12 **Abstract.** In order to identify and quantify key-species associated with non-exhaust emissions and exhaust
13 vehicular emissions, a large comprehensive dataset of particulate species has been obtained thanks to simultaneous
14 near-road and urban background measurements coupled with detailed traffic counts and chassis dynamometer
15 measurements of exhaust emissions of a few in-use vehicles well-represented in the French fleet. Elemental
16 Carbon, brake-wear metals (Cu, Fe, Sb, Sn, Mn), n-alkanes (C19-C26), light molecular weight PAHs (Pyrene,
17 Fluoranthene, Anthracene) and two hopanes (17 α 21 β Norhopane and 17 α 21 β hopane) are strongly associated with
18 the road traffic. Traffic-fleet emission factors have been determined for all of them and are consistent with most
19 recent published equivalent data. When possible, light-duty and heavy-duty duty traffic emission factors are also
20 determined. In absence of significant non-combustion emissions, light-duty traffic emissions are in good
21 agreement with emissions from chassis dynamometer measurements. Since recent measurements in Europe
22 including those from this study are consistent, ratios involving copper (Cu/Fe and Cu/Sn) could be used as brake-
23 wear emissions tracers as long as brakes with Cu remain in use. Near the Grenoble ring road, where the traffic
24 was largely dominated by diesel vehicles in 2011 (70 %), the OC/EC ratio estimated for traffic emissions was
25 around 0.4. Although the use of quantitative data for source apportionment studies is not straightforward for the
26 identified organic molecular markers, their presence seems to well-characterized fresh traffic emissions.

27 1 Introduction

28 Traffic is a major source of particulate matter in urban environments through both exhaust and non-exhaust
29 emissions. Thanks to stringent regulations, vehicles with more efficient catalytic converters and diesel particle
30 filters have been progressively introduced into the European fleet. As a consequence particulate exhaust emissions
31 have strongly decreased and non-exhaust particulate emissions (particles resuspended by moving traffic and those
32 from the wear of brakes, tyres, road surface...) will contribute to the major part of particulate vehicular emissions
33 in the near future (Amato et al., 2014). Current research estimates that non-exhaust emissions already substantially
34 contribute to traffic emissions, with differences between sites due to local meteorology, local emissions, or traffic
35 characteristics (e.g. Omstedt et al., 2005; Thorpe and Harrison, 2007; Bukowiecki et al., 2010; Lawrence et al.,
36 2016). Even with electric vehicles, traffic will continue to be a source of PM through non-exhaust emissions (Pant
37 and Harrison, 2013; Timmers and Achten, 2016).

1 Also, knowledge on the deleterious impacts of PM from vehicular emissions on human health is increasing. There
2 is now strong evidence that traffic-related PM is responsible for adverse health effects due to the health effect of
3 both carbonaceous material from exhaust emissions and redox-active metals in traffic-generated dust including
4 road, brake and tyre wear (Kukutschová et al., 2009; Cassee et al., 2013; Amato et al., 2014 and references therein;
5 Pardo et al., 2015; Poprac et al., 2017). Recently, on the one hand, Shirmohammadi et al. (2017) and Weber et al.,
6 (2018) have shown the important role of non-tailpipe emissions to the oxidative potential of particulate matter
7 species identified as tracers of vehicle abrasion; and on the other hand, the health impacts of coarse particles is
8 now better documented (Beelen et al., 2014; Cheng et al., 2015; Malig et al., 2013). Therefore, a better knowledge
9 on vehicular emissions is required to better understand their contribution to urban atmospheric PM₁₀ concentration
10 levels and related health effects.

11 Chassis dynamometer measurements allow the determination of exhaust vehicular emissions under controlled
12 testing conditions but, because of high costs, these tests often include small sets of vehicles that cannot be
13 representative of large variation in engine type, age and maintenance history of vehicles. They also do not represent
14 the variability of driving types in various environments. All of these are parameters that strongly influence real-
15 world vehicular emissions. Additionally, these tests cannot simulate accurately the effect of dilution on particle
16 equilibrium in the road atmosphere (Kim et al., 2016), the possible rapid aging effects (e.g. Platt et al., 2017), and
17 non-tailpipe emissions (e.g. Thorpe and Harrison, 2008). For all these reasons, it is thought that more realistic
18 estimates of vehicle emissions are determined from air quality measurements in the near-road atmosphere (Phuleria
19 et al., 2017), including car-chasing, tunnel or roadside measurements (Pant and Harrison, 2013 and references
20 therein; Jezek et al., 2015).

21 In this study, a large comprehensive dataset on the chemical composition of PM₁₀ from exhaust and non-exhaust
22 emissions has been obtained thanks to two complementary campaigns: 1) simultaneous near-road and urban
23 background measurements coupled with detailed traffic counts for the estimation of real-world vehicular emissions
24 including non-exhaust emissions and, 2) chassis dynamometer measurements of exhaust emissions of a few in-use
25 vehicles well-represented in the French fleet for the identification of key species in exhaust emissions. This study
26 focuses on PM₁₀ in order to take into account for the entire breathable fraction of non-exhaust particulate emissions,
27 a large part of which are coarse particles (Thorpe and Harrison, 2008; Grigoratos and Martini, 2014). Possible
28 particulate tracers of exhaust and non-exhaust vehicle emissions are examined and quantified. Emission factors
29 and when possible, typical ratios, are derived from these data.

30 **2 Methodology**

31 **2.1 Chassis dynamometer measurements**

32 Vehicles were operated on a chassis dynamometer, and exhaust emissions were measured using a sampling train
33 including a Constant Volume Sampling (CVS) system in which emissions are diluted with filtered air and sampled
34 using quartz filters and polyurethane foams (PUF).

35 **2.1.1 Vehicle types and driving cycles**

36 Five vehicles representative of the most frequent vehicle classes in the French fleet in circulation were selected
37 (Euro 3 Diesel, Euro 4 diesel, Euro 4 diesel retrofitted with particle filter, Euro 2 petrol, Euro 4 petrol). They were
38 in-use private cars since rental vehicle may not be representative of the national fleet (low mileage). All vehicles

1 were operated using commercial diesel and petrol fuels. Selection criteria and characteristics of tested vehicles are
2 described in the Supplementary Information (SI).

3 Driving cycles designed to be representative of real driving conditions in Europe are performed in this study
4 (André, 2004). The ARTEMIS urban cycle represents driving conditions in urban areas (repeated acceleration and
5 vehicle speed below 40 km/h), while the ARTEMIS rural-road cycle represents driving conditions on main roads
6 in suburban and rural areas outside cities (flowing traffic conditions). These cycles represent most driving
7 conditions encountered on the RN87/E712 highway, where the road side experiments took place, during congested
8 and flowing traffic conditions, respectively. Since urban journeys include cold vehicles, the influence of the cold
9 start on urban emissions has been systematically tested.

10 **2.1.2 Exhaust sampling**

11 Vehicles were operated on a chassis dynamometer using a CVS system to dilute exhaust emissions with filtered
12 ambient air. The filtration system included four filters and a cartridge in series: a M6-F7-F9, M5, F7 EN-779-2012
13 filters; a HEPA H13 EN1822-2009 filter; and a cylindrical cartridge of charcoal scrubber.

14 Regulated emissions were determined with continuous monitors for CO, CO₂, NO_x, and total hydrocarbons
15 (HORIBA system). Particulate matter (PM) and volatile organic compounds (VOC) were sampled out from the
16 dilution tunnel with a servo-controlled system designed by Serv'Instrument for this study. Two driving cycles in
17 series were performed in order to collect enough matter for molecular speciation. PM was collected on quartz
18 filters (Tissuquartz™, diameter 47 mm), at flow rates depending on both emission levels of the vehicles being
19 tested and the types of analyses (from 5 to 50 L.min⁻¹ for EC/OC measurements and from 30 to 50 L.min⁻¹ for
20 organic molecular speciation). Dilution factors ranged from about 15 to 40. Conditions of vehicle tests are detailed
21 in the supplemental section (Table I-2). Filter face velocities for chassis dynamometer samplings dedicated to
22 organic speciation were similar or close to the one of atmospheric near-road measurements, while, because of very
23 high concentration levels, lower sample flow rates are used for PM samplings dedicated to EC and OC
24 measurements in the exhaust of diesel vehicles non-retrofitted with Particulate Filter (Euro 3 and Euro 4 diesel
25 vehicles). These very low filter velocities may influence the adsorption of organic vapours by the Quartz filter
26 (McDow and Huntzicker, 1990; Turpin et al., 2000 ; Vecchi et al., 2009), while EC would not be affected by filter
27 face velocity (Vecchi et al., 2009). Quartz filters were pre-baked at 500°C for 8h before being used. Samples were
28 stored at -18°C in aluminum foil and sealed in polyethylene bags until analyses.

29 Analysis of test blank filters (collected following the same procedure as vehicle test filters including driving cycle
30 durations with filtered air) showed contaminations from the CVS system. It was obvious that some organic
31 compounds measured in test blanks result from the desorption of semi-volatile organics deposited into the CVS,
32 that is favoured by cleaner air. Since blank levels decreased in time with passing air dilution through the system,
33 our procedure included such a step maintained for a duration corresponding to at least two driving cycles before
34 each vehicle test. Test blanks are used to correct measurements.

35 **2.2 Near-road and urban background measurements**

36 The joint PM-DRIVE (PM-Direct and Indirect on-road Vehicular Emissions) and MOCOPO (Measuring and
37 mOdelling traffic Congestion and POLLution) field campaign took place from September 9th to 23rd, 2011. It

1 included meteorology and traffic measurements, near-road/urban background PM₁₀ sampling (this study) and near-
2 road on-line measurements (discussed in DeWitt et al., 2015).

3 **2.2.1 Description of traffic and urban background sites**

4 The Grenoble conurbation is a large city with about 700,000 inhabitants. It is located in the southeast of France in
5 the French Alps and is surrounded by three mountain ranges (Vercors, Chartreuse, and Belledone). The traffic site
6 was located (45.150641 N, 5.726028 E) about 15 m away from the southern part of the Grenoble ring road (the
7 RN87/E712 highway with 2×2 lanes) (26 m from the roadway central axis). Total traffic flow for the 4 lanes was
8 on average 95,000 and 65,000 vehicles a day on workday and weekend, respectively, with frequent congestion
9 during extended commuting hours. Stop-and-go traffic in both directions generates large braking activity at that
10 time. This sampling site was highly equipped during the joint PM-DRIVE / MOCOPO field campaign.
11 Simultaneous measurements took place at an urban background site (Les Fresnes) which is located about 2 km
12 away from the traffic site, on the rooftop of a school. This site belongs to the regional air pollution network
13 managed by Atmo Auvergne-Rhône-Alpes (<http://www.atmo-auvergnerhonealpes.fr/>). The locations of both sites
14 are presented on Figure 1.

