Abstract. We analyse simulations performed for the Chemistry-Climate Model Initiative (CCMI) to estimate the return dates of the stratospheric ozone layer from depletion caused by anthropogenic stratospheric chlorine and bromine. We consider a total of 155 simulations from 20 models, including a range of sensitivity studies which examine the impact of climate change on ozone recovery. For the control simulations (unconstrained by nudging towards analysed meteorology) there is a large spread (±20 DU in the global average) in the predictions of the absolute ozone column. Therefore, the model results need to be adjusted for biases against historical data. Also, the interannual variability in the model results need to be smoothed in order to provide a reasonably narrow estimate of the range of ozone return dates. Consistent with previous studies, but here for a Representative Concentration Pathway (RCP) of 6.0, these new CCMI simulations project that global total column ozone will return to 1980 values in 2049 (with a 1-σ uncertainty of 2043-2055). At Southern Hemisphere mid-latitudes column ozone is projected to return to 1980 values in 2045 (2039-2050), and at Northern Hemisphere mid-latitudes in 2032 (2020-2044). In the polar regions, the return dates are 2060 (2055-2066) in the Antarctic in October and 2034 (2025-2043) in the Arctic in March. The earlier return dates in the NH reflect the larger sensitivity to dynamical changes. Our estimates of return dates are later than those presented in the 2014 Ozone Assessment by approximately 5-17 years, depending on the region, with the previous best estimates often falling outside of our uncertainty range. In the tropics only around half the models predict a return of ozone to 1980 values, at around 2040, while the other half do not reach the 1980 value. All models show a negative trend in tropical total column ozone towards the end of the 21st century. The CCMI models generally agree in their simulation of the time evolution of stratospheric chlorine and bromine, which are the main drivers of ozone loss and recovery. However, there are a few outliers which show that the multi-model mean results for ozone recovery are not as tightly constrained as possible. Throughout the stratosphere the spread of ozone return dates to 1980 values between models tends to correlate with the spread of the return of inorganic chlorine to 1980 values. In the upper stratosphere, greenhouse gas-induced cooling speeds up the return by about 10-20 years. In the lower stratosphere, and for the column, there is a more direct link in the timing of the return dates of ozone and chlorine, especially for the large Antarctic depletion. Comparisons of total column ozone between the models is affected by different predictions of the evolution of tropospheric ozone within the same scenario, presumably due to differing treatment of tropospheric chemistry. Therefore, for many scenarios, clear conclusions can only be drawn for stratospheric ozone columns rather than the total column. As noted by previous studies, the timing of ozone recovery is affected by the evolution of N₂O and CH₄. However, quantifying the effect in the simulations analysed here is limited by the few realisations available for these experiments compared to internal model variability. The large increase in N₂O given in RCP 6.0 extends the ozone return globally by ~15 years relative to N₂O fixed at 1960 abundances, mainly because it allows tropical column ozone to be depleted. The effect in extratropical latitudes is much smaller. The large increase in CH₄ given in the RCP 8.5 scenario compared to RCP 6.0 also lengthens ozone return by ~15 years, again mainly through its impact in the tropics. Overall, our estimates of ozone return dates are uncertain due to both uncertainties in future scenarios, in particular of greenhouse gases, and uncertainties in models. The scenario uncertainty is small in the short term but increases with time, and becomes large by the end of the century. There are still some model-model differences related to well-known processes which affect ozone recovery. Efforts need to continue to ensure that models used for assessment purposes accurately represent stratospheric chemistry and the prescribed scenarios of ozone-depleting substances, and only those models are used to calculate return dates. For future assessments of single forcing or combined effects of CO₂, CH₄, and N₂O on the stratospheric column ozone return dates, this work suggests that is more important to have multi-member (at least 3) ensembles for each scenario from every established participating model, rather than a large number of individual models.
1) Introduction

It is well established that stratospheric ozone depletion over the past few decades has been mostly driven by the increase in stratospheric chlorine and bromine originating from the use of halogenated ozone-depleting substances (ODSs). The production of these ODSs has now been largely controlled by the 1987 Montreal Protocol on Substances that Deplete the Ozone Layer, and its subsequent amendments and adjustments. For this reason, the protocol has been recognised as one of the most successful international environmental treaties ever enacted. Following its implementation, the atmospheric burdens of many ODSs have peaked and are now declining at a rate dependent on their respective atmospheric lifetimes, which are typically many decades. This has led to the overall levels of tropospheric chlorine and bromine peaking in 1993 and 1998, respectively (WMO, 2014). These levels are now slowly decreasing and are expected to return to their 1980 values, an arbitrary reference date before the discovery of the Antarctic ozone hole, around the middle of this century. Accordingly, stratospheric ozone is expected to recover from the effects of halogen-induced decreases on a similar timescale, which is already detectable in the Antarctic and upper stratosphere (e.g. see Solomon et al., 2016; Chipperfield et al., 2017; Strahan and Douglass, 2018 and references therein). However, other atmospheric changes, notably climate change through increasing levels of greenhouse gases (GHGs) are also expected to modify the rate of return of ozone and its subsequent evolution (e.g., Shepherd and Jonsson, 2008; Eyring et al., 2010a). The effect of this climate impact is likely to be different in various latitudinal and altitudinal regions of the stratosphere and, for the polar regions, depends on the dynamical evolution of the polar vortices.

The prediction of ozone recovery and return therefore requires the use of three-dimensional (3D) coupled chemistry-climate models (CCMs) which contain details of the important stratospheric chemical processes, as well as a realistic, interactive representation of stratospheric temperature and dynamics (Morgenstern et al., 2010, 2017 and references therein). In these models, the simulated composition of the atmosphere is fully interactive, wherein the radiatively active gases, e.g., carbon dioxide (CO₂), water vapour (H₂O), nitrous oxide (N₂O), methane (CH₄), chlorofluorocarbons (CFCs), and ozone (O₃) affect model heating and cooling rates and therefore dynamics. The representation of stratospheric chemistry includes species and chemical reactions contained in the odd oxygen (Oₓ), nitrogen (NOₓ), hydrogen (HOₓ), chlorine (ClOₓ), and bromine (BrOₓ) chemical families as recommended, for example, by the NASA Chemical Kinetics and Photochemical Data for Use in Atmospheric Studies evaluation reports (e.g., Sander et al., 2011). These chemical recommendations also include heterogeneous processes on sulfate aerosols and polar stratospheric clouds (PSCs). In addition, many of the CCMs include a detailed representation of tropospheric chemistry.

A process-oriented evaluation of CCMs was performed as part of the Stratospheric Processes And their Role in Climate (SPARC) Chemistry Climate Model Validation Activity (CCMVal). Quantitative performance metrics (Eyring et al., 2008; Waugh and Eyring 2008) were used in an extensive effort to evaluate the ability of CCMs to represent key processes related to dynamics, transport, chemistry, and climate. These CCMs have been used in support of several international assessments of ozone depletion and recovery (e.g., Austin et al., 2003, 2010; WMO/UNEP 2003, 2007, 2011, 2014; Eyring, et al., 2007, 2010a, b, 2013b). The models used in this current paper have benefitted from the testing and development that came out of these studies and many are direct updates of the models tested in CCMVal.
Radiative, dynamical and chemical processes affect ozone recovery and return date. The radiative effects of changing GHG concentrations and ozone-induced temperature changes can affect the wave driving of the atmosphere and subsequently can accelerate the Brewer-Dobson (Brewer, 1949) (BD) circulation (Rind et al., 1990, 2001; Butchart and Scaife, 2001; Sigmond et al., 2004, Eichelberger and Hartmann, 2005; Butchart et al., 2006, 2010; Olsen et al., 2007; Garcia and Randel, 2008; McLandress et al., 2010, Polvani et al., 2017a, b). These studies have shown that the acceleration of the BD circulation is a robust result across the majority of CCMs. This acceleration can affect ozone recovery by causing faster removal of ODSs and hence earlier ozone recovery, although decreases in tropical stratospheric ozone may result in column ozone remaining permanently below the 1980 value at these latitudes. Butchart and Scaife (2001) estimated that the recovery of the global ozone layer could be brought forward by 8-10 years. This shortening of the ozone recovery was also found by Morgenstern et al. (2018) for the models represented in this study, although it is important to note that the use of surface mixing ratios in studies largely removes the feedback between circulation changes and ODS return dates. In addition, this strengthening of the BD circulation leads to a decrease in the mean age of stratospheric air by about 0.05 years per decade (Butchart et al., 2010).

