 1997–98 and
2009–10 show up in the reduction of seasonal IH exchange for CH$_4$ and CO as well as CO$_2$. The similar behaviour of detrended anomalies of mlo–cgo difference in CH$_4$, CO and CO$_2$ and their correlations with $u_{duct}$ is shown in Table 3 for Feb–Apr. We note the quite high correlations of CH$_4$ and CO with CO$_2$ ($r = 0.697$ and $r = 0.645$ respectively) and the significant anti–correlations of all these three species with $u_{duct}$ ($r = -0.448$, $r = -0.605$ and $r = -0.500$ respectively).

In fact, for Mar-May the correlation between CH$_4$ and CO$_2$ is even larger at $r = 0.728$ (and with $u_{duct}$ it is $r = -0.474$) while between CO and CO$_2$ it is $r = 0.611$ (and with $u_{duct}$ it is $r = -0.507$). These results are of course consistent with Fig. 5 of FF16 and are further evidence of similarities of IH transient eddy transport of these three gases. Table 3 also shows that the Feb-Apr correlation of H$_2$ with CO$_2$ and anti–correlation with $u_{duct}$ have smaller magnitudes ($r = 0.296$ and $r = -0.218$ respectively). These results for anomalies are probably related to corresponding similarities and differences in the seasonal mean values (not shown) of these gases in Feb–Apr, as discussed below.

Anomalies in mlo–cgo differences in CSIRO monitored N$_2$O are generally poorly correlated with those in CO$_2$ as shown for Feb-Apr and Jun-Aug in Tables 3 and 4 respectively (the maximum 3 month average correlation is $r = 0.274$ for Mar-May) and this is mirrored in generally poor correlation with the dynamical indices shown in Tables 3 and 4. This reflects the fact that natural exchanges with equatorial agriculture and oceans are the main sources (Ishijima et al., 2009), and the seasonal range in mlo-cgo difference is only around 0.2% of the mean N$_2$O level, more than 10 times less than is the case for the other species.

### 6.2 Hadley circulation and mean IH transport of CSIRO monitored trace gases

We examine the role of the Hadley circulation on the mean transport of trace gases focusing on the boreal summer period of Jun–Aug. Table 4 shows the correlations between the detrended anomalies of mlo–cgo difference in CH$_4$, CO and H$_2$ with CO$_2$ and with the dynamical indices $\omega_p$ and $\nu_p$ (Table 1). We note that the largest Jun-Aug correlation is between H$_2$ and CO$_2$ ($r = 0.680$) and the correlations between CH$_4$ and CO with CO$_2$ are considerably smaller ($r = 0.246$ and $r = 0.108$ respectively) while for Apr-Jun the latter correlations are more comparable at $r = 0.583$ and $r = 0.496$ respectively. These correlations with CO$_2$ are also reflected in the respective correlations of the other trace gases with $\omega_p$ and $\nu_p$. We note from Table 4 that the Jun-Aug correlations of H$_2$ with $\omega_p$ and $\nu_p$ are $r = 0.427$ and $r = 0.442$ respectively which is slightly less than the corresponding correlations between CO$_2$ and the dynamical indices ($r = 0.522$ and $r = 0.539$ respectively) but considerably larger than for CH$_4$ and CO. For May-Jul the correlation of H$_2$ with $\omega_p$ is slightly larger with $r = 0.526$.

Again, the different behaviour of the trace gas anomalies may be related to their different seasonal mean values; the seasonal mean IH difference for H$_2$ peaks in boreal summer while for CH$_4$ and CO it is relatively low with a minimum in August. The distribution and variability of surface exchange is different for each of the trace gases and there is potential for this to interact with the restricted extent and seasonal meandering of the regions of uplift to influence IH exchange of a species. For example, 70% of the global total CH$_4$ emissions are from mainly equatorial biogenic sources that include wetlands, rice
agriculture, livestock, landfills, forests, oceans and termites (Denman et al., 2007) and CO emissions contain a significant contribution from CH$_4$ oxidation and from tropical biomass burning.