15 **2.2.2 Aerosol and gas measurements**

16 On both traffic and urban background sites, PM₁₀ HiVol (DA80, 30 m³ h⁻¹) samplers collected PM₁₀ on quartz
17 fibre filters (Tissuquartz™, diameter 150 mm) with a time resolution of 4 hours. Filters were preheated at 500 °C
18 during 3 h. After sampling, filters were individually placed in aluminum foil, sealed in polyethylene bags and
19 stored at -18 °C until analysis. In addition, both sites were equipped with NO_x (NO and NO₂) and CO monitors.
20 PM₁₀ and PM_{2.5} mass concentrations were also continuously measured using 8500C series TEOM-FDMS (Filter
21 Dynamics Measurement System and Tapered Element Oscillating Microbalance mass sensor housed in a single-
22 cabinet compact enclosure).

23 **2.2.3 Traffic measurements**

24 Traffic counters (double electromagnetic loops) were installed in order to identify the passing of all vehicles, the
25 length of their chassis and their speeds, the determination of the 2 vehicle classes used in this study (light-duty
26 and heavy-duty vehicles), and the identification of periods of stop-and-go or flowing traffic. Vehicle mean speeds
27 are computed as the harmonic mean speed of the cars passing over the detector (flow speed i.e. the spatial mean
28 speed) (Hall, 2001).

29 Traffic cameras mounted on a roadway gantry were also used to monitor traffic at the measurement site. They
30 were used to capture the license plate numbers of passing vehicles. Plate numbers were later used to classify
31 vehicular traffic into different categories: EURO standards and fuel type (diesel or petrol). The traffic of the
32 highway is detailed elsewhere (DeWitt et al., 2015; Fallah Shorshani et al., 2015). On weekdays, the average
33 hourly traffic included 2,850 diesel vehicles (including about 200 heavy-duty vehicles) and 1,025 petrol vehicles.
34 The harmonic vehicle mean speed was about 80 km/h and ranged from 52 to 94 km/h (note that the RN87 highway
35 has a speed limit of 90 km/h). A sample is considered affected by congested traffic above a threshold of more

1 22,000 vehicles during the 4-h sampling periods (corresponding to vehicle speed below 70 km/h) (see SI file).
2 However, braking may occur below this threshold for congestion.
3 The vehicle fleet was close to the national one for the year 2011, with 72% diesel vehicles, and EURO 3 and 4
4 vehicles representing most of the vehicles (30 and 36% respectively). Virtually all heavy-duty vehicles are diesel.

5 **2.2.4 Meteorological measurements**

6 A Young meteorological station was installed at the traffic site to capture wind speed and direction, while relative
7 humidity, and temperature data and rain data are obtained from two stations located in Grenoble conurbation (see
8 SI file section IV).

9 The wind speed was low during the field campaign (on average 0.98 m/s, ranging from 0.50 to 2.5 m/s). The
10 temperature was warm (on average 17.6°C, peaked to 27°C) and was higher before the first rain event (on Sunday
11 17/09/11) with average temperatures of 21°C and 15°C, respectively, before and after the rain event. Two rain
12 events occurred during the campaign, the first one from the morning of 17/09/11 to the night of 18/09/11 night (34
13 mm of rain) and the second one from the night of 18/09 to 19/09/11 afternoon (12.7 mm). They corresponded to
14 summer storms.

15 **2.3 Chemical analyses**

16 The measurements of carbonaceous material (EC and OC) in PM samples were performed using the Thermo-
17 Optical Transmission (TOT) method on a Sunset Lab analyser (Jaffrezo et al., 2005; Aymoz et al., 2006) following
18 the EUSAAR2 temperature protocol (Cavalli et al., 2010). Ionic species were analyzed with Ionic Chromatography
19 (IC) following a well-established method (Jaffrezo et al., 1998; Waked et al., 2014). Metals were analyzed using
20 Inductively Coupled Plasma Spectrometry (ICP-MS) (Waked et al., 2014). The chemical speciation of organic
21 particles are performed by Gas Chromatography–Mass Spectrometry (GC-MS), except PAHs that were measured
22 by liquid chromatography (HPLC) using a fluorescence detector (Piot, 2011; Golly et al., 2015).

23 Hence, a large number of particulate chemical species have been measured in the filter samples simultaneously
24 collected at the traffic and urban background sites, including EC, OC, 9 major ions (Cl^- , NO_3^- , SO_4^{2-} , oxalate, Na^+ ,
25 NH_4^+ , K^+ , Mg^{2+} , Ca^{2+}), 33 metals and trace elements (Al, As, Ba, Ca, Cd, Ce, Co, Cr, Cs, Cu, Fe, K, La, Li, Mg,
26 Mn, Mo, Na, Ni, Pb, Pd, Pt, Rb, Sb, Sc, Se, Sn, Sr, Ti, Tl, V, Zn, Zr), 3 sugars (galactosan, mannosan,
27 levoglucosan), 15 PAHs (phenanthrene, anthracene, fluoranthene, pyrene, retene, benzo(a)anthracene, chrysene,
28 benzo(e)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(a)pyrene, benzo(ghi)perylene,
29 dibenzo(a,h)anthracene, indeno(1,2,3-cd)pyrene, coronene), 30 n-alkanes (from C10 to C40), 2 branched alkanes
30 (pristane and phytane) and 10 hopanes (trisorneohopane, 17α -trisorneohopane, $17\alpha,21\beta$ -norhopane, $17\alpha,21\beta$ -
31 hopane, $17\alpha,21\beta$,-22S-homohopane, $17\alpha,21\beta$,-22R-homohopane, $17\alpha,21\beta$,-22R-bishomohopane, $17\alpha,21\beta$,-22S-
32 bishomohopane, $17\alpha,21\beta$,-22S-trishomohopane, $17\alpha,21\beta$,-22R-trishomohopane).

33 The same array of chemical species were also quantified in the filter samples from the chassis dynamometer
34 experiments.

35 **2.4 Data analysis**

1 A series of multivariate data analysis tools have been used in order to define which species are related to traffic,
2 to identify influential parameters, and to quantify their respective influences. Thanks to simultaneous
3 measurements at near-traffic and background sites, local increments in concentration at the traffic site have been
4 calculated as the difference between near-traffic and urban background concentrations. Sign and Rank Signed-
5 Wilcoxon tests have been used to estimate if concentrations measured at the near-traffic site are significantly higher
6 than concentrations measured at the urban background site and can possibly be ascribed to local traffic emissions.
7 As a complementary indication of relation to traffic, Spearman correlations with traffic data (total traffic, light-
8 duty traffic, heavy-duty traffic), with NO_x (as an indicator of traffic emissions) and with EC (as an indicator of
9 diesel traffic emissions) (Morawska and Zhang, 2002; Reche et al., 2011) have also been examined. Results for
10 species for which concentrations are significantly higher at the near-traffic site (then including both positive
11 increments and p-values below 0.05 from Sign and Signed Wilcoxon tests) are presented in Tables 1a and 1b.
12 Increments in concentrations for all species strongly associated with traffic are transformed into emissions
13 according to a well-established procedure (e.g. Pant and Harrison, 2013; Charron and Harrison, 2005; details in
14 the SI section V). This method enables the calculation of average emission factors for the mixed traffic fleet of the
15 RN87 highway assuming that (1) increments in concentration (near-traffic site minus urban traffic site) are from
16 local traffic, (2) emissions of NO_x are known and estimated from emission inventories (COPCETE that uses
17 emission functions from European COPERT4 averaged for fleet composition and speed) and detailed traffic counts
18 and (3) atmospheric dilution affects similarly all pollutants. Average emission factors (EFs) are expressed in
19 mg.veh⁻¹.km⁻¹ or µg.veh⁻¹.km⁻¹ (Tables 2a,b,c,d). Since it is thought that nearby industrial activities influence the
20 concentrations of Ti, Cr, Fe and Mn in the morning, these data are excluded from the calculations. Standard
21 multiple Linear Regression analyses (SPSS software) are performed between computed average emission data and
22 light-duty and heavy-duty vehicle counts. The coefficients of the regressions represent average EFs for local
23 heavy-duty and light duty traffics (Table 3). The constants represent the parts not related to local traffic. They are
24 all not significant (p-values above 0.4 for metals and organics, p-value of 0.061 for EC) confirming the above
25 assumption that mostly local traffic contributes to local increments in concentration. Results from Multiple Linear
26 Regressions are not available for all species strongly related to traffic since its use requires normally-distributed
27 data and the model must be validated through residues analyses.

28 **3 Results**

29 Average concentrations measured at the traffic site are presented in the SI (section II). Four-hour PM₁₀
30 concentrations ranged from 4.9 to 45.1 µg.m⁻³ (on average 24.1 µg.m⁻³) and was strongly dominated by EC (on
31 average 5.9 µg.m⁻³) and OC (on average 5.4 µg.m⁻³). At this site in the vicinity of traffic dominated by diesel
32 vehicles, EC and OC concentrations were of similar magnitude. EC concentrations peaked at commuting time in
33 the early morning and at the end of the afternoon, and follows quite well the evolution of traffic; the temporal
34 evolution of OC is closer to that of sulphate with somewhat stronger variability following those of traffic. The
35 other major constituents of PM₁₀ were sulphate (on average 1.2 µg.m⁻³), iron (on average 1.0 µg.m⁻³) and calcium
36 (on average 0.8 µg.m⁻³). Strong showers during the weekend in the middle of the two-week campaign led to PM₁₀
37 concentrations below 10 µg/m³ during a few hours (see Figure 3 and SI VII for individual particulate species).

38 **3.1 Identification of species related to local on-road traffic**

1 Tables 1a and 1b present species for which concentrations are significantly higher at the near-traffic site and
2 assumed from local emissions and Figure X present median concentrations measured at both sites. These species
3 could be distributed into two main groups according to both the significance of the contribution of traffic to
4 atmospheric levels and the strength of relations with traffic indicators (traffic counts, NO_x and EC concentrations).