Increases in GHGs lead to cooling of the upper stratosphere (e.g., Fels et al., 1980; Rind et al., 1990) which slows down temperature-dependent odd-oxygen loss processes and increases upper stratospheric ozone (e.g., Haigh and Pyle, 1982; Brasseur and Hitchman, 1988; Pitari et al., 1992; Rosenfeld et al., 2002; Waugh et al., 2009; Oman et al., 2010; Bekki et al., 2013; Marsh et al., 2016). Evolution of N₂O and CH₄ can also impact ozone recovery by both chemistry and climate processes (Randeniya et al., 1997; Chipperfield and Feng, 2003; Ravishankara et al., 2009; McLandress et al., 2010; Revell et al., 2012; Morgenstern et al., 2014; Revell et al., 2015; Kirner et al., 2015).

A number of studies have used detailed coupled CCMs to predict the future evolution of stratospheric column ozone. For example, using the GFDL model, Austin and Wilson (2006) showed that the October monthly mean Antarctic ozone return to 1980 abundances mainly depends on halogen loading and will not occur until ~2065. They also showed that Arctic ozone returns about 25-35 years earlier than Antarctic ozone does, while Li et al. (2009) showed that in the tropics ozone may never return to 1980 values due to changes in transport. However, due to various biases and weaknesses amongst various CCMs, our best estimates of ozone return dates come from multi-model assessments such as CCMI.

The aim of this paper is to provide updated estimates of the return dates of stratospheric ozone in different latitude regions. The year at which column ozone is expected to return to a particular, historic level is a key metric for quantifying the recovery of the ozone layer (e.g., Table 2-5, WMO 2014). Note that we estimate return dates based on mean atmospheric behaviour, independent of the extremes caused by dynamically driven variability, for example. Our estimates of return dates are based on analysis of the new, extensive range of CCMI simulations which have been produced using updated and improved models compared to previous studies such as CCMVal-2. All models compute the impact on ozone of future stratospheric cooling, the intensification of the Brewer-Dobson circulation, as well as numerous other dynamical and chemical factors. Three types of uncertainties are considered: internal variability, model uncertainty, and scenario uncertainty. Internal variability refers to short-term variations in computed ozone, which are not dependent on long-term change driven by ODSs and GHGs. Model uncertainty represents the fact that various CCMs can provide different return dates, for the same prescribed time series of ODSs and GHGs, due to alternate representations of processes such as the impact of rising GHGs on stratospheric circulation. Finally, scenario uncertainty
means that the return date found by a CCM will be sensitive to the particular, prescribed time series of ODSs and GHGs used as model input.

The layout of the paper is as follows. Section 2 briefly summarises the models, scenarios, and simulations used in this study. Section 3 describes how the results of the CCM simulations are processed in order to smooth over interannual variability and adjust some model ozone values for biases compared to observations. Section 4 presents our main results on the return and recovery of stratospheric ozone and how it varies between different simulations and between models. Finally, Section 5 presents our conclusions.

2) Models, Scenarios, and Simulations

The model simulations used in this work are taken from the Chemistry–Climate Model Initiative (CCMI), which is a joint activity from the International Global Atmospheric Chemistry (IGAC) project and SPARC. One of the main goals of CCMI is to provide support for the quadrennial Scientific Assessment of Ozone Depletion, produced by the World Meteorological Organisation (WMO) Global Ozone Research and Monitoring Project and United Nations Environment Programme (UNEP). This is done through the provision of scenarios and input forcings that the models can use for standard experiments. This paper provides analysis to support the results that will be presented in the forthcoming 2018 assessment.

Descriptions of the CCMI experiments used in this work are given in Table 1. These scenarios are discussed in detail in Eyring et al. (2013a) and Morgenstern et al. (2017). Table 2 summarises the simulations performed by each model considered here. Briefly, there are three reference simulations designed to understand both past and future ozone evolution. The first (labelled REF-C1) is a hindcast simulation of the recent past [1960-2010] that is closely tied to the following observed time-dependent forcings: 1) greenhouse gases (GHGs) and ozone-depleting substances (ODSs); 2) 11-year solar variability; 3) sulfate aerosol surface area density (including background and volcanically active periods); 4) sea surface temperatures (SSTs) and sea ice concentrations (SICs); 5) additional organic bromine from very short-lived substances (VSLS); and 6) tropospheric ozone and aerosol precursor emissions. The meteorology in REF-C1 is free-running. The second reference simulation (labelled REF-C1SD) has the same observed forcings as REF-C1, with the additional constraint that model temperature and dynamics are nudged to analysed meteorology, i.e., specified dynamics (SD). The third reference scenario (labelled REF-C2) includes both a hindcast and forecast period [1960-2100]. It should be noted that for REF-C2, several of the models used in this study have an interactive ocean/sea ice modules (Morgenstern et al., 2018). For this scenario, the hindcast forcings are similar to REF-C1 with the main exception that the SSTs/SICs are based on model results (Morgenstern et al., 2018). The forecast component of the REF-C2 scenario uses GHGs (i.e., CO₂, CH₄, and N₂O) that follow the Intergovernmental Panel on Climate Change (IPCC) Coupled Model Intercomparison Project Phase 5 (CMIP5) Representative Concentration Pathways 6.0 (RCP 6.0) scenario (Meinshausen et al., 2011; Masui et al., 2011).

Table 2 shows the number of realisations that were available for each simulation from every model. For REF-C1 a total of 19 models performed 38 realisations, including 8 models which performed multi-member ensembles. For simulations REF-C1SD and REF-C2 the numbers are 13 models (13 realisations) and 19 models (33 realisations), respectively. In addition to these reference simulations, eight additional sensitivity scenarios based on the REF-C2 simulation were defined by CCMI. SEN-C2-RCP26 (5 models, 5 realisations), SEN-C2-RCP45 (7, 9) and SEN-C2-RCP85 (8, 10) follow RCP 2.6, 4.5 and 8.5, respectively. These scenarios diverge from
the REF-C2 definition in year 2000. SEN-C2-fODS (8, 12) and SEN-C2-fGHG (8, 13) are identical to REF-C2, except that concentrations of ODSs and GHGs, respectively, are fixed at 1960 levels. Finally, there are three scenarios that examine the sensitivity of ozone return to N2O and CH4. Scenario SEN-C2-fN2O [1960-2100] is the same as REF-C2 but with surface N2O mixing ratios fixed to 1960 values. This results in the N2O surface abundance being ~40% higher in 2100 for the REF-C2 scenario versus the SEN-C2-fN2O scenario. Scenario SEN-C2-fCH4 [1960-2100] is the same as REF-C2 but with surface CH4 abundance fixed to 1960 values; the late 21st century REF-C2 surface abundance of CH4 is 30-50% higher than in SEN-C2-fCH4. Scenario SEN-C2-CH4RCP85 [2000-2100] replaces the REF-C2 RCP 6.0 CH4 surface abundance with that from RCP8.5. Since the RCP8.5 surface CH4 is considerably larger than in REF-C2, there is 110-125% more CH4 in SEN-C2-CH4RCP85 relative to REF-C2 in the late 21st century. There are 8 (8), 8 (8), 6 (6) CCMs (realisations) included for SEN-C2-fN2O, SEN-C2-fCH4 and SEN-C2-CH4RCP85, respectively. For scenarios SEN-C2-RCP26 and SEN-C2-CH4RCP85, in particular, the numbers of realisations available are limited.

3) Methodology

We present an analysis based on seven latitude bands: Southern Hemisphere (SH) polar (90°S-60°S), SH mid-latitudes (60°S-35°S), tropics (20°S-20°N), Northern Hemisphere (NH) mid-latitudes (35°N-60°N), NH polar (60°N-90°N), near-global (60°S-60°N) and global (90°S-90°N). For the SH and NH polar regions we only consider the months of October and March, respectively, which typically correspond to the end of the winter/spring ozone loss periods. For the other latitude bands, we use annual means from each model simulation. We use 60°S-60°N for the near-global means, and 90°S-90°N for the global means, to allow for various latitudinal definitions of “global” ozone analyses in WMO ozone assessments (e.g. WMO 2011: WMO, 2014). In their analysis of CCMVal-2 simulations, Eyring et al. (2010b) used time-series additive model (TSAM) (Scinocca et al., 2009) but here we show absolute ozone time series to identify models to be excluded as outliers. As shown in Table 2, there are variations in the number of simulations for each reference/sensitivity experiment. Therefore, we decided to calculate the model averages (means and median) for each scenario using the following procedure.

- First, we calculate the zonal mean October, March or annual mean time series for each realisation. If more than one realisation is available for a particular model then we calculate an ensemble mean of monthly/annual mean time series. If only one realisation is available then we apply a 3-point (i.e. 3-year) boxcar smoothing to remove the short-term variations and somewhat mimic the effect of averaging an ensemble.