A more detailed examination of the inter–annual variation of the mlo–cgo difference in H$_2$ during boreal summer is presented in Fig. 8. It shows the detrended H$_2$ data in comparison with the corresponding CO$_2$ data and with the $\omega_p$ and $v_p$ indices.

First we note that the detrended CO$_2$ data in the top panel has very similar inter–annual variation to the FF–adjusted C$_mlo$–cgo in Fig. 7(b). We also see that the qualitative behaviour of H$_2$ mirrors many aspects of CO$_2$, as expected from the correlations in Table 4. In particular, the increase in the IH difference of H$_2$ in 2010 is even more pronounced than for CO$_2$. For CO$_2$ and for H$_2$ there is a steady reduction in the IH difference from around 2013 leading to a local minimum in 2016. In both of these respects these gases broadly follow the changes in the Hadley circulation including the strengthening during 2015–2016.

Vertical lines in Fig. 8 indicate other times between 1992 and 2016 when transitions occur in both these trace gases and in the Hadley circulation characterized by $\omega_p$ and $v_p$.

Surface exchanges of H$_2$ have similarities to those of CO$_2$ in that they occur mostly at mid–northern latitudes and are mainly due to emissions from fossil fuel combustion. However H$_2$ also has mid–northern latitude photochemical sources peaking in August (Price et al., 2007). These boreal summer sources are almost offset by a combined soil and hydroxyl sink, but the overall interhemispheric partial pressure difference is boosted by a significant reduction in the Southern Hemisphere photochemical source at that time. For both species, the most northern excursions of the inter–tropical convergence zone that occurs at Pacific latitudes encounter increasing concentrations of both gases.

As noted above, anomalies in mlo–cgo differences in N$_2$O are poorly correlated with those in CO$_2$ and in dynamical indices (Tables 3 and 4). Indeed the 3 month average anti-correlation with $u_{duct}$ that has the largest magnitude is $r = -0.133$ for Mar-May and the largest correlations with $\omega_p$ is $r = 0.359$ for Apr-Jun and with $v_p$ is $r = 0.350$ for May-Jul.

### 6.3 Interhemispheric exchange of SF$_6$

In the case of SF6 we have analysed the mlo–cgo difference in available NOAA HATS data from 1998 to 2012 when cgo HATS measurements ceased. Correlations (Tables 3 and 4) of detrended anomalies in IH differences in SF$_6$ with those in CO$_2$ are as follows: the Feb–Apr correlation is $r = 0.619$, the Mar-May correlation is $r = 0.722$, the Apr-Jun correlation is $r = 0.595$, the May–Jul correlation is $r = 0.303$ and the Jun–Aug correlation is $r = 0.223$. The corresponding correlations with dynamical indices are as follows: for Feb–Apr the correlation with $u_{duct}$ is $r = -0.617$, the May–Jul correlations with $\omega_p$ is $r = 0.465$, the Jun–Aug correlation with $\omega_p$ is $r = 0.433$, the May–Jul correlation with $v_p$ is $r = 0.517$ and the Jun–Aug correlation with $v_p$ is $r = 0.385$. We note that SF$_6$ has an anti-correlation with $u_{duct}$ for Feb-Apr that has larger magnitude than for CO$_2$ and even CO. Thus, there is again a significant influence of the Pacific westerly duct, in late boreal winter and spring, and of the Hadley circulation, in boreal summer and late spring, as measured by these indices, on the mlo–cgo differences of SF$_6$; these SF$_6$ differences exhibit a similar step change in 2009-2010 as shown for CO$_2$ in Figs. 2 and 7.
7 Conclusions