5 **3.1.1 Species strongly associated with local traffic**

6 Cu, Fe, Mn, Sb, Sn have concentrations strongly correlated with traffic indicators (Table 1a). Their local
7 increments in concentration due to traffic range from 54% to 84%. The concentrations of these species are linearly
8 related to each other with near-zero intercepts (Figure 4) confirming that they come from the same source.
9 Similarly to this study, Amato et al. (2011a) and Harrison et al. (2012) measured strong increments for Fe, Cu, Sb
10 and Sn concentrations at traffic sites with strong correlations between them. Here, Cu, Fe and Sn are the metals
11 that are the most closely related (Pearson $r^2 \geq 0.8$), while relationships with Mn and Sb are more scattered (Pearson
12 $r^2 < 0.5$) and more closely related to the heavy-duty traffic (Table 1a).

13 Cr and Ti are also species significantly correlated to traffic indicators but to a lower extent than Cu, Fe, Mn, Sb
14 and Sn. Cr (Boogaard et al., 2011 ; Amato et al., 2011a) and Ti (Amato et al., 2011a) also showed higher
15 atmospheric concentrations at street locations than at urban background sites in previous studies. Cr and Ti show
16 a behaviour different from that of other elements coming from brake wear. They present sharp peaks in the
17 morning, poorer correlations with copper, and significant correlations with Al (Figure 4 and Table 1a). When the
18 very high morning concentrations are removed (mornings of workdays), their temporal variations are much closer
19 to the ones of metals from brake wear emissions. This suggests that another source influenced Cr and Ti
20 concentrations near the traffic site in the morning, possibly nearby metalworking activities. Similarly, while
21 morning peaks are less obvious in the temporal variations, the exclusion of morning data for Fe and Mn improves
22 their correlations with Cu (Figure 4).

23 Many of these species are metals that are known to arise from brake wear emissions (Thorpe and Harrison, 2008;
24 Pant and Harrison, 2013; Grigoratos and Martini, 2014, 2015). Indeed, Fe could come from the lining (steel or
25 iron powder) in semi-metallic brake, from fibres as steel, or cast iron rotor wear for low metallic brake. Cu is a
26 high-temperature lubricant present in linings and it is also included in fibres as brass to increase braking
27 performance. Sb is an element of brake lining both in filler as antimony sulphate and in lubricant as antimony
28 trisulphide. Chromium oxides are elements of the filler of brake linings used for their thermal properties, and
29 potassium titanate fibers are present as a strengthener in organic linings (Sanders et al., 2003; Grigoratos and
30 Martini, 2014 and references therein). Cr could also come from lubricant oil combustion (Pulles et al., 2012).

31 Only three light molecular weight PAHs (An, Fla, Pyr) are strongly associated with traffic indicators even though
32 only the particulate phase is determined (Table 1b). It is well-established that light molecular weight PAHs are
33 emitted by diesel vehicles, while higher molecular weight PAHs are rather associated with petrol vehicle emissions
34 (Zielinska et al., 2004; Phuleria et al., 2006 and 2007; Pant and Harrison, 2013). Not surprisingly, in this site
35 dominated by diesel vehicles, high molecular weight PAHs (from 5 rings) are more significantly correlated with
36 levoglucosan, suggesting a closest relation to biomass burning emissions than to on-road petrol vehicles.
37 Proportional concentrations of An, Pyr, and Fla suggest that they mainly come from the same source, likely diesel
38 exhaust emissions (Figures 3 and 4). Specifically, Pyr and Fla show high increments in concentration (as an
39 indication of the low contribution of the urban background compared to strong traffic contribution, and/or rapid

1 photochemical degradation) and strong linear relationship without any significant intercept (as an indication of
2 common origin). Concentrations of An have more variability and larger contribution from the urban background.
3 The n-alkanes C19 to C26 and two hopanes (17 α 21 β norhopane and 17 α 21 β hopane) are species that are not
4 significantly, or only weakly, correlated to total traffic. However, they are significantly correlated with NO_x and
5 EC and some of them with heavy-duty traffic. The n-alkanes between C18 and C25 are the predominant ones in
6 vehicle exhaust and correspond to the high boiling point components in diesel fuels (Alves et al., 2016). Hopanes
7 are known to arise from unburnt lubricating oil emissions (Rogge et al. 1993a; Zielinska et al., 2004), and
8 17 α 21 β Norhopane is considered as a tracer for lubricating oil (Kleeman et al., 2008). While n-alkanes have been
9 measured in the exhaust of test diesel vehicles in our study (Table 4), hopanes and steranes were below the
10 quantification limit for all selected vehicles. It was assumed that the tested vehicles (passenger cars, none of them
11 was a super-emitting vehicle) did not emit enough unburnt oil for the proper quantification of hopanes. At the
12 sampling site, the temporal variations of the concentrations of these species show higher values on the second
13 week of the field campaign than on the first one. This observation can be explained by much larger heavy-duty
14 traffic during this period (almost twice the traffic of the first week).

15 **3.1.2 Other species**

16 This second group corresponds to species with local increments below 50% and no significant, or only weak,
17 correlations with traffic indicators. It is highly heterogeneous since it includes OC, NO₃⁻, Na⁺, Ca²⁺, Mg²⁺, Ba, Co,
18 Phenanthrene (Phe), Benzo(a)Anthracene (BaA) and some n-alkanes (C18, and from C27 to C33). Most of species
19 from this group are obviously emitted by the traffic but they seem to be less specific than species from the first
20 group since other sources can largely contribute to their emission levels.

21 Not surprisingly NO₃⁻ is not significantly related to primary traffic indicators. However its concentrations are
22 significantly higher at the traffic site (p<0.001, and median increment of 28%). Additionally, the temporal pattern
23 of NO₃⁻ is different from that of indicators of regional origin (for example SO₄²⁻, SI section VII). Amato et al.
24 (2011a) found similar contributions of traffic to NO₃⁻ concentrations at two traffic sites in Barcelona (34% and
25 25% respectively). They assumed that NH₄NO₃ is quickly formed in the road plume enriched in NH₃ emitted by
26 vehicles. Indeed, the important introduction of vehicles equipped with DeNOx technology such as 3-way catalysts
27 or selective catalytic reduction systems have led to recent increasing vehicular NH₃ emissions (Kean et al., 2009;
28 Suarez-Bertoa and Astorga, 2016) responsible for significant changes in the chemistry of the atmosphere in
29 roadside areas.

30 OC concentrations are significantly higher at the traffic site (p<0.001; increment of 23%), and are weakly but
31 significantly correlated with traffic indicators. Amato et al., (2011a) found slightly higher increments of 34% and
32 41% for OC at their 2 traffic sites. Deconvolution of sources from simultaneous PM₁ AMS measurements
33 concluded that about 20% of the total PM₁ organic mass could be attributed to vehicular emissions (DeWitt et al.,
34 2015). Additionally, the temporal pattern of OC concentrations clearly shows a dominant regional contribution
35 (Figure 3 and SI section VII). All these results agree that in summer time, the majority of OC is of regional origin,
36 despite a clear influence of traffic.

37 Na⁺, Ca²⁺, Mg²⁺ and Sr concentrations are also significantly higher at the traffic site (p<0.05, increments from 33%
38 to 43%, except for Sr for which urban background concentrations are most of the time below detection limit).
39 When three high concentrations for Mg²⁺ concentrations and one for Sr concentration are excluded (all probably

1 not related to traffic), both present temporal variations close that of calcium (Figure 3). All are at least significantly
2 correlated to the heavy-duty traffic ($p < 0.05$). Since Ca^{2+} , Mg^{2+} and Sr are strongly affected by rain events (assumed
3 to influence the silt loading of the road), their incremental concentrations are believed to be from resuspended
4 dust, as concluded in other studies (e.g. Lough et al., 2005, Amato et al., 2011a).

5 Ba and Co concentrations are significantly higher at the traffic site ($p < 0.05$, increments of 37% and 36%
6 respectively). Ba concentrations present a temporal behaviour close to the ones of Cu, Fe, Sn and Mn and,
7 accordingly, is known as an element of the filler of brake linings. Higher Ba atmospheric concentrations at street
8 locations than at urban background sites have also been observed in previous studies (Harrison et al., 2012). On
9 the contrary, Co concentrations do not show any correlation with traffic indicators and are correlated with tracers
10 of regional origin (Table 1a). Co is sometimes measured in brake pads (e.g. Hulskotte et al., 2014); and Amato et
11 al. (2011) found similar increments for Co at their traffic sites (respectively 33% and 47%). All of these suggest
12 that a possible contribution of brake wear to Co concentrations cannot be excluded, despite the lack of correlation
13 with traffic indicators.

14 The concentrations of Phe, BaA, C18 and C27-C33 alkanes are significantly higher at the traffic site and some of
15 them are significantly correlated with NO_x and EC. Accordingly these species were detected in the exhaust
16 emissions of diesel vehicles sampled from our chassis dynamometer experiments. However most of them are also
17 significantly correlated with levoglucosan measured at the traffic site, particularly BaA. Indeed the temporal
18 pattern of BaA shows similarities with both the one of Pyr (strongly related to traffic, see below) and levoglucosan
19 (tracer of biomass burning peaking in the evening) (Figure 3). It is therefore believed that most of them are largely
20 emitted by biomass burning and are not specific of road traffic emissions.

21 **3.2 Quantification of traffic fleet emissions for species associated with traffic**

22 Average emission factors (EFs) are presented in Tables 2a,b,c,d. Most EFs show large standard deviations. This
23 variability reflects the presence of vehicles with various emission levels (diesel/petrol; different standards and
24 engine load; cold start/hot vehicles; presence of a few high emitting vehicles). It could also be related to the
25 variability of the vehicle fleet (on-average 5% heavy vehicles but ranging from 0.3% to 12%) and to the various
26 traffic conditions (from fluid with speeds up to 90 km/h to congested with stop-and-go traffic).

27 Table 3 presents average EFs for heavy-duty and light duty traffics, their standard deviations and confidence
28 intervals at 95%.