- These single time series for individual models are used to calculate the multi-model mean (MMM) and corresponding standard deviations for each year. We also calculate the ‘1-σ multi-model mean’ (MMM1S) where we exclude models lying outside 1σ of the MMM for each year. Finally, all of the single time series are used to calculate the median model (MedM) along with the 10th and 90th percentiles.

- To calculate smoothed and adjusted time series with respect to a reference year (e.g. 1960, 1980), we apply a 10-point boxcar smoothing to the individual model time series as well as the MMM, MMM1S and MedM time series.

- In order to make a robust estimate of ozone return dates we need to account for the different biases between the model simulations and observations. We calculate the mean
biases between observational data and the REF-C2 MMM, MMM1S and MedM timeseries for the 1980-1984 time period. We choose the REF-C2 simulation as that is the reference that is used to estimate ozone return dates. An adjusted timeseries for each individual model is then calculated by subtracting the respective observational bias. This procedure also results in the multi-model mean agreeing with the observations in the 1980-1984 period.

- Finally, using the MMM1S timeseries from REF-C2 as a reference line, the MMM1S timeseries from REF-C1, REF-C1SD, SEN-C2-fODS, SEN-C2-fGHG, SEN-C2-fCH4 and SEN-C2-fN2O are adjusted for the year 1980. The MMM1S timeseries from simulations starting in year 2000 (SEN-C2-RCP45, SEN-C2-RCP85) are adjusted for the year 2000 using the REF-C2 reference.

We compare the CCM simulations with selected observations to provide a basic evaluation of their performance. In particular, to test the height-resolved evolution of the modelled ozone fields we use BSVertOzone v1.0 (Bodeker Scientific Vertical Ozone, hereafter referred to as "BSVertOzone"), which is an updated and further developed version of the BDBP (Binary Database of Profiles) v1.1.0.6 that is described in detail in Bodeker et al. (2013). BSVertOzone consists of monthly mean zonal mean ozone values on either pressure or altitude levels (from Earth’s surface to about 70 km), where ozone is provided in mixing ratio or number density. For the data presented here the following improvements over the latest version of the BDBP were made: (1) ozone measurements from different data sources that are used as input for the monthly mean zonal mean calculation were updated (different satellite measurements and ozone soundings); (2) additional data sources were added (Microwave Limb Sounder, MLS, ozone profiles and recent years of ozone soundings); (3) drifts and biases between measurements from different data sources are adjusted (using a chemical transport model as transfer standard); (4) uncertainties are propagated from individual measurements through all preparation and calculation procedure steps to the final product; and (5) the calculation of the monthly mean zonal mean values was updated to correctly take into account the variable measurement frequencies of the different available data sources. The methodology of filling data gaps to construct a globally filled database is an updated version of the method described in Bodeker et al. (2013) where a pre-filling processing step was added. A more detailed description of BSVertOzone can be found in Hassler et al. (2018).

BSVertOzone spans 70 pressure levels that are approximately 1 km apart (878.4 hPa to 0.046 hPa). For the calculation of the partial columns, ozone was interpolated to the exact boundaries of the partial columns from the two closest BSVertOzone pressure levels, and then ozone was integrated between the determined levels. The boundaries for the partial columns were defined as follows: tropospheric column (surface-tropopause), lower stratospheric column (tropopause – 10 hPa), upper stratospheric column (10 hPa and above; for BSVertOzone this means up to 0.046 hPa). The tropopause pressure was defined as 100 hPa in the tropics (20°S-20°N), 150 hPa in the mid-latitudes (20°-60°N/S), and 200 hPa in the polar regions (60°-90°N/S). CCM partial columns were integrated between the same partial column boundaries, but directly from the CCM pressure levels. No additional interpolation of CCM ozone profiles or BSVertOzone profiles was performed.
4) Results

4.1 Adjustment of model results

**Figure 1** shows October mean total column ozone (TCO) from the REF-C2 simulations for the Antarctic to illustrate how the model simulations compare before and after adjustment to fit observations. (Other regions are shown in the Supplementary Material (SM) **Figures S1-S5**). **Figure 1a** shows the mean TCO time series from the individual models (with a 3-point boxcar smoothing if only 1 realisation is available) along with three estimates of the model mean. These are the overall multi-model mean (MMM), the mean of the models which lie within 1σ of the MMM (MMM1S), and the median model (MedM). While all models show the characteristic behaviour of depletion followed by recovery, there is a large spread of around 150 DU between the model values at any time. This complicates the determination of the ozone return dates relative to a baseline. Therefore, **Figure 1b** shows the same model runs after bias-correcting the individual model values to the observations over the period 1980-1984 and applying a 10-point boxcar smoothing. This correction to the models also forces the model means to fit the observations during this time period. With the bias correction, the individual models clearly give a more coherent picture and therefore, throughout this paper we generally show just the adjusted model results (unless indicated otherwise). However, it is important to note that the values of the multi-model mean, which are used for our best estimate of ozone return dates, are similar between **Figures 1a** and 1b. Evidently, given enough model simulations, this approach of adjusting the model time series does not significantly alter the best estimate but does provide a smaller, more meaningful range of uncertainty. In other words, positive and negative model biases appear to be equally represented in the CCMI ensemble, but removing them will allow comparison of model returns to the same common 1980 baseline. Concerning the different methods to estimate the model average, for the Antarctic October case shown here the results are very similar. The difference is in the estimated range of variability which is shown by the shading. The 10th and 90th percentiles of the median give the largest spread of around 100 DU. The 1σ variation of the MMM is around ±40 DU. As expected the 1σ variation of the MMM1S, which has removed the outlying models, is smaller and around ±25 DU in this case. The MMM1S has an advantage over the median approach for the scenarios where there are not many realisations, and hence the 10th/90th percentiles cannot be derived robustly. Therefore, we use the MMM1S and the 1σ deviation (of the forecasts provided by the adjusted models) to determine our best estimate of return dates and associated uncertainty, respectively.

4.2 Column ozone return dates

**Figure 2** compares the MMM1S TCO from REF-C2 with the standard CCMI historical simulations REF-C1 and REF-C1SD, in which the models are nudged towards analysed meteorology. Results are shown for both the direct and adjusted comparisons for the Antarctic and Arctic. The top panels show that, as expected, the REF-C1SD simulations reproduce better the observed evolution of TCO, as well as capturing much of the observed interannual variability. In particular, in the Antarctic the REF-C1SD mean reproduces the observed increase and then decrease in ozone after the year 2000. This was also shown in Hardiman et al. (2017) who investigated the contributions of dynamics, transport and chemistry to these differences and is consistent with chemical transport model analyses in Chipperfield et al. (2015, 2017). For the Arctic it is noticeable that the REF-C1SD simulations give significantly lower TCO than the REF-C1 in the 1990s. This is related to the series of cold Arctic winters during this period when low TCO was caused through large chemical loss (e.g. 1994/95 and 1995/96) along with dynamical contributions (e.g. 1996/97). The mean of the free-running REF-C1 simulations do not capture these low-column-ozone events. In contrast, **Figure 2** shows that the REF-C2 mean
gives a more climatological picture of gradually varying ozone. The REF-C1 and REF-C2 means for the hindcast period are consistent. Therefore, within the limitations of the comparison of the heavily smoothed lines, the choice of ocean / sea ice representation does not seem to affect the climatological TCO evolution in the regions shown, although as noted by Zhang et al. (2016) sea ice loss may affect zonally asymmetric TCO trends.

Figure 3 shows TCO results of the REF-C2 MMM1S for five latitude bands and the near-global (60°S-60°N) values. Also shown are the means from the sensitivity simulations SEN-C2-IGHG and SEN-C2-ODS, which isolate the impacts of GHG and ODS changes. In all cases the shading gives the MMM1S 1σ variability. The TCO return dates from REF-C2, and the estimated range of that based on the 1σ variability, are summarised in Table 3 and plotted in Figure 4 (left panel). Globally the models predict a return to 1980 TCO values in 2049, with a 1σ spread from 2043-2055. Earlier return dates are predicted in the NH mid-latitudes (2032), NH polar region (2034), and SH mid-latitudes (2045). In contrast, the return date from the large depletion in the SH polar region is much later at 2060. The 1σ variability gives the smallest range of return dates in the Antarctic (11 years) and SH mid-latitudes (11 years). The corresponding ranges in the NH, where dynamical variability is larger, are 24 years in mid-latitudes and 18 years near the pole. In the tropics, the MMM1S shows a return to 1980 values towards 2058, followed by a turnaround and further decline. Note that individual models differ in whether they predict a return to 1980 values or not, before predicting the decrease at the end of this century (see SM Figure S4). The MMM1S near-global (60°S-60°N) column ozone also shows a decline after about 2080, which is mostly due to a decline in the tropics, with a small contribution from NH mid-latitudes. Dynamical decreases in tropical TCO due to increased upwelling would be expected to cause increases in TCO at mid-high latitudes. For these variations in near global TCO after 2080 small changes of 2-3 DU in the tropospheric column, especially in the NH, are important factors (see Figure 9 below). The right panel of Figure 4 and Table 4 show the return dates of stratospheric column ozone (SCO, see below).