The major El Niño of 2015 and 2016 coincided with record global warming, with 2016 having the highest global average surface temperatures and 2015 the third highest (2017 had the second highest). The strength of the Hadley circulation also increased to unprecedented levels during 2015-2016 and had a major impact on the mean interhemispheric (IH) transport of CO₂ and on the difference in CO₂ concentration between Mauna Loa and Cape Grim (C_mlo-cgo). This study has focussed on the roles of IH transient eddy and mean transport of CO₂ on interannual variations in C_mlo-cgo and has established dynamical indices that characterize the broad features of this transfer (Table 1). Interestingly, some of these indices are based on regions that lie close to or overlap the region of the Niño 3.4 SST index (5°N-5°S, 120°W-170°W) where ENSO is strongly coupled to the overlying atmosphere (L’Heureux et al., 2017).

One of these indices, \(u_{duct}\), which is a measure of eddy IH transport of CO₂, was introduced in FF16. This index is the 300 hPa Pacific zonal wind averaged between 5°N-5°S and 140°W-170°W and is strongly correlated with the Southern Oscillation (SOI) index (\(r \sim 0.8\) in Fig. 4(a) of FF16). A particular focus of that study was to propose an explanation for the record step in CO₂ IH difference between 2009 and 2010 and it was concluded that the closing of the Pacific duct (negative \(u_{duct}\)) during the El Niño of 2010 was a significant contributing factor. It was also noted that there were half a dozen other occasions going back to the 1960s when the closing of the Pacific duct was related to an increase in CO₂ IH difference (Keeling et al., 2009).

Here, we have extended the analysis of the relationship between \(u_{duct}\) and C_mlo-cgo to 2016. We again find that during boreal winter-spring, and particularly during Feb-Apr when eddy transport of CO₂ from the Northern to Southern Hemispheres is most active, there is an increase in C_mlo-cgo during the El Niño of 2015-2016. However, while the timing of the increases in these years, and for other occasions going back to 1992, agree with the closing of the Pacific duct the magnitude is more variable indicating the contribution of other processes discussed in Section 2. We have analysed the intermittent nature of the opening and closing of the Pacific westerly duct. In particular, episodes in February 2015 have been related to results from NASA (2016) data in the movie ‘Following Carbon Dioxide through the Atmosphere’. The movie provides further evidence of the propagation of Rossby waves through the open Pacific westerly duct and the transfer of CO₂ into the Southern Hemisphere. We have also noted that large scale uplift slightly downstream of Asia occurs when the Pacific duct is open allowing these substantial emissions to be transported directly, via Rossby wave dispersion, through the duct.

A major focus of this article has also been the role of changes in the mean IH CO₂ transport from the Northern to Southern Hemispheres due to variability in the Hadley circulation. We have introduced indices (Table 1) that measure this transfer based on the 300 hPa \(\omega\), the vertical velocity in pressure coordinates, between 10°N and 15°N and 200 hPa \(v\), the meridional wind between 5°N and 10°N, both zonally averaged (\(\omega_H\) and \(v_H\)) and with averaging restricted to the Pacific sector 120°E-240°E (\(\omega_p\) and \(v_p\)). The correlations for Jun-Aug between C_mlo-cgo and \(\omega_p\) or \(v_p\) (\(r \sim 0.5\)) have roughly similar magnitudes to those in Feb-Apr involving \(u_{duct}\). The indices \(\omega_p\) and \(v_p\) provide similar predictability of the role of the Hadley circulation in mean IH CO₂ transport as \(u_{duct}\) does for eddy transport. We have also found that, during 2009-2010 the effects of
and $v_p$ reinforce to make the step in $C_{mlo-cgo}$ large. In contrast, for 2015-2016 $\omega_p$ and $v_p$ counteract $u_{duct}$ and the record Hadley circulation primarily determines the annual Mauna Loa and Cape Grim CO$_2$ difference. The effects of interannual changes in mean and eddy transport on IH gradients in CO$_2$ (and CH$_4$, CO, H$_2$, N$_2$O and SF$_6$) has been examined for the period 1992 to 2016.