29 **3.2.1 EC/OC emissions**

30 The traffic-fleet EF for EC determined in this study ($39 \text{ mg.veh}^{-1}.\text{km}^{-1}$) is slightly higher than the ones determined
31 in tunnel studies in Austria, China, California, and near a heavily-trafficked highway in Switzerland (about 21
32 $\text{mg.veh}^{-1}.\text{km}^{-1}$ for Handler et al., 2008; Hueglin et al., 2006; Cui et al., 2016; and $31 \text{ mg.veh}^{-1}.\text{km}^{-1}$ for Gillies et
33 al., 2001), while it is similar to the one of a tunnel study in Portugal ($39 \text{ mg.veh}^{-1}.\text{km}^{-1}$) (Alves et al., 2015).
34 Conversely, the traffic-fleet EFs for OC in Austria and China (about $19 \text{ mg.veh}^{-1}.\text{km}^{-1}$) are similar to ours, while
35 the ones for urban tunnels in Portugal (Alves et al., 2015) and U.S. (Gillies et al., 2001) are higher ($39 \text{ mg.veh}^{-1}.\text{km}^{-1}$
36 and $25 \text{ mg.veh}^{-1}.\text{km}^{-1}$ respectively). Different traffic fleet and traffic conditions may explain these small
37 divergences. Part of the differences may also be due to the different measurement techniques used for the
38 distinction between EC and OC.

1 The average light-duty traffic-fleet EF for EC is in excellent agreement with the EFs of Euro 3 and Euro 4 diesel
2 vehicles obtained from chassis dynamometer measurements in our study for which the highest EFs were clearly
3 observed when vehicles are cold (Figure 5a). Indeed, these two types of vehicles represented the largest proportion
4 of passenger's cars on the RN87 freeway in 2011 (Fallah Shorshani et al., 2015), as well as in the French national
5 fleet. Similarly to results for diesel vehicles tested by Fujita et al. (2007) and Lough et al. (2007), EC has the
6 highest emission factor in diesel exhaust. It also could be noted that the heavy-duty traffic-fleet EF for EC is about
7 5-times higher than the one determined for light-duty traffic.

8 The emissions of OC could not be discriminated between light-duty and heavy-duty traffic (coefficients not
9 significantly different from zero). However, it can be observed that the traffic-fleet EF for OC is larger than could
10 be expected from exhaust measurement of test vehicles (Table 4, Figure 5b). Note that traffic-fleet EFs for OC
11 from other studies (Handler et al., 2008; Alves et al., 2015, Cui et al., 2016; He et al., 2008) are at least as high as
12 ours, and the EFs for exhaust OC from Cheung et al. (2010) for Euro 4 diesel vehicles (with and without Diesel
13 Particulate Filter) is similar to ours. There are many likely explanations for the traffic-fleet EF for OC being higher
14 than expected: proportionally larger contribution of the heavy-duty traffic to OC than to the EC; contribution of
15 non-exhaust emissions to the OC (e.g. tyres wear); contribution of high emitting vehicles; and rapid formation of
16 secondary OC in the roadside atmosphere. Further studies are required to assess the respective importance of these
17 processes. In particular, a better knowledge of particle size distribution of OC emitted by traffic might be useful.

18 Average OC/EC ratios on increments in concentrations and emissions are respectively 0.33 and 0.44 (Table 5) that
19 is in excellent agreement with observations in a roadway tunnel in Lisbon and with roadside enrichment of OC/EC
20 in Birmingham, U.K. (Pio et al., 2011; Alves et al., 2016). Pio et al. concluded that OC/EC ratios of 0.3-0.4
21 characterizes vehicle fuel combustion at their sites and similar conclusions could be made for Grenoble. However,
22 the OC/EC ratio is expected to depend on vehicle fleet. Indeed, in the exhaust of test diesel vehicles without particle
23 filters (Table 4), OC/EC ratios are lower than 0.4, while they are respectively 6.1 and 1.7 in the exhaust of Euro 2
24 petrol vehicle (urban cold cycle) and Euro 4 petrol vehicle (road cycle) (no average OC/EC ratios has been
25 determined for petrol vehicles because of many measurements below detection limit). Other recent chassis
26 dynamometer measurements (Lough et al., 2007) showed that most OC/EC ratios are above 2 for petrol vehicles
27 (except for two smoker vehicles) and below 0.5 for diesel vehicles (except idling conditions), with even lower
28 ratios for older and heavier diesel vehicles. Because in 2011, diesel vehicles represented about 70% of total
29 vehicles on the RN87 highway, the OC/EC ratio found in this study is lower than the ones of many other studies.
30 For examples, OC/EC ratios from EFs or increments in concentrations were 0.90 ± 0.21 in a tunnel in Austria
31 (Handler et al., 2008); on average 0.52 for a traffic fleet with 40% diesel vehicles in Spain (Amato et al., 2011a)
32 and 0.5 in Marseille where petrol two-wheelers are much more numerous (El Haddad et al., 2009). However, since
33 the OC/EC ratio in the exhaust of the diesel vehicle equipped with particle filter was higher (0.7) possibly due to
34 the more efficient trapping of EC than OC by the particle filter, one can expect that in the future the OC/EC ratio
35 reflecting vehicle fuel combustion would increase with the progressive introduction of vehicles equipped with PF.

36 **3.2.2 Metals from brake wear emissions**

37 Fe presents by far the third highest traffic emission rate after those of EC and OC ($6.7 \text{ mg.veh}^{-1}.\text{km}^{-1}$, Tables 2).
38 Cu also shows a high emission factor from traffic ($300 \text{ } \mu\text{g. veh}^{-1}.\text{km}^{-1}$ respectively). Similarly, major contributions
39 of Fe and Cu to PM_{10} vehicular emissions were found in other locations (e.g. Kam et al., 2012; Harrison et al.,

1 2012). The analysis of brake wear debris (Apegyei et al., 2011 ; Sanders et al., 2003 ; Kukutschová et al., 2009 ;
2 Hulskotte et al., 2014) and brake material (Gigoratos and Martin, 2015; Hulskotte et al., 2014) confirmed that Fe
3 is the major element of brakes and that Cu is another important element. Indeed, maximum contents of 60% by
4 mass for Fe (Gigoratos and Martin, 2015) and of 15% for Cu (Denier van der Gon et al., 2007) have been reported
5 for brake lining materials. Fe, Cu, Zn, Sn would represent about 80-90% of metals presents in brake pads and Fe
6 95% of metals in brake discs (Hulskotte et al., 2014)

7 Our results can be compared with other European traffic EFs determined for PM₁₀ species measured in roadside
8 environments or tunnels, and with data derived from average brake wear composition (details in SI, section VIII).
9 Most PM₁₀-EFs are consistent with other roadside traffic fleet emissions (Johansson et al., 2009; Bukowiecki et
10 al., 2009) and with data corresponding to braking emissions of 8 mg.veh⁻¹.km⁻¹ (Hulskotte et al. 2014), but larger
11 than the estimations aimed to quantify brake wear only (Bukowiecki et al., 2009). Our traffic-fleet EF for Sb is
12 much lower than similar EFs determined in other studies, while Ba emissions show large variability from a study
13 to another. EFs related to brake wear component emissions are lower in tunnel environments (Handler et al., 2008;
14 Alves et al., 2015), except for the oldest study (Gillies et al., 2001). This could be explained by less stop and go
15 traffic in such environments. Indeed, interestingly, many EFs determined by Handler et al. (2008) are about half
16 the ones found in this study. Even though this proportionality is not found for Ba, Sb and Ti, this supports that
17 brake wear metal EFs are strongly related with braking strength. The low Sb emissions of our study may possibly
18 be related to the introduction of Sb-free brake pads (von Uexküll et al., 2005; Apegyei et al., 2011).

19 EFs for brake wear metals (Cu, Fe, Sb and Sn) are 8 to 13 times higher for the heavy-duty traffic than for the light-
20 duty traffic (Table 3). The estimations from Bukowiecki et al. (2009) for brake wear only are much lower than
21 ours but somewhat proportional (factors 4.6 to 6.8 for light-duty EFs and from 4.3 to 8.5 for the heavy-duty traffic
22 – Sb excluded). This consistence between brake profiles suggests that brake compositions would be similar in
23 different European countries. Traffic-fleet light-duty EFs for brake wear metals are much higher than the ones
24 from chassis dynamometer exhaust measurements (this study: Table 4; Cheung et al., 2010), confirming the
25 dominant contribution of braking for these elements.

26 The sum of traffic-fleet EFs for metals related to brake wear (Ba, Cr, Cu, Fe, Mn, Sb, Sn, Ti - Table 2b) leads to a
27 total of 7.3 mg/km that should be lower than the real emission factors for brake wear dusts since it only includes
28 metals, and does not take into account of carbonaceous material and other unquantified compounds of brakes (S,
29 Zn, Al, and Si, for the most important ones). Hulskotte et al. (2014) determined a brake profile from the analysis
30 of 65 brake pads and 15 brake discs from 8 very common car brands in Europe. The consistence between with
31 their data and ours suggests that brakes spent in France are quite similar to the ones spent in The Netherlands.
32 Then, their average brake profile data are used to estimate the average emission factor for brake wear assuming
33 that the total proportion of metals is kept, and, according to Hulskotte et al., that 70% of the wear arise from the
34 disc. This latter assumption is supported by other researches (Sander et al., 2003; Varrica et al., 2013), even though
35 the generation mechanisms of brake wear particles have not been fully understood yet (Grigoratos and Martini,
36 2014). Since exhaust emissions (chassis dynamometer measurements or EFs from COPCETE inventory when
37 available) represent less than 5% of total emissions for Cr, Cu, Fe, Mn, Sb, Sn, and Ti, traffic-fleet EFs for these
38 elements are assumed to be entirely due to the emissions of brake wear dusts. So by adding to the sum of traffic-
39 fleet EFs for metals related to brake wear the portion that corresponds to the elements and compounds not
40 quantified in this study (C, S, Zn, Al, Si, Zr, Mo, V, Ni, Bi, W, P, Pb, Co), the rough estimation of 9.2 mg/km for

1 emissions related to brake wear is got for the RN87 highway traffic. This estimation includes particles directly
2 emitted during braking and those resuspended, and emissions from light and heavy-duty traffic. It should be
3 highlighted that this EF for brake wear emissions is almost twice the particle emission standards for the exhausts
4 of the most recent vehicles (Euro 5 and Euro 6 vehicles, 5 mg/km).