Our predictions of TCO return dates can be compared with previous estimates, particularly those used in past WMO Ozone Assessments. WMO (2011) used results from the CCMVal-2 experiments to derive ozone return dates and these are shown in Table 3. As no major update to CCMVal-2 had occurred, these same CCMVal-2 values were also used as the best estimates in the subsequent WMO (2014) assessment. However, that assessment also showed results from a subset of four CCMVal-2 models, selected for their good representation of stratospheric circulation (Figures 2-21 and 3-15 from that assessment), and analysis of five CMIP5 models (Figure 2-23; Eyring et al., 2013). We have included an analysis of these CMIP5 simulations in Table 3. Note that the CCMVal-2 runs used the A1b GHG scenario while the additional runs shown in WMO (2014) used RCP 6.0 or 4.5. This study represents the first comprehensive update of TCO return dates since CCMVal-2. Compared to those values our return dates (albeit for a different GHG scenario) are later by values ranging from 4 years in the Arctic, 10 years in the Antarctic to 10-11 years at mid-latitudes. Similar differences are seen in the tropics, where not all models show a return. Interestingly, the subset of four CCMVal-2 models that performed new experiments for WMO (2014), based on RCP 6.0 or 4.5, also showed later return dates than CCMVal-2, more in accord with our simulations. Compared to the CMIP5 models, which also use the RCP 6.0 scenario, our return dates are also later. The difference is small in northern mid-latitudes but it is as large as 14 years in the Antarctic (2046 compared to 2060).

There are three major differences in the assumptions used for the CCMVal-2 runs compared to the CCMI simulations, all of which likely contribute to our present estimate of up to a 17 year later return of total column ozone to the 1980 level. First, future atmospheric CO₂ rose more rapidly in the A1b scenarios used for CCMVal-2 compared to the RCP 6.0 scenario used by
CCMI (Figure S13). Within A1b, CO₂ reaches 454 ppm in year 2032, which was the year given for recovery of total column ozone in WMO (2011). This same mixing ratio for CO₂ is reached 9 years later within RCP 6.0. As a result, climate-driven changes in circulation within CCMI, which accelerate the recovery of the global ozone layer, will be similarly delayed. Next, the specification of CH₄ within A1b resulted in a more rapid rise compared to RCP 6.0 (Figure S13). For A1b in year 2032, atmospheric CH₄ is projected to be 44% larger than the 1980 value. For RCP 6.0, CH₄ is projected to rise by only 17% relative to 1980. As detailed in Section 4.5, the slower rise in CH₄ assumed for CCMI reduces the chemically-induced increase of ozone in both the stratosphere and troposphere, contributing to a longer time for total column ozone to return to 1980 levels. The differences in the assumptions for future N₂O between A1b and RCP 6.0 are small, and therefore not responsible for our later return dates. Finally, the return of effective equivalent stratospheric chlorine to 1980 levels is delayed by about 5 years in the baseline WMO (2011) scenario (used in this study) compared to the scenario used to drive CCMVal-2, reflecting new knowledge of lifetimes and emissions of various ODSs between the times these two scenarios were formulated. Since the return dates used in our study are based on analysis of results from 20 models, whereas the WMO (2011) return dates were based on results of 17 models, we have also examined the impact of restricting our return date estimates to a subset of the common models used by WMO (2011). Return dates for global and near-global ozone found using only 9 common models differ by only 1 to 3 years compared to values given in Table 3 for the complete set of models. Therefore, the primary causes of the later dates for global and near-global ozone to return to 1980 levels reported in Table 3, compared to WMO (2011) return dates, are assumptions regarding future atmospheric levels of CO₂, CH₄, and ODSs inherent to CCMVal-2 and CCMI. As our estimates are based on a large number of dedicated stratospheric simulations, with many models which have benefitted from further testing and development since CCMVal-2, we would argue that our values provide the best current estimates.

The sensitivity simulations in Figure 3 also illustrate the effect of climate change and ODS changes on total column ozone recovery, confirming the results of previous studies (e.g. Morgenstern et al., 2018 and references therein). The smallest impact of climate change is predicted in the Antarctic where the simulation with fixed GHGs is very similar to REF-C2. In the mid-latitudes, increasing GHGs brings forward the return dates by about 10 (NH) to 20 (SH) years. In the Arctic, there is a larger impact. However, the variation of the MMM1S line for SEN-C2-4GHG stays close to the 1980 reference line without crossing it, showing the challenge in extracting a return date (or range of dates) from the model runs. In the tropics, the competing effects of changes in ODSs, which increase ozone, and changes in GHGs, which decrease ozone, are clearly illustrated. In this region, the small rise in ozone due to ODS recovery is masked by decreases due to GHG increases. The net result is a decrease in tropical TCO in REF-C2.

4.3 Ozone profile variations

We now consider ozone recovery of partial columns in the lower (tropopause-10hPa; Figure 5) and upper (10 hPa and above; Figure 6) stratosphere separately. The figures include partial column observations derived from the composite BSVertOzone data set (Bodeker et al., 2013; Hassler et al., 2018). This composite dataset has the advantage, compared to observations from any single instrument, of being fully height resolved and available continuously over 1979-2016. BSVertOzone consists of several different data sets. We use here the Tier 1.4 data set that is based on observations, but has been created by applying a least squares regression model to attribute variability to various known forcing factors (natural and anthropogenic) for ozone. The variability in this data set is reduced compared to pure observations, since it describes only the
variability for which basis functions were included in the regression model. This data set is therefore optimised for the use in comparisons with CCM simulations that do not exhibit the same unforced variability as reality. Figures S10 and S11 in the Supplementary Material show results from the specific altitudes of 50 hPa and 5 hPa, respectively, compared to GOZCARDS observations (Froidevaux et al., 2015). In the lower stratosphere, where ozone has a long photochemical lifetime, the adjusted results from the models show some variations, especially in the polar regions. Overall, in the extra-tropical regions the models follow the observed behaviour in the BSVertOzone dataset although the MMM1S appears to overestimate depletion in the Antarctic and underestimate it in the Arctic. Interestingly, in the tropics the BSVertOzone dataset indicates ongoing decreases after the year 2000 while the models show a levelling off and turnaround. This observed decrease in tropical lower stratospheric ozone has been noted by Ball et al. (2018) and is not captured by the models shown here. There are also significant differences between the models in the tropics where the lower stratosphere column does not return to 1980 values in all REF-C2 simulations. This is also the case for the near-global lower stratospheric column, reflecting the large influence of the tropics. In the upper stratosphere (Figure 6), ozone behaves more similarly in all regions and between all models (i.e. depletion followed by recovery to values larger than 1980) as dynamical variations are less important. Therefore, there is generally less spread in the model forecasts of ozone recovery than over the whole stratosphere, although the ULAQ-CCM, CHASER and CESM1-CAM4 models are outliers in certain regions. Note that the models consistently underestimate the BSVertOzone values and appear to show larger depletion. At this altitude, the feedback of temperature changes on ozone becomes important (Haigh and Pyle, 1982) and there is a larger increase in ozone than determined by ODS changes alone due to stratospheric cooling. As the CCMs are based on similar photochemical data, they should be expected to exhibit similar climate sensitivities, although they may predict different magnitudes of climate change. The reason for the disagreement between models and BSVertOZone in the upper stratosphere requires further investigation, but these upper stratospheric differences will not have a large impact on column ozone return years.