The sign and strength of zonal winds in the Pacific westerly duct ($u_{duct}$) are related to Rossby wave dispersion and breaking and are correlated with corresponding changes in near-equatorial transient kinetic energy (Fig. 6, Frederiksen and Webster 1988) resulting in intermittent changes in the mixing of trace gases. This effect may not be adequately represented in the parameterizations (Frederiksen et al. 2017b) used in atmospheric circulation and transport models. Model determinations of short term variations in the Hadley circulation exchange are also susceptible to uncertainties in representations of the equatorial convective dynamics (Lintner et al. 2004). Over at least 25 years, much of the variability in CO$_2$ between the two surface monitoring sites of Mauna Loa and Cape Grim can be associated with dynamical near-equatorial atmospheric indices of global significance in a changing climate. The changing nature of the seasonal and interannual changes in CO$_2$ IH Pacific duct eddy and mean Hadley circulation transfer between 1992 through to 2016 provides an interesting case study and potential test of inversion models of atmospheric transport.

We plan to further explore trace gas IH transfer focusing on Southern Hemisphere CO$_2$ stable isotope data in a study that distinguishes between mean IH transfer and eddy transfers of both current season emissions and accumulated Northern Hemisphere fossil fuel emissions.

Data availability. Meteorological data is available from the NOAA/ESRL web site: [http://www.esrl.noaa.gov/psd/](http://www.esrl.noaa.gov/psd/) and from the NASA web site: [https://giovanni.gsfc.nasa.gov/giovanni/](https://giovanni.gsfc.nasa.gov/giovanni/) and trace gas data for CSIRO monitored species CO$_2$, CH$_4$, CO, H$_2$ and N$_2$O and the NOAA monitored SF$_6$ are available from the World Data Centre for Greenhouse Gases website: [https://ds.data.jma.go.jp/gmd/wdcgg/cgi-bin/wdcgg/catalogue.cgi](https://ds.data.jma.go.jp/gmd/wdcgg/cgi-bin/wdcgg/catalogue.cgi).

Author contributions. J. S. Frederiksen provided information on atmospheric dynamics and the roles of transport mechanisms and R. J. Francey provided the trace gas information. Both contributed to the writing of the paper.

Competing interests. The authors declare that they have no conflicts of interest.

Acknowledgements. We thank Nada Derek and Stacey Osbrough for assistance with the graphics and Paul Steele has provided valuable advice on the manuscript. The sustained focus and innovation of CSIRO GASLAB personnel, and skilled trace gas sample collection by personnel at the Bureau of Meteorology Cape Grim Baseline Atmospheric Program and NOAA’s Mauna Loa stations underpin the progress reported here. The dynamics contributions were prepared using data and software from the NOAA/ESRL Physical Sciences Division web site: [http://www.esrl.noaa.gov/psd/](http://www.esrl.noaa.gov/psd/) except, as stated in Section 6, where NASA MERRA data was also used from the web site: [https://giovanni.gsfc.nasa.gov/giovanni/](https://giovanni.gsfc.nasa.gov/giovanni/).
acknowledge NASA Goddard Flight Center and their Production Team for the movie ‘Following Carbon Dioxide through the Atmosphere’ available at the website: [https://svs.gsfc.nasa.gov/12445](https://svs.gsfc.nasa.gov/12445). The trace gas data for CSIRO monitored species $\text{CO}_2$, $\text{CH}_4$, $\text{CO}$, $\text{H}_2$ and $\text{N}_2\text{O}$ and the NOAA monitored $\text{SF}_6$ are available from the World Data Centre for Greenhouse Gases website: [https://ds.data.jma.go.jp/gmd/wdcgg/cgi-bin/wdcgg/catalogue.cgi](https://ds.data.jma.go.jp/gmd/wdcgg/cgi-bin/wdcgg/catalogue.cgi). Trace gas data is also available upon request from the corresponding author (jorgen.frederiksen@csiro.au).