5 According to inventories atmospheric copper is largely from brake wear. Indeed brake wear represents 50-75% of
6 European Cu emissions (Denier Van der Gon et al., 2007) and 64% of French Cu emissions (CITEPA, 2018).
7 Since Sb is another well-known constituent of brake with very few other atmospheric sources, Cu/Sb ratio was
8 often considered as a candidate to trace brake wear emissions (Gietl et al., 2010; Pant and Harrison, 2013). Pant
9 and Harrison (2013) reviewed Cu/Sb ratios in brake wear particles and found ratios from 1.3 to 9.1 that strongly
10 depend on the PM size fraction. The estimation for the Cu/Sb ratio (11.7 ± 5.1 for incremental PM_{10}) is close to the
11 ones for PM_{10} elemental concentrations in other European locations including London, U.K. (on average 9.1, Gietl
12 et al., 2010), Barcelona, Spain (7.0-7.9, Amato et al., 2011a); Bern and Zurich, Switzerland (respectively 13.2 and
13 8.5, Hueglin et al., 2005) and in road dust below 10 μm collected in Barcelona, Zürich and Girona (respectively
14 6.8 ± 0.9 , 13.5 ± 6.1 , 17.0 ± 8.9 , Amato et al., 2011). However, lower PM_{10} Cu/Sb ratio are found for other European
15 traffic sites, in Sweden (4.6 ± 2.3 , Sternbeck et al., 2002 and 3.8, Johansson et al., 2009); in Portugal (about 2, Alves
16 et al., 2015) and in Vienna, Austria (1.6, Handler et al., 2008). To complicate the matter further, published data
17 from the analysis of brake pads and discs are even more scattered, roughly from 1.3 to 2000 (Adachi et al., 2004;
18 Canepari et al., 2008; Ijima et al., 2007), and often different than the chemical composition of brake wear particles
19 (Grigoratos and Martini, 2015). The poorer relationship between Cu and Sb (Pearson $r^2 = 0.4$) than those observed
20 between Sn, Cu and Fe (Pearson $r^2 > 0.8$) and the lower EF for Sb of this study than observations at other sites may
21 be explained by the introduction of Sb-free brake pads. Thus, while the occurrence of Sb may be largely explained
22 by braking activities, the use of a typical factor for braking activities using Sb seems to be less obvious.

23 The very strong linear relationships found between Fe, Cu, Mn and Sn with no significant intercept (virtually equal
24 to zero) suggests that ratios including these compounds also worth attention. Even though Fe is much less specific
25 of brake wear emissions than Cu or Sb, Hulskotte et al. (2014) observed a stable Cu/Fe ratio of about 4 % in
26 different European kerbside locations (The Netherlands: Boogaard et al., 2011; England: Gietl et al., 2010;
27 Switzerland: Hueglin et al., 2005). They concluded that brake wear is probably the single source of both copper
28 and iron in urban aerosols. The review of other recent studies leads to similar conclusions. Pio et al. (2013)
29 determined an average Fe/Cu ratio of 21 (and then, $Cu/Fe = 0.048$) from tunnel and busy roads measurements in
30 Portugal. Cu/Fe ratios at two traffic sites in Barcelona ranged from 0.034 to 0.058 (Amato et al., 2011a). Except
31 for the site of Weerdsingel in Utrecht, Cu/Fe ratios calculated from average PM_{10} elemental concentrations
32 measured at 8 street locations in The Netherlands also ranged from 0.039 to 0.048 (Boogaard et al., 2015). Only
33 Alves et al. (2015) found a much higher Cu/Fe ratio in PM_{10} collected in a tunnel in Portugal mainly due to a very
34 low EF for Cu compared to other studies. The Cu/Fe ratio determined in our study for light-duty traffic
35 (0.041 ± 0.010) is very similar to the ones found in the majority of these European roadside sites (Table 5), while
36 the ratio determined for the heavy-duty traffic (0.070 ± 0.017) is slightly larger due to proportionally higher
37 emissions of Cu. Again, this suggests that brake materials used in different European countries are very similar
38 and that the Cu/Fe ratio could be used as an indication of brake wear emissions.

39 Ratios with Mn and Sn are more rarely discussed in the literature, and published information is scarce. Cu/Sn ratios
40 of 6.2 and 4.3 can be calculated from data published by Handler et al. (2008) and Johansson et al. (2009),

1 respectively. Amato et al. (2011a) found Cu/Sn ratio that ranged from 4.7 to 4.8 and did not estimate ratios with
2 Mn because of the possible influence of a local steel source. Cu/Mn ratios of 3.7; 4.9 and 3.0 (Bern) and 4.4
3 (Zurich) are respectively calculated from the studies of Handler et al. (2008), Johansson et al. (2009), and Hueglin
4 et al. (2005). All these ratios are close to the ones of this study (Cu/Sn=4.1±1.0; Cu/Mn=3.6±1.6, Table 5), showing
5 that they are possible other candidates to trace brake wear emissions. Cu/Sn would be the strongest candidate since
6 the relation between these 2 elements is closer ($r^2=0.84$ for Cu/Sn vs. $r^2=0.47$ for Cu/Mn, see SI).

7 **3.2.3 Emissions of organic markers of diesel exhaust and lubricating oil**

8 As previously observed (Schauer et al., 2002; Perrone et al., 2014; El Haddad et al., 2009), n-alkanes are abundant
9 organic compounds of total quantified organic compounds emitted by vehicles on road.

10 In agreement with other chassis dynamometer measurements (Rogge et al.; 1993a; Cheung et al., 2010; Perrone et
11 al., 2014; Cui et al., 2017), the most important n-alkanes in diesel exhaust emissions are C19 to C26, while, most
12 emissions were below detection limit for the two petrol vehicles (Table 4). Schauer et al. (2002) showed that n-
13 alkanes are present in particulate exhaust emissions of non-catalyst equipped petrol vehicles, but they are almost
14 absent in the exhaust of catalyst-equipped petrol motor vehicles. In 2011 virtually all petrol vehicles were catalyst-
15 equipped (Fallah Shorshani et al., 2015). C19-C26 n-alkanes are also the most important in roadside increments
16 in concentration and as a further indication of road traffic contribution, the Carbon Preference Index (CPI, for
17 calculation see SI section VI) is very close to unity (0.99) indicating equal distribution between odd and even
18 carbon number typical of anthropogenic emissions (Harrad et al., 2003; Cincinelli et al., 2007; Kam et al., 2012;
19 Alves et al., 2016). Light-duty traffic-EFs for C23 and C24 are in agreement with the ones of the Euro 3 diesel
20 vehicle from chassis dynamometer measurements (upper range) and with the ones determined by Perrone et al.
21 (2014) for Euro 3 diesel vehicles (C23: 16.3 $\mu\text{g}/\text{km}$; C24: 12.7 $\mu\text{g}/\text{km}$). Good agreements are also found for C25
22 and C26. However, the traffic-EFs determined by Perrone et al. for C21 is half the one of this study, the one for
23 C20 is 1/5 of the one of this study. All EFs determined by Perrone et al. for Euro 4 diesel vehicles are larger the
24 ones of the Euro 4 diesel vehicle of this study, but of similar size of magnitude.

25 The relative contributions of the n-alkane series in diesel exhaust show Gaussian-like shapes peaking between C20
26 and C22 (Rogge et al., 1993a; Morawska and Zhang, 2002; El Haddad et al., 2009; Cheung et al., 2010; Fujitani et
27 al., 2012; Perrone et al., 2014; Cui et al., 2017). In this study, the dominant alkanes are C21 in the exhaust of test
28 diesel vehicles and C22 in traffic RN87 emissions (Figure 6). Fujitani et al. (2012) showed that shifts from C20 to
29 C22 and differences between real-atmosphere measurements and exhaust measurements are entirely explained by
30 gas-to-particle partitioning at different dilution ratios (dominant n-alkanes were C20 and C22 at dilution ratios of
31 14 and 238 respectively). Accordingly, in this study, C21 is the dominant n-alkane at diesel exhaust dilution ratios
32 of about 80; and a shift toward a heavier n-alkane has been observed in the roadside atmosphere. N-alkanes
33 normalized by OC ($\mu\text{g}/\text{g}$) (Figure 6) show values for Euro 3 and Euro 4 diesel emissions and RN87 traffic
34 emissions that are about half of the values measured in a tunnel in Marseille (El Haddad et al., 2009). Much higher
35 values are found with the vehicle retrofitted with PF (Figure 6). These high values are due to very low OC
36 emissions by the vehicle equipped with PF and clearly show less effective reduction of n-alkanes than total OC.
37 Because of their semi-volatile nature, n-alkanes may pass the particle filter in their gaseous phase at higher
38 temperatures. While the n-alkanes series from C19 to C26 peaking around C20-C22 seems to be characteristics of
39 diesel emissions, increase of the n-alkane/OC values could be expected for the future.

1 Low molecular weight PAH's (An, Fla, Pyr) are frequently associated with particulate diesel exhaust emissions
2 (e.g. Kleeman et al., 2008; Keyte et al., 2016). Accordingly, both chassis dynamometer and *in-situ* measurements
3 indicate that diesel vehicles is a major source of these chemical species. Indeed, they are almost absent in petrol
4 exhaust emissions and are strongly related to RN87 traffic emissions. EFs for PAHs determined for the heavy-
5 duty traffic are much higher than the ones determined for light-duty traffic: from 6-times higher for Fla, up to 20-
6 times higher for Pyr (Table 3). High emissions of Pyr by heavy-duty vehicles have already been observed anywhere
7 else (Liacos et al., 2012; Cui et al., 2017). While the comparison between EFs determined during different
8 conditions is not straightforward in absence of gas phase measurements due to the high vapour pressure of the
9 lowest molecular weight organics (Fujitani et al., 2012; Polo Rehn, 2013), quite good agreements are found
10 between chassis dynamometer measurements and traffic-EFs; and with data from other studies. Indeed, again the
11 light-duty traffic-EFs for Fla and Pyr are quite consistent with the ones of the diesel Euro 3 measured with chassis
12 dynamometer. The light-duty traffic-EF for An is proportionally lower, somewhere between the ones of test Euro
13 3 and Euro 4 vehicles. The average EF for Pyr for the Euro 3 diesel vehicle of this study (Table 4) is close to the
14 ones of Perrone et al. (2014) for Euro 3 diesel vehicles (740 ± 300 ng/km for passenger cars and 1810 ± 570 ng/km
15 for commercial utility vehicles). Traffic EFs for Fla and Pyr are also in good agreement with average EFs in a
16 tunnel in China ($40\text{-}50 \text{ km.h}^{-1}/784\text{-}2776 \text{ veh.h}^{-1}/18.4\text{-}35.1\% \text{ HDV}$, He et al., 2008). These satisfying agreements
17 suggest that EFs determined in this research may be quite well representative of in-use vehicles. However, gas-
18 particle partitioning and photochemical degradation processes may make difficult the use of quantitative data for
19 these markers, as already observed (Zhang et al., 2005; Phuleria et al., 2007; Katsoyiannis et al., 2011; Tobiszewski
20 and Namieśnik, 2012).