Since the main driver of past ozone depletion and ozone recovery is the evolution of stratospheric halogen loading, we pay particular attention to how well the CCMs model the time-dependent abundance of organic and inorganic chlorine and bromine. These are based on prescribed scenarios should be fields for which the CCMs agree well. Figure 7 shows the evolution of the modelled inorganic chlorine (\( \text{Cly} = \text{HCl} + \text{ClONO}_2 + \text{HOCl} + \text{ClO} + 2\text{Cl}_2\text{O}_2 + \text{Cl} + \text{BrCl} + \text{OCIO} + \ldots \)) and total chlorine (\( \text{Cly} + \text{organic} \)) in the upper and lower stratosphere in the Antarctic from the REF-C2 simulations. This region was chosen as an example to illustrate model-model differences. Long-term variations in the modelled chlorine loading are determined by the specified surface mixing ratios of the ODS. Through this, the different models are constrained to show the same approximate timescale for chlorine to return to its values in e.g. 1980. If the stratospheric ODSs were simulated using emissions, rather than specified surface mixing ratios, then the timing of the model return dates would vary depending on the speed of the model circulation (Douglass et al., 2008). Despite this constraint, the models do show a variation in the Cly loading at any time, especially in the lower stratosphere where the fractional conversion of organic chlorine to Cly is smaller. Nevertheless, some models show lower Cly than would be expected based on differences in circulation (EMAC-L47MA, EMAC-L90MA, CCSRNIES). Moreover, in the upper stratosphere, where most chlorine would be in the form of Cly, there are still large variations between the models. The reasons for this require further investigation beyond the scope of this study, but, if models are conserving chlorine in their chemistry and transport schemes, the evolution of Cly at 5 hPa should closely track that of the specified tropospheric chlorine with a lag of around 3-6 years. Figure 7 also includes Microwave Limb Sounder (MLS) observations of the October vortex-mean volume mixing ratio
of HCl + ClO. This provides a lower limit of the amount of Cly present, though it will be a good approximation in these locations. The year-to-year variation at 50 hPa (around 250 pptv) is due to variability in the polar vortex and chlorine activation, which is not an issue at 5 hPa. The comparison with the MLS data clearly shows that the three models with low Cly are unrealistic.

Bromine loading is another driver of ozone depletion and recovery. Figure S12 compares total inorganic bromine modeled at 5 and 50 hPa in the Antarctic from the models. The highest values of bromine are reported by the SOCOL3 and EMAC-L90MA models. For SOCOL3, the model was run using surface mixing ratios of 1.63 and 1.21 ppt for CHBr3 and CH2Br2, respectively, which results in a bromine content for these very short lived substances (VSLS) of 7.31 ppt. This is larger than the 5 ppt estimate for total bromine of VSLS suggested for use in CCM models by Eyring et al. (2013a). Within EMAC-L90MA, bromine sources are explicitly represented by considering oceanic emission of CHBr3 and CH2Br2, three other VSLS species, as well as sea salt (Warwick et al., 2006). The tendency of Bry within EMAC-L90MA to be larger than found by other models, and to exceed an empirical estimate based on field observations in the Tropical Western Pacific, has been noted in a recent model intercomparison study focused on bromine (Wales et al., 2018). The EMAC-L90MA over-estimate is likely caused by the oceanic emission terms being too large. The outlier is CHASER-MIROC, which has a bromine loading that peaks near 9 ppt in the upper stratosphere of the Antarctic, which is more than a factor of two less than surface mixing ratios of bromocarbons that reach the stratosphere (e.g., Wales et al., 2018) as well as the mean value of peak Bry from the other models. The low value of Bry within CHASER-MIROC is due to the consideration of only CH2Br, without scaling to represent either halons and VSLS bromocarbons, for the simulations conducted for CCMI. Within this model, the BrO+ClO cycle will have an unrealistically low effect on O3.

The decline in stratospheric halogen loading is a main driver in the increase of stratospheric ozone. However, ozone is also affected by other stratospheric factors, notably driven by changing climate, such as rising temperature in the upper stratosphere. Moreover, differences in this estimated climate effect is a source of variations between the projections provided by the models analysed here. This climate effect is illustrated by the difference in the return dates to 1980 levels of stratospheric chlorine versus ozone. Figure 8 (top and middle rows) shows how these return dates compare for local changes in the polar upper stratosphere and lower stratosphere, as well as column ozone return versus lower stratospheric Cly. For the upper stratosphere in both polar regions, the ozone return dates are much earlier than the Cly return dates and span a slightly larger range. In the lower stratosphere and for the column in the Antarctic there is a much closer correspondence between the Cly return date (at 50 hPa) and the ozone return date. For the Arctic, the ozone return dates are earlier than for Cly (see also Figure 3). Figure 8 also shows the large spread in return dates between individual models. However, these return dates do generally correlate with each other so that an earlier Cly return date corresponds to an earlier ozone return date. Some exceptions to this occur – e.g. for the CMAM and EMAC-L90 models.

Figure 9 shows the evolution of the tropospheric partial column ozone (PCO) from simulations based on scenario REF-C2. In the Antarctic (October), the MMM1S shows very little change from year 1980 through the forecast period. This is most likely due to limited tropospheric ozone precursor abundance in the polar SH region (e.g., low NOx). In the other five regions, the MMM1S evolution typically shows 2-5 DU enhancement going from year 1980 to the peak tropospheric PCO in the forecast period. The models then generally show a decrease in the final few decades of the century. It is also interesting to note the large spread across participating CCMs in tropospheric PCO in the 21st century. For example, the SH and NH mid-latitude panels
show, for year 2060, the range across the models is ~8-10 DU. The range is even larger near the end-of-the 21st century where the NH mid-latitudes and Arctic (March) ranges are ~15 DU and ~20 DU, respectively. Several models have less tropospheric PO in year 2100 relative to year 1980. This is suggestive that the tropospheric chemistry sensitivity to mainly CH₄ is very different in the CCMs. There is more discussion of this topic in Section 4.5.

4.4 Sensitivity of ozone return to climate change

Figure 10 shows the sensitivity of the tropospheric PO evolution to assumed GHG RCP scenarios. The CH₄ temporal trend is the largest in SEN-C2-RCP85, followed by REF-C2, and SEN-C2-RCP45 scenarios. As discussed later in Section 4.5, an increase in tropospheric CH₄ will enhance the NOₓ-HOₓ-smog net ozone production (Haagen-Smit et al., 1950). Therefore, the larger future trend in CH₄ as represented in the SEN-C2-RCP85 scenario, relative to the REF-C2 scenario (Figure S12), increases the year 2100 global annual average MMM1S tropospheric PO by ~5 DU. Previous studies (e.g. Shindell et al., 2009; Eyring et al., 2013; Morgenstern et al., 2018) have also found that the tropospheric impact of CH₄ increases is a major contributor to the TCO changes. Because of this difference in tropospheric PO between scenarios we will only consider the evolution of SCO for derivation of return dates in the RCPs and SEN-C2 simulations in the discussion below.

Figure 11 shows the sensitivity of the SCO return dates to the assumed GHG RCP scenarios. The relative change is smaller in the Antarctic, where recovery is largely determined by Cly loading, but larger in all other regions. However, the absolute changes between, for example, the Antarctic (October) and Arctic (March) are similar. Simulation SEN-C2-RCP26 (not shown), which assumes only small climate change but for which we only have 5 realisations, does not return to 1980 values at all except in the Arctic. Globally and at mid-low latitudes, simulation SEN-C2-RCP45 shows a behaviour between the RCP 2.6 and RCP 6.0 simulations. Compared to REF-C2, the simulation with the largest impact of climate change, SEN-C2-RCP85, shows a similar behaviour globally, but with regional differences, i.e. a positive effect on ozone at all latitudes except the tropics, where ozone decreases the most under RCP 8.5. The impact on return dates in different regions is summarized in Figure 12. This figure shows the return date for each model (coloured dots) along with the MMM1S (red triangle) for each scenario, all for six regions. The grey triangle is the MMM1S for the REF-C2 scenario (see Figure S4, right panel). The uncertainty in the MMM1S is represented by the solid vertical line. The SCO magnitude and range for all scenarios is listed in Table 4. For all regions shown in Figure 12, the derived MMM1S return date for SEN-C2-RCP45 is within the uncertainties range of the MMM1S return date for REF-C2. This is also true for SEN-C2-RCP85, although in the Antarctic (Oct.) region where the MMM1S return date for SEN-C2-RCP85 MMM1S is shortened by 12 years the uncertainty range only just overlaps with the MMM1S from REF-C2.

4.5 Sensitivity of ozone return to methane and nitrous oxide

We now focus on the sensitivity simulations (Table 1) which examine the individual roles of CH₄ (SEN-C2-fCH4 and SEN-C2-CH4RCP85) and N₂O (SEN-C2-fN2O), and their combined impact with CO₂ (SEN-fGHG), on ozone recovery. We will only consider stratospheric ozone columns (SCO), thereby eliminating any impact from changes in tropospheric ozone discussed above. We first give a general overview based on prior studies of the expected ozone recovery impacts of changing CH₄, N₂O and the combined GHGs. We then discuss the individual ozone recovery impacts of N₂O, CH₄, and GHGs based on this work. The derived impacts are compared to the REF-C2 recovery dates. We will not attempt here to diagnose the reason why
models vary in the derived impacts; these details are beyond the scope of this study and will be addressed in future work.