21 In agreement with previous observations (Phuleria et al., 2006 and 2007; He et al., 2008; El Haddad et al., 2009;
22 Alves et al., 2016; Pant et al., 2017), $17\alpha,21\beta$ -norhopane and $17\alpha,21\beta$ -hopane are the two dominant hopanes
23 associated with traffic emissions. Very few traffic-EFs are available for hopanes in the recent literature and most
24 data available from recent studies are related to fuel consumption (e.g. Phuleria et al., 2006 and 2007). Traffic
25 hopane EFs of this study are much lower than those computed for tunnels in China (He et al. 2008; Cui et al. 2016).
26 In order to compare with European tunnel data, traffic-EFs are normalized by OC emissions. The normalized
27 abundance of $17\alpha,21\beta$ -norhopane ($246 \mu\text{g}$ per g of OC) is similar to the one for a tunnel in Lisbon (Alves et al.,
28 2016) but almost half the ones for tunnels in Marseille and Birmingham (El Haddad et al., 2009; Pant et al., 2017).
29 Conversely, the value for $17\alpha,21\beta$ -hopane ($301 \mu\text{g}$ per g of OC) is very close to the ones found in tunnels in
30 Birmingham and Marseille but twice the one for the tunnel in Lisbon. These divergences and the quantification of
31 heavy-duty traffic emissions require further work in order to be able to define specific EFs and normalized
32 abundances for hopanes.

33

34 **3.2.4 Other non-exhaust emissions**

35 The average traffic-fleet EFs for Ca^{2+} is the fifth highest traffic-fleet emission factor after EC, OC, Fe and NO_3^- .
36 While the emissions of Ca^{2+} could not be discriminated between light-duty and heavy-duty traffics
37 (autocorrelation), this much larger emission factor than the ones measured in the exhaust of diesel vehicles is in
38 agreement with its origin. If Ca^{2+} mainly comes from road dust resuspension, it does not only depend on the
39 intensity of traffic but also on the amounts of calcium deposited on the road (silt loading). Bukowiecki et al. (2009)
40 used the mass concentration measured 1-hour earlier in order to empirically account for the observed

1 autocorrelation behaviour in the calcium time series due to the accumulation of resuspended dust. The time series
2 resolution of 4 hours for collected particles in this study does not allow such calculations. Note that contrary to
3 Bukowiecki et al., most other trace elements that could be regressed in this study do not have the same behaviour
4 as Ca^{2+} . This could be explained by the removal of road dusts thanks to frequent rain events before and during the
5 sampling period.

6 Since EU tyres contain about 1% zinc oxide (Pant and Harrison, 2013) and Zn is the most abundant metallic
7 element in tyres commercialized in the U.S. (Apeageyi et al., 2011), Zn is often proposed as a key tracer of tyre
8 wear emissions. In this study, similarly to other works (Boogaard et al., 2011; Amato et al., 2011), Zn
9 concentrations did not show any roadside increment. This suggests the prevalence of other sources of Zn in the
10 Grenoble-Alpes conurbation, as well as in other urban environments. Further research are needed to determine
11 proper tracers of tyre wear emissions.

12 **4. Conclusions**

13 Thanks to a very large comprehensive dataset of particulate species collected from a simultaneous near-road and
14 urban background measurement field campaign and chassis dynamometer experiments of a few in-use passenger
15 cars, this study was able to determine emission factors for many particulate species from road traffic and to identify
16 and quantify tracers of exhaust and non-exhaust vehicular emissions that could be used in source apportionment
17 studies. Near-road measurements are made near a freeway with various driving conditions from free-flowing to
18 stop-and-go traffic, including frequent and severe braking events during periods of congestion (morning and
19 afternoon commuting times of weekdays).

20 EC has the highest traffic emission factors and is strongly associated with diesel traffic. The emission factor for
21 EC for the light-duty traffic is similar to the ones of passenger diesel cars without particle filters. EC emissions
22 from heavy-duty vehicles are estimated to be 5 times higher than those for light duty vehicles. The traffic-fleet EF
23 for OC is slightly larger than those deduced from exhaust measurement of test vehicles. This later observation
24 would require further investigations in order to delineate the several possible causes for such observation. The
25 determination of the particle size distribution of OC could improve knowledge of the organic emissions of traffic.
26 In this environment dominated by the diesel traffic, the OC/EC ratio is below 0.4 (increments in concentration or
27 emissions), as it is in diesel exhaust emissions. However, this ratio depends on the traffic fleet and then may change
28 in the future with the progressive introduction of vehicles retrofitted with particle filter.

29 Results showed the important contribution of metals from brake wear to particulate vehicular emissions. In
30 particular, Fe has the third higher traffic emission factor after EC and OC. Total brake wear emissions are estimated
31 for the RN87 highway, they are on average almost twice the particle emission standards for the exhausts of newer
32 vehicles (from Euro 5). We have shown that Cu is another important contributor to PM_{10} from traffic and it could
33 be an excellent tracer of brake wear emissions in most environments. Even though they are less specific than Cu,
34 other metals such as Fe and Sn may be used to trace brake wear emissions through typical ratios. In particular,
35 ratios Cu/Fe of about 0.041 for light-duty traffic may possibly be the best option for estimating the brake wear
36 emissions due to the traffic of European passenger cars. Cu/Fe ratios in agreement with literature values for other
37 kerbside sites, while Cu/Fe ratios may be different for urban background or rural sites (e.g. Hueglin et al., 2005;
38 this study: Les Frênes' data), suggest similar brake composition for these elements throughout Europe (as long as
39 Cu-free brakes do not increase in use). Our measurements support more the use of Cu/Sn than that of Cu/Mn and

1 Cu/Sb as tracers of brake wear emissions possibly due to an additional source of Mn and the introduction of Sb-
2 free brake pads. Similarly to OC, the determination of the particle size distribution of metals may possibly improve
3 the discrimination between influential sources in urban areas.

4 Particulate organic emission data for European motor vehicles is scarce. In this study, a few PAHs, n-alkanes and
5 hopanes have been identified as organic molecular markers of fresh diesel traffic emissions and their emission
6 factors have been quantified. In agreement with previous works, low molecular weight PAHs (mainly An, Fla,
7 Pyr) are associated with diesel exhaust emissions. Pyrene and Fluoranthene are the ones the most strongly
8 associated with fresh diesel exhaust emissions. Pyrene is more largely emitted by the heavy-duty traffic. Similarly
9 to PAHs, n-alkanes from C19 to C26 are also associated with diesel vehicles, even though the determination of
10 the concentration of the dominant alkanes (from C20 to C23) strongly depends on measurement conditions. While
11 the comparison with other recent studies can be difficult in the absence of gas quantification for *in situ*
12 measurements, a quite good agreement is found for most organics between chassis dynamometer and near-road
13 measurements and between this study and other recent studies. However, the change of the gas-particle partitioning
14 of low molecular PAHs and n-alkanes according to ambient temperature and dilution factors, and their possible
15 short-term photochemical degradation may compromise their use as quantitative markers of fuel combustion.

16 Hopanes are markers of lubricating oil in the emissions of high-emitting vehicles (Rogge et al. 1993a; Zielinska
17 et al., 2004). In this study two hopanes (17 α ,21 β -norhopane and 17 α ,21 β -hopane) have been clearly associated
18 with the traffic and more closely related to the heavy-duty traffic. However the quantification of ratios hopanes to
19 OC showed divergences with other studies that require a better understanding.

20 This study determines many quantitative data of traffic exhaust and non-exhaust emissions that could help in a
21 better definition of traffic emissions in source apportionment studies.

23 **Author contributions**

24 AC was responsible for the design and coordination of the PM-DRIVE project, data analyses and designed the
25 vehicle experiments. JLJ, JLB and NM contributed to the design of the PM-DRIVE project. CB was responsible
26 for the design and coordination of the MOCOPO project and designed the traffic measurements. JLJ was
27 responsible for the field experiments and PM analyses (metals, ions, EC, OC). JLB was responsible for organic
28 speciation. HC and GG were responsible for regulated PM and gas sampling. LPR and BG contributed to field
29 measurements, PM analyses and interpretation of data. The paper was prepared by AC. JLJ, JLB, BG, LPR, NM,
30 CB contributed to the interpretation of the results and discussions on the paper.

32 **Competing interests:** The authors declare that they have no conflict of interest.

33 **Acknowledgements**

34 This work was funded by CORTEA-ADEME (PM-DRIVE program 1162C0002) that includes the funding of
35 chassis dynamometer and near-road field/urban background campaigns and PREDIT (MOCOPO programme) that
36 includes the near-road field measurements of regulated pollutants and traffic characteristics. Lucie Polo-Rehn's
37 PhD was funded by the Région Rhône-Alpes. Rain data was supplied by Météo France. The authors would like to
38 thank Patrick Tassel, Pascal Perret and Mathieu Goriaux (chassis dynamometer experiments), Julie Cozic and
39 Jean-Charles Francony (sample analyses) for their contribution to this work. We also thank Michel André for

1 supplying COPCETE emission factors. Part of the chemical analysis was performed on equipment provided by
2 Labex OSU@2020 (ANR10 LABX56).

Table 1a: Median increments to concentrations measured near the RN87 highway in comparison to those measured in the urban background site (given in % of total concentrations) for species for which concentrations are significantly higher at the near-traffic site according to Sign and Rank Wilcoxon tests ($p < 0.05$). PM_{coarse} (difference between PM₁₀ and PM_{2.5}) is also included in this table. R are Spearman correlation coefficients with traffic, heavy-duty traffic (HDV), nitrogen oxides (NO_x), and elemental carbon (EC). N_T: number of samples collected at the traffic site (Echiroles), N_{UB}: number of samples collected at the urban background site (Les Frênes site). \$: concentrations at Les Frênes are most of the time below detection limit. * mean statistically significant at the 95% level, ** at the 99% level. Species significantly correlated with traffic indicators and for which local traffic contributions are above 50% are highlighted.

Table 4: Average emissions factors (median and IQR: interquartile range) determined by chassis dynamometer measurements for different types of passenger cars: Euro 3 diesel (E3D), Euro 4 diesel (E4D), Euro 2 Petrol (E2P), Euro 4 Petrol (E4P) and Euro 4 diesel equipped with particle filter (E4D+PF) using urban, urban cold, road real-driving cycles. Und: undetermined.

Ratios on	Cu/Sb	Cu/Fe	Cu/Sn	Cu/Mn	OC/EC
Roadside concentrations	10.4 ±4.5	0.045 ±0.015	4.7 ±1.0	3.6 ±1.6	1.00 ±0.49
Incremental concentrations	11.7 ±5.1	0.043 ±0.015	5.4 ±1.8	6.4 ±5.9	0.33 ±0.22
LDV Emission factors	12.8 ±5.2 [§]	0.041 ±0.010 [§]	4.8 ±1.1 [§]	und.	und.
HDV Emission factors	13.7 ±4.3 [§]	0.070 ±0.017 [§]	6.6 ±1.1 [§]	und.	und.
Traffic emission factors	12.6 ±4.7	0.046 ±0.015	5.6 ±1.8	5.7 ±2.9	0.44 ±0.32

Table 5: Ratios for road-side, incremental (road-side minus urban background) concentrations, and RN87-traffic emission factors, with standard deviations. [§]: using Taylor expansion for approx.: $var\left(\frac{x}{y}\right) = \frac{1}{\mu_y^2} var(x) + \frac{\mu_x^2}{\mu_y^4} var(y) - 2\frac{\mu_x}{\mu_x^3} Cov(x, y)$

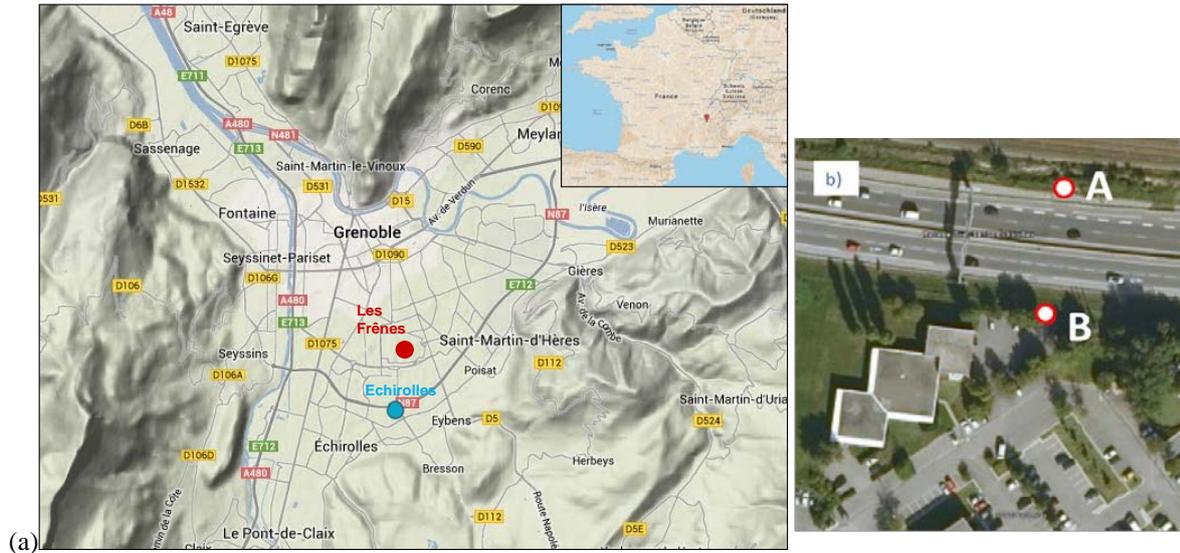

Figure 1: (a) Location of sampling sites in Grenoble-Alpes conurbation: the roadside site (Echirolles) and the urban background site (Les Frênes). (b) Echirolles sampling site: sampling and measurement devices are around the B point; the traffic electromagnetic loop monitoring are beneath the road (on the AB line), on the left, the cameras linked to automatic license plate recognition code are located on overhead gantries.

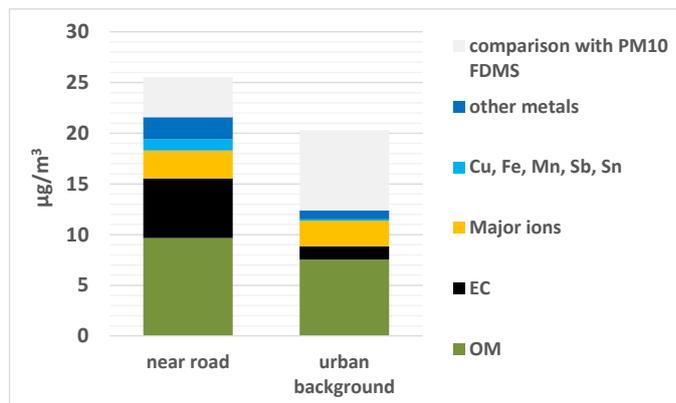

Figure 2: Median concentrations measured at the roadside site (Echirolles) and urban background site (Les Frênes) and comparison with respective median TEOM-FDMS PM₁₀ concentrations. OM is computed using the factor 1.8 estimated for Grenoble city (Favez et al., 2010).

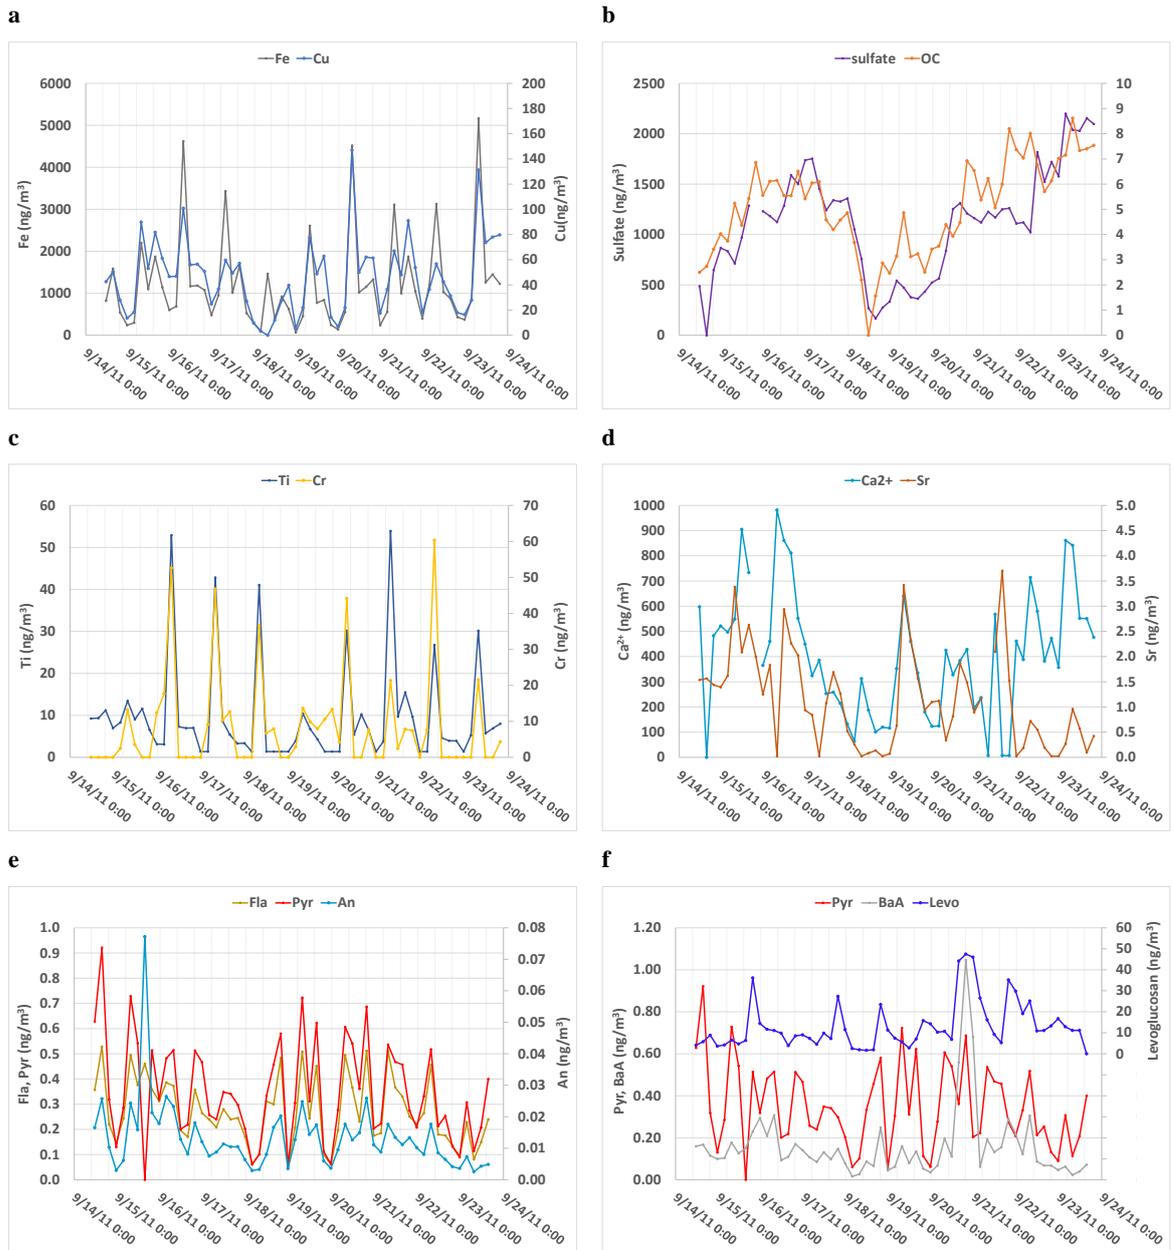

Figure 3: 4-hour concentrations measured at the traffic site: a: iron and copper; b: sulfate and organic carbon; c: chromium and titanium; d: calcium and strontium; e: fluoranthene, pyrene and anthracene; f: pyrene, benzo(a)anthracene and levoglucosan.