Many studies have investigated the impacts of CH₄, N₂O, and CO₂ evolution on ozone abundance and recovery (e.g., Haigh & Pyle, 1979; Le Texier et al., 1988; Rosenfield et al., 2002; Randeniya et al., 2002; Royer et al., 2002; Chipperfield and Feng, 2003; Portmann and Solomon, 2007; Shepherd et al., 2008; Ravishankara et al., 2009; Oman et al., 2010; Fleming et al., 2011; Revell et al. 2012, 2015, 2016; Kirner et al., 2015; Butler et al., 2016; Keeble et al., 2017). In summary, increases in CH₄ and N₂O will generate higher amounts of hydrogen oxides (HOₓ) and nitrogen oxides (NOₓ), respectively. It is well known that increased NOₓ will enhance catalytic stratospheric ozone loss (Crutzen, 1970). Therefore, one would expect the ozone return date to be extended for temporal increases in N₂O, or shortened for decreases in N₂O. Nonetheless, the effect of future increases of N₂O varies with altitude and also depends on the temporal evolution of other GHGs (Wang et al., 2014; Revell et al., 2015). For changes in CH₄ the situation is more complicated. In a similar manner to NOₓ, increased HOₓ will decrease upper stratospheric ozone. However, CH₄ can also affect the partitioning of reactive chlorine through the reaction of CH₄ + Cl → HCl + CH₃, with more CH₄ leading to an increase in stratospheric ozone via a decrease in the abundance of reactive chlorine. Overall, temporal increases in CH₄ lead to increases in stratospheric column ozone (Revell et al., 2012). In the troposphere, increases in CH₄ will enhance chemical production through NOₓ-HOₓ-smog process (Haagen-Smit et al., 1950). This tropospheric ozone net production and subsequent tropospheric partial column change is shown for the REF-C2 simulations in Figure 9. It should be noted that UMSLIMCAT shows a small tropospheric trend since the ozone is prescribed in the troposphere. UMUKCA-UCAM has only simplified tropospheric chemistry, whereas NIWA-UKCA has a representation of C2-C3-isoprene oxidation. In addition, the tropospheric trend is affected by the coupling to the stratosphere via changes in stratophosph-to-troposphere exchange and photolytic feedbacks. Although CO₂ is chemically inert below about 60 km, increases in its abundance (along with CH₄ and N₂O) will cool the stratosphere (Haigh & Pyle, 1979). This cooling will slow down the catalytic ozone destruction cycles and increase ozone, therefore temporal increases in CO₂, CH₄, and N₂O will shorten the ozone return date due to this process, which is most important in the upper stratosphere and mesosphere. The warming of the troposphere and the cooling of the stratosphere can also affect the Brewer-Dobson circulation and therefore impact ozone through transport (e.g., Polvani et al., 2017a,b and references therein). The cooling process operates throughout the stratosphere, but is most important for dynamical processes in the lower to middle stratosphere. Outside of the tropics, a speed-up of the Brewer-Dobson circulation would shorten the ozone recovery date, while a slow-down of the BD circulation would extend it.

All of the above-mentioned chemical, radiative, and dynamical impacts are represented within the REF-C2 simulations (using RCP 6.0 GHGs for the future period). Here we examine the sensitivity scenarios for N₂O and CH₄ individually, along with the combined GHGs scenario impacts relative to the REF-C2 scenario. It should be noted that for the two CH₄ and one N₂O sensitivity scenarios, there is only one realisation available for each model, whereas for many models the REF-C2 scenario has multiple ensemble members (Table 2). The SEN-C2 temporal abundances compared to REF-C2 are shown for N₂O, CH₄, and CO₂ in Figure S13. For N₂O (SEN-C2-fN2O), the abundance is approximately 290 ppbv and 405 ppbv for 1960 and 2100, respectively, an increase of 115 ppbv (~40%). For CH₄ (SEN-C2-fCH4) the abundance is 1.24 ppmv in 1960 and a maximum of 1.96 ppmv in the 2070s, an increase of 57%. The SEN-C2-RCP85 scenario increases CH₄ over that given by the REF-C2 scenario by 2.1 ppmv in 2100, an increase of 128%. The CO₂ change in REF-C2 from 1960 to 2100 is 352 ppmv, approximately a 110% increase.
Figure 13 shows the evolution of October mean SCO in the Antarctic region for the REF-C2, SEN-C2-fN2O (fixed N₂O at 1960 conditions), SEN-C2-fCH₄ (fixed CH₄ at 1960 conditions), and SEN-C2-CH₄RCP85 (RCP8.5 CH₄ abundance) scenarios. The SCO observations are again based on the BSVertOzone data set (Bodeker et al., 2013). The panels show results from eight different models. Solid lines show 10-year smoothed SCO for a given simulation. Shading indicates the 1-σ standard derivation from an ensemble of realisations (or 3-box smoothed line if only one realisation is available). In addition, the SEN-C2-fODS (fixed ozone-depleting substances in 1960) is shown. This scenario shows the behaviour of SCO without the evolution of halogens (i.e., no ozone depletion and recovery due to halogens). This scenario does include the previously discussed impacts of N₂O, CH₄, and CO₂ on SCO. However, since there is no ozone depletion period from ODSs in this simulation, it does not make sense to calculate an ozone recovery date. The red lines in all panels show the evolution of SCO for the REF-C2 scenario, which can be directly compared to the BSVertOzone dataset. For each model, the REF-C2 simulations have been bias corrected to the BSVertOzone dataset for the 1980-1984 period. The SEN-C2 simulations are then adjusted to the bias corrected REF-C2 ensemble mean for the 1960 period. Comparison of the SCO for the REF-C2 simulations show that models generally compare well to BSVertOzone for the depletion period, although CMAM and UMSLIMCAT appear to be biased low. In summary, when one examines the relative impact on the ozone return date across the eight models from the four SEN-C2 scenarios, there is no consistent pattern. Therefore, the result suggests that the Antarctic region is not sensitive to the perturbations presented in this work.

This is not the case when one examines the annual average SH mid-latitude region (Figure 14). Generally, across the models the ozone return date varies as follows. The SEN-C2-fN2O (light blue line) simulations return before the REF-C2 simulations. This is consistent with our understanding that less NOₓ produced from a fixed 1960 N₂O abundance will allow the SCO to recover earlier than the increasing NOₓ in a REF-C2 scenario. However, it should be noted that there can be a smaller impact of N₂O on the return date due to cancellation of the upper and lower stratospheric response of N₂O on ozone (Morgenstern et al., 2018). The SCO from the SEN-C2-CH₄RCP85 simulations (dark blue line), for the four models which performed this run, also tends to have a recovery date that is earlier than the REF-C2 simulations. Again, with more CH₄ specified in the 21st century, ozone will recover faster due to the sequestrering of reactive chlorine into HCl and the stratospheric cooling effect of slowing down ozone loss rates. The impact of increased HOₓ production from increased CH₄, causing more ozone depletion to extend the recovery, does not dominate over these two processes. In contrast, the SEN-C2-fCH₄ simulation (purple line), has less CH₄ in the 21st century than the REF-C2 simulation and therefore has later return date. Finally, the SEN-C2-fGHG simulation generally has the latest ozone return date. The corresponding time evolution results for the SEN-C2 scenarios for the Arctic (March), annual average NH mid-latitude region, and annual average near-global (60°S-60°N) are shown in Figures S14, S15, and S16, respectively.

The SCO return dates for the simulations based on the four sensitivity scenarios are also summarised and compared to the REF-C2 scenario in Figure 12 (see above) and Table 4. The individual model details regarding the SCO return date (similar in format to Figure 8) between the SEN-C2 simulations and the REF-C2 simulations are shown in Figures S17-S20. We first discuss the change in SCO return dates between the SEN-C2-fGHG and REF-C2 simulations. The Antarctic (October) region difference between the two scenarios is small, within 2 years. The uncertainty range for both scenarios are approximately ±12 years. The SH mid-latitudes region shows that the MMM1S SCO recovery date is extended in the SEN-C2-fGHG case by ~16 years relative to the REF-C2 case. This extended SCO recovery period is even larger in the
NH mid-latitudes and Arctic (March) by ~25 years. This is consistent with the GHG cooling impact on ozone loss rates and a lack of strengthening of the BD circulation. In this comparison, having 1960 abundances of GHGs compared to the REF-C2 evolution means less cooling of the stratosphere and therefore an extension of the SCO recovery date. In addition, the CH$_4$ abundance is less in SEN-C2-fGHG which also decreases sequestering of reactive chlorine into HCl and acts to extend the SCO recovery date. Both of these factors override the direct impact of less production of NO$_x$ and HO$_x$ from N$_2$O and CH$_4$ which would shorten the SCO recovery. Interestingly the near-global (annual) average SCO return date is not that different between the two scenarios. This is most likely due to the fact that when the BD circulation strengthens, tropical ozone is reduced and extratropical ozone is increased. Therefore, the net impact on the stratospheric column ozone return date cancels out for this process in the global average. Figure 12 and Table 4 shows the comparison of the SCO return dates for the SEN-C2-fN2O and the REF-C2 simulations. In this comparison, one would expect that SEN-C2-fN2O with 1960 abundances of N$_2$O would bring forward the SCO recovery date. This is certainly true for the near-global (annual) average comparison, where the MMM1S SEN-C2-fN2O SCO recovery date is shortened by ~20 years relative to the REF-C2 case. This is mostly due to a shortening of the return date in the tropics; at mid-high latitudes there is little change. As noted above, the future rise in N$_2$O can lead to significant increases in lower stratospheric ozone, particularly for regions where the loss rate of ozone due to halogens exceeds that due to NO$_x$ prior to the perturbation of N$_2$O. The effect of N$_2$O on ozone varies as a function of latitude and altitude (Wang et al., 2014), complicating the sensitivity to the ozone return date to variations in N$_2$O (Morgenstern et al., 2018). Figure 12 and Table 4 also shows the comparison of the SCO return dates for the SEN-C2-fCH4 simulations. Here all regions except the Antarctic (and the tropics, for which the return date is undefined) show an extension of the SCO return date. This is consistent with the discussion above for the fixed GHG scenario. The near-global (annual) average SCO return date is extended by ~5 years. For the SEN-C2-CH4RCP85 scenario the MMM1S near-global (annual) average SCO return date is reduced relative to the REF-C2 scenario by ~15 years. As expected, this is an opposite effect to that derived from the SEN-C2-fCH4 scenario. In the other regions for SEN-C2-CH4RCP85 MMM1S there is less separation between the REF-C2 reference and the CH$_4$ perturbation scenario. Unfortunately for this work, there was only one realisation from each modelling group for the SEN-C2-fN2O, SEN-C2-fCH4, and SEN-C2-CH4RCP85 scenarios. Therefore, the signal from the perturbation on the SCO return date may be affected by the internal variability of each CCM. For future assessments of single forcing or combined effects of CO$_2$, CH$_4$, and N$_2$O on SCO the return date, a recommendation based on this work is to have at least three ensemble members per scenario type.

5) Summary and Conclusions

We have analysed simulations performed for the Chemistry-Climate Modelling Initiative (CCMI) to estimate the return dates of the stratospheric ozone layer from depletion caused by anthropogenic stratospheric chlorine and bromine. CCMI represents an extensive multi-model exercise to study the future evolution of the ozone layer under changing climate conditions. Here we consider a total of 155 simulations from 20 models, including a range of sensitivity studies. For the control simulations (unconstrained by nudging towards analysed meteorology) there is a large spread in the predictions of the absolute ozone column. Therefore, the model results need to be adjusted for biases against historical data. Also, the interannual variability in the model results need to be smoothed in order to provide a reasonable and useful estimate of the range of ozone return dates.
The total column ozone return dates calculated here differ from those presented in the previous WMO/UNEP assessment (WMO, 2014). The differences could be explained by the choice of GHG scenario for the baseline estimate (A1b in WMO (2014) versus RCP 6.0 here), and some model updates including realistic tropospheric chemistry. In addition, the time series for surface ODSs used here results in a return of stratospheric halogen loading to the 1980 value that is about 5 years later than assumed for the CCM runs examined in WMO (2014). The CCMI models project that global total column ozone will return to 1980 values in 2049 (with a 1-σ uncertainty of 2043-2055). At mid-latitudes, Southern Hemisphere ozone is projected to return to 1980 values in 2045 (2039-2050), and Northern Hemisphere ozone in 2032 (2020-2044). In the polar regions, the return dates are 2060 (2055-2066) in the Antarctic in October and 2034 (2025-2043) in the Arctic in March. The earlier return dates in the NH reflect larger impact of dynamics on ozone in this hemisphere. In the tropics only around half the models predict a return to 1980 values, at around 2040, while the other half do not show a return to 1980 values (giving the mean of 2058). All models show a negative trend in tropical total column ozone towards the end of the 21st century.

An important result from the simulations presented here is the strong regional differences in the future evolution of total column ozone due to the effects of climate change. These climate effects are least evident in the Antarctic spring where future ozone depends largely on halogen loading. In contrast, in the NH the models predict a super-recovery while in the tropics the models predict a possible further decrease in column ozone, possibly without any return to 1980 values.

There is different behaviour in the partial column ozone between the lower and upper stratosphere. In the lower stratosphere, where ozone is long-lived and affected by dynamics, there are differences in the timescale for recovery between the polar regions and mid-latitudes. Moreover, in the tropics, increased upwelling prevents the return of PCO in many models. In contrast in the upper stratosphere the predicted behaviour is similar in all regions. Ozone returns to values larger than in 1980 by 2040 and carries on increasing due to the effect of stratospheric cooling. For the upper stratosphere, the CCM predictions do not vary a lot and are in good agreement with past observations, indicating that relevant processes are represented adequately in the models. For the lower stratosphere, some obvious differences are seen between the CCM results, indicating possible inadequate descriptions of dynamical (transport) and chemical (heterogeneous) processes due to temperature biases (in the polar regions and tropics) in the CCMs.

The CCMI models generally agree in their simulation of the time evolution of stratospheric inorganic chlorine (Cly), which is the main driver of ozone loss and recovery, although there is some inter-model variability. The situation is similar for the simulation of inorganic bromine but with a larger relative spread between the models due to varying treatments of short-lived species and a model without a representation of halons. However, there do appear to be issues with the chemistry and/or transport in a few of the model simulations. Throughout the stratosphere the spread of ozone return dates to 1980 values between models tends to correlate with the spread of the return of Cly to 1980 values. In the upper stratosphere, greenhouse gas-induced cooling speeds up the return by about 10-20 years. In the lower stratosphere, and for the column, there is a more direct link in the timing of the return dates, especially for the large Antarctic depletion. Comparisons of total column ozone between the models is affected by different predictions of the evolution of tropospheric ozone within the same scenario, presumably due to differing treatment of tropospheric chemistry. Therefore, for some scenarios clear conclusions can only be drawn for stratospheric ozone columns.
As noted by previous studies, the timing of ozone recovery is affected by the evolution of N₂O and CH₄. However, the effect in the simulations analysed here is small and at the limit of detectability from the small number of realisations available for these experiments compared to internal model variability. The sensitivity scenarios examined in this study did show that a future decline of N₂O below an RCP6.0 projection (i.e., back to 1960 abundances) could reduce the global SCO return date by up to 15 years. In the opposite sense, an increase of CH₄ above the RCP6.0 projection (i.e., using RCP8.5 abundances) could again reduce the global SCO return date by up to 15 years. Both the N₂O and CH₄ global column ozone sensitivities are mainly realised through chemical impacts in the tropics.

Overall, our estimates of ozone return dates are uncertain due to both uncertainties in future scenarios, in particular of GHGs, and uncertainties in models. The scenario uncertainty is small in the short term but increases with time, and is large by the end of the century. For the models, while it is possible that they all may be missing important but unknown processes, there are still some model-model differences related to known first-order processes which affect ozone recovery. Work needs to continue to ensure that models used for assessment purposes accurately represent stratospheric chemistry and the prescribed scenarios of ozone-depleting substances, and only those models are used to calculate return dates. Nevertheless, the agreement between the results presented here and previously published work gives some confidence that we can model the future evolution of the ozone layer. For future assessments of single forcing or combined effects of CO₂, CH₄, and N₂O on the stratospheric column ozone return dates, this work suggests that is more important to have multi-member (at least 3) ensembles for each scenario from each established participating model, rather than a large number of individual models.

Table 3. Total column ozone (TCO) return dates to 1980 baseline from REF-C2 simulations using different averaging methods. Values in brackets indicate recovery dates based on either 1-σ standard deviation or 10th and 90th percentile estimates. The number 2100 in italics indicates that the estimated ozone uncertainty range has not returned to the 1980 values within the time range of the model simulation. The MMM for RCP 6.0 derived from the CMIP5 models (Eyring et al., 2013b) is shown in column two.