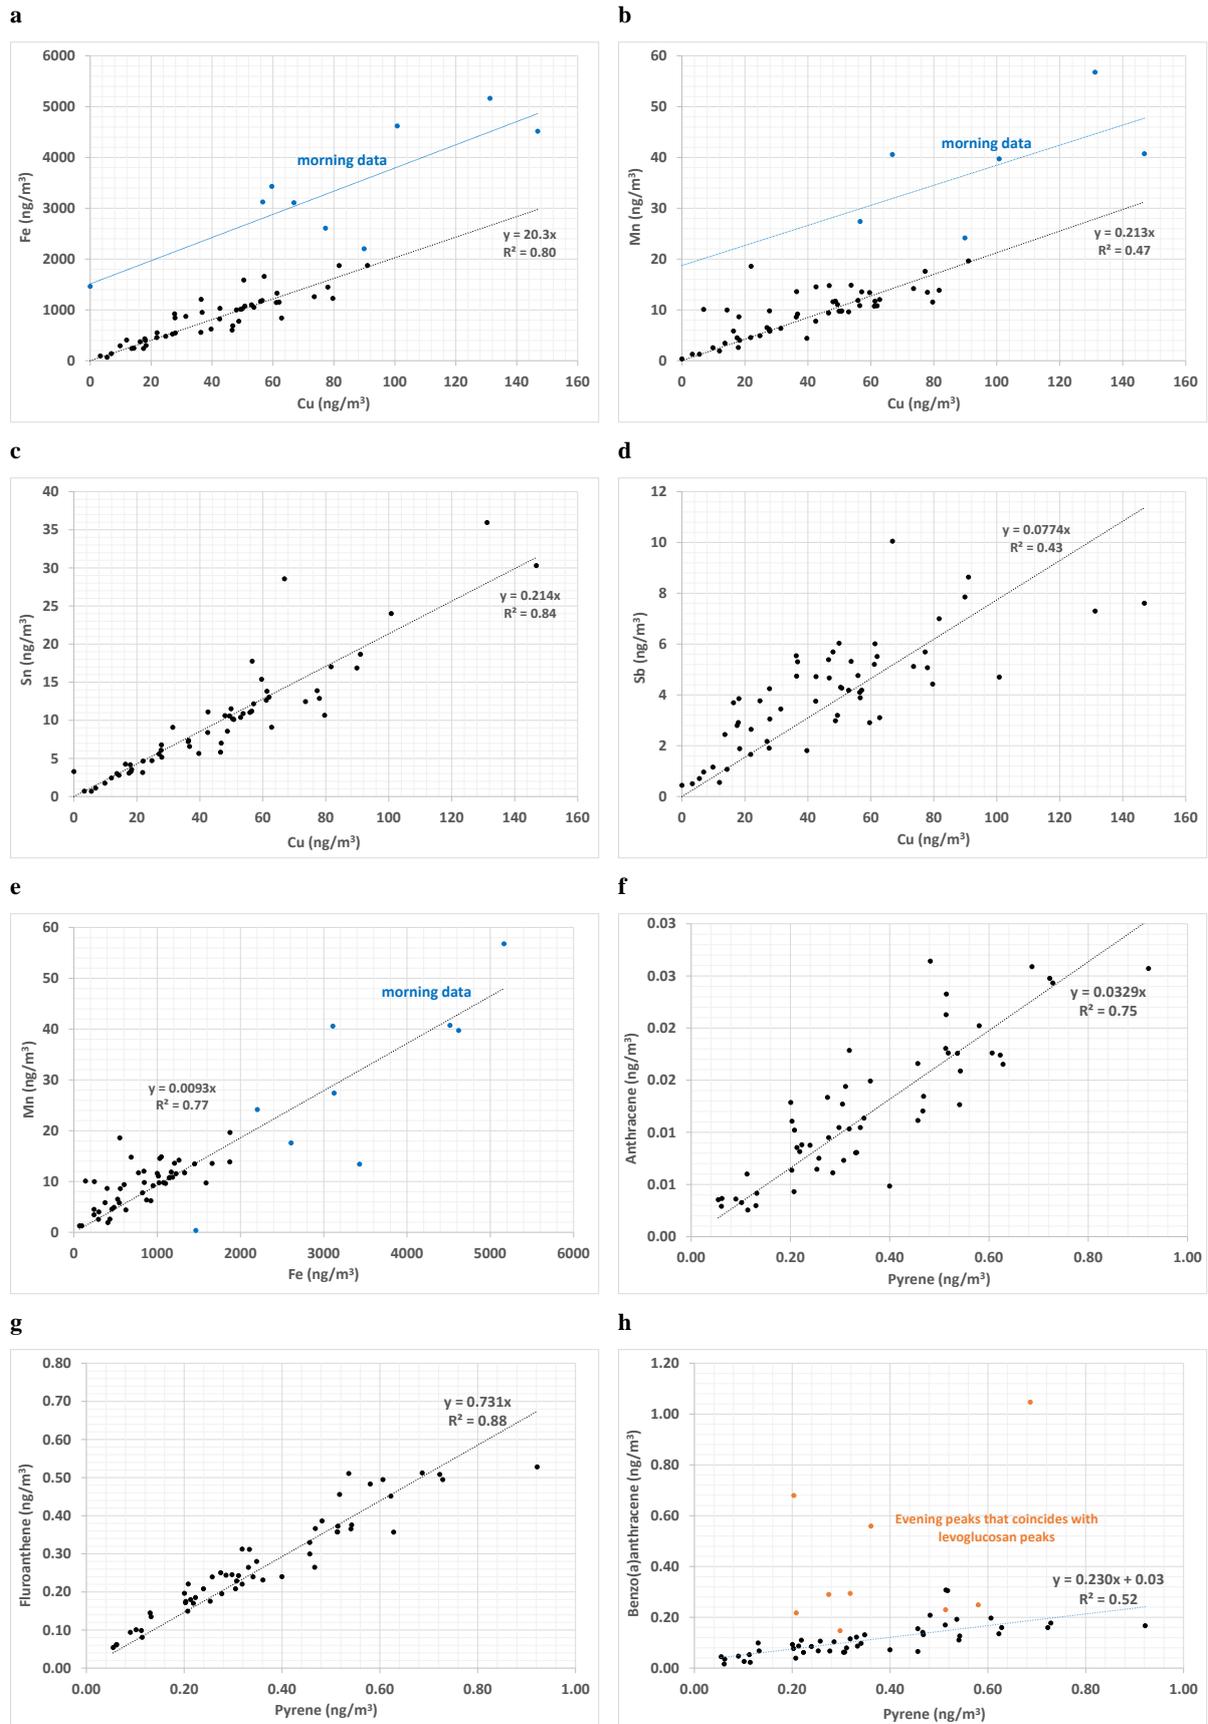

Figure 4: Scatterplots and linear relationships for a few species : a : iron vs. copper ; b : manganese vs. copper ; c : tin vs. copper ; d : antimony vs. copper ; e : manganese vs. iron ; f : anthracene vs. Pyrene ; g : fluoranthene vs. Pyrene ; h : benzo(a)anthracene vs. pyrene

5

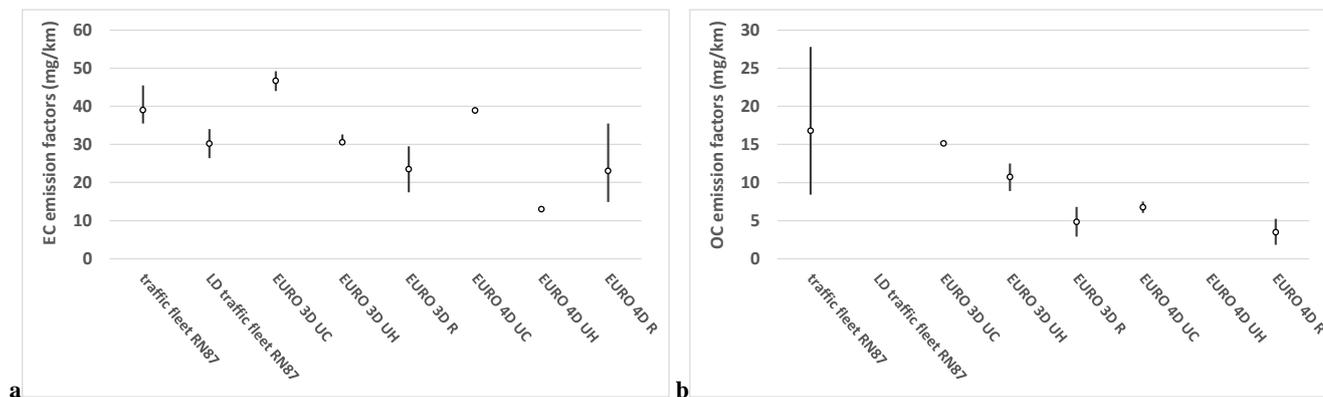

Figure 5: Emission factors for EC (a) and OC (b) for the mixed traffic fleet and the light duty traffic of the RN87/E712 freeway and from the chassis dynamometer measurements of exhaust emissions of EURO 3 and EURO 4 vehicles for respectively urban cold (UC), urban hot (UH) and road (R) driving cycles. The emission factor for OC for the LD traffic fleet could not be determined and no data available for the hot driving conditions for the Euro 4 diesel vehicles.

10

15

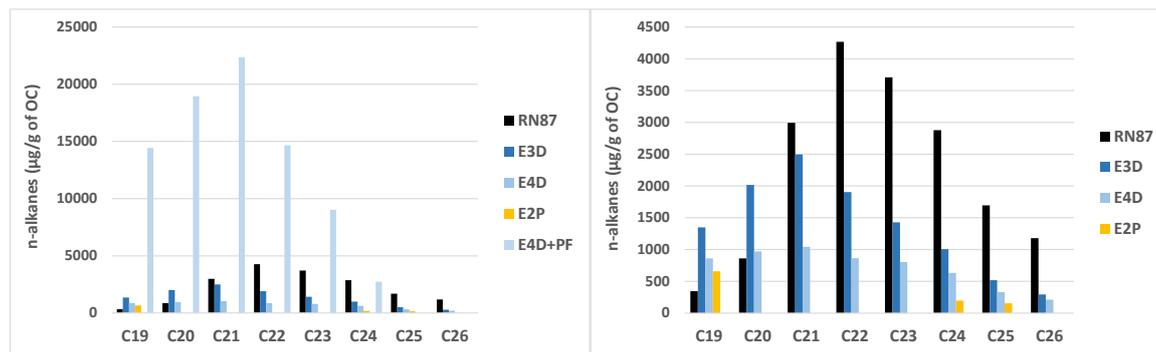

Figure 6: n-alkanes emissions normalized by OC emissions at the traffic site (RN87/E712) and from the exhaust of a Diesel Euro 3 vehicle (E3D), a Diesel Euro 4 vehicle (E4D), a Diesel Euro 4 vehicle equipped with a particle filter (E4D+PF) (on the left only) and a Euro 2 Petrol vehicles.