**Figures**

Figure 1. (a) Total column ozone time series (DU) for Antarctic in October from 19 individual CCMs for the REF-C2 simulations along with observations from the Solar Backscatter Ultraviolet (SBUV) merged ozone dataset (MOD) (Frith et al., 2017). The MMM, median (MedM) and MMM1S are shown with thick green, blue and red lines, respectively. The light blue shaded region indicates the 10th and 90th percentile range. Light green and red regions show 1-σ variability w.r.t. MMM and MMM1S lines, respectively. (b) Same as panel (a) but adjusted total ozone time series w.r.t. mean 1980-1984 observations and after application of 10-point boxcar smoothing. The dashed black line indicates 1980 reference value.
Figure 2. MMM1S total column ozone time series (DU) from REF-C1 (blue), REF-C1SD (dark cyan) and REF-C2 (red) simulations for the (left) SH polar (October) and (right) NH polar (March) regions. The dashed black lines show the 1980 reference value for each latitude band. The shaded regions show 1-σ variability w.r.t. the MMM1S lines of the same colour. The top row shows the unadjusted modelled values and the bottom row shows the time series adjusted w.r.t. mean 1980-1984 observations and after application of a 10-point boxcar smoothing. Also shown are the merged SBUV observations.
Figure 3. MMM1S total column ozone time series (DU) from REF-C2 (red), SEN-C2-fGHG (dark green), and SEN-C2-fODS (brown) simulations for five latitudinal bands and the near-global (60°S-60°N) mean (see main text). The dashed black lines show the 1980 reference value for each latitude band. Also shown are the merged SBUV observations.
Figure 4. Estimated MMM1S return dates (red triangles) from the REF-C2 simulations for (left) total column ozone (TCO) and (right) stratospheric column ozone (SCO) for different latitude bands. The estimated 1-σ uncertainties are shown with vertical black lines. Estimates for individual models are shown with coloured dots. Some individual models do not predict a return of column ozone in the tropics and so this uncertainty is indicated by a dashed line.
Figure 5. Evolution of partial column ozone (DU) for the lower stratosphere (tropopause - 10 hPa) from the REF-C2 simulations from 14 individual models, along with the MMM1S. Also shown are estimates of the partial column from the Bodeker Scientific Vertical Ozone (BSVertOzone) database, which is based on a compilation of satellite, balloon and ground-based measurements (Bodeker et al., 2013).
Figure 6. As Figure 5 but for the upper stratosphere (≥ 10 hPa).
Figure 7. Evolution of (left) inorganic chlorine (Cl\textsubscript{y}, ppb) and (right) total (organic + inorganic) chlorine from the REF-C2 simulations for 17 individual models and the MMM1S over the Antarctic in October at (top) 5 hPa and (bottom) 50 hPa. The dashed black lines show the 1980 reference value. Also shown in the left panels are observed October mean values of the sum of HCl and ClO from version 4 of the Microwave Limb Sounder (MLS) data (Waters et al., 2006; Livesey et al., 2017) from 2005 to 2017 (black dots) and the mean value over that period (red square). Note that not all models are plotted in the right-hand panels.
Figure 8. Correlation plots of ozone return dates against Cly return dates for (left) the Antarctic and (right) the Arctic from REF-C2 simulations for individual models and the MMM1S at (top) 5 hPa, (middle) 50 hPa and (bottom) stratospheric column (SCO). The red triangle is the multi-model mean. The dashed blue line is the 1:1 line between Cly and ozone return dates. The model symbols are the same as those used in Figure 4.
Figure 9. Evolution of tropospheric partial column ozone (DU) (surface - tropopause) from 14 individual models and the MMM1S for the REF-C2 simulations. Also shown is the tropospheric partial column ozone derived from BSVertOzone data.
Figure 10. Evolution of tropospheric partial column ozone (DU) (surface-tropopause) MMM1S for REF-C2 and the RCP scenarios SEN-C2-RCP45 and SEN-C2-RCP85. Also shown is the tropospheric partial column ozone derived from BSVertOzone data.
Figure 11. As Figure 10 but for stratospheric column ozone (SCO).
Figure 12. Estimated MMM1S return dates (red triangles) from stratospheric column ozone time series for (top) SEN-C2-fGHG, SEN-C2-fN2O and SEN-C2-fCH4 and (bottom) SEN-C2-CH4RCP85, SEN-C2-RCP45 and SEN-C2-RCP85. Estimated uncertainties are shown with vertical black lines. Grey triangles indicate SCO return dates from REF-C2 (Figure 4). Estimates for individual models are shown with coloured dots. Points with return dates (and uncertainties) that are greater than year 2100 are not shown.
Figure 13. Evolution of Antarctic October mean stratospheric column ozone (DU) from 8 selected models for the REF-C2, SEN-C2-fCH4, SEN-C2-fN2O, SEN-C2-fODS, SEN-C2-fGHG and SEN-C2-CH4RCP85 simulations. Each panel gives the name of the model shown. The solid lines are the 10-year smoothed SCO for a given simulation. The shading on the lines shows either the standard deviation from an ensemble of realisations from that model, or the deviation from a 3-box smoothed line if only 1 realisation is available. Note that not all models have performed all simulations. Also shown in each panel is the SCO derived from BSVertOzone data (filled black circles).
Figure 14. As Figure 13 but for SH mid-latitude annual mean.
Response to Reviewers’ comments “Estimates of Ozone Return Dates from Chemistry-Climate Model Initiative Simulations” by Sandip Dhomse et al.

We thank the reviewers very much for their comments. These are repeated below in italics, followed by our responses after the ‘>>’.

Anonymous Referee #1

This work presents a detailed analysis of the ozone return dates from Chemistry-Climate Model Initiative (CCMI) simulations. The authors concluded that there exist strong regional differences in the future trend of total column ozone and its return date. The paper is well written and the results obtained in this study are useful for the research community. I would recommend publication with minor revision. The specific comments are listed below.

Page 6, L15: Is a 10-point boxcar smoothing necessary? And whether this smoothing has an impact on the estimates of the return dates?

>> We perform the smoothing to remove interannual variability – our aim is to determine a robust estimate of the return date which reflects the average behaviour of the atmosphere rather than on short-term dynamical variability. This point is now made in new text in the Introduction on what we are aiming for with a return date.

Page 7, L27: I cannot see the shading in Fig.1. If have, the shaded region is hardly detectable.

>> The shading is there in the original figure but is very pale. It is within about 25 DU of the MMM line. Unfortunately it almost completely disappears in the ACPD pdf conversion. We will aim to improve this in the final figures.

Page 7, L33: ‘of the adjusted models’ is misleading. It should be adjusted time series.

>> OK. We have changed this to ‘forecasts provided by the adjusted models’.

Page 8, L2: This conclusion may be right for zonal mean TCO, but sea-ice loss may affect zonally asymmetric TCO trends (Zhang et al., 2018). The authors should give some comments about why there is significant difference between REC-C1 and REFC1SD during the 1990s in the Arctic for the adjusted time series (Fig.2d), which is not seen in the unadjusted series (Fig.2b). Zhang, J., Stratospheric ozone loss over the Eurasian continent induced by the polar vortex shift, 2018, Nature Communications, 9(1):206

>> OK. We have added a reference to the Zhang et al. paper. The Arctic REF-C1 v REF-C1SD difference in the 1990s is likely related to the series of cold Arctic winters in this period which resulted in large column ozone loss. The mean of the free-running REF-C1 simulations do not capture this. We have added some text on this.

Page 8, Line 5: The Antarctic and global ozone recovery rate before 2047 in REF-C2 is nearly the same as that in SEN-C2-fGHG (Fig.3). But this feature is not seen for the other four latitudes. It is understandable that GHG has a little impact on Antarctic ozone; however, it is
strange that GHG doesn’t affect global mean ozone significantly before 2050. Does the tropical ozone loss cancel the extratropical ozone recovery?

>> Please note that the polar regions are not included in the ‘near global’ mean plotted in Figure 3. In terms of the other regions, yes there is some cancellation of mid-latitudes (fGHG later) and the tropics (fGHG earlier). Please also note that the stratospheric column values are given in Table 4 and this shows similar behaviour, indicating that it is a stratospheric effect.

Page 8, L20-22: Since the decline of the tropical ozone column is mainly due to transport, there should be a corresponding increase in the mid-high latitude TCO. Is it justified that the decline of the global TCO after about 2080 is mostly due to the decline of the tropical TCO?

>> The reviewer raises an important point (see also his/her comment below on SCO). Again, please note that the ‘global’ referred to near-global, i.e. excluding the polar regions where ozone continues to increase through 2100. Figure 9 shows the partial tropospheric ozone column. This does also show a decrease after 2080, by around 2-3 DU at low-mid latitudes, which is similar to the TCO decline. Moreover, the tropospheric decrease is larger in the NH than the SH, similar to the TCO. Therefore, we have clarified the text on this point (and on the SCO below).

Page 8, L35-40: It is interesting that the return dates in this study are all later than those detected from CCMval-1,2 and CMIP5 simulations. Do authors have any comments on this result? Is it resulted from the methodology used in this work?

>> We have added a more detailed discussion on this. Factors include the update WMO halocarbon scenario and different climate forcings.

Page 9 L10: The authors should provide more information of the vertical pressure of BSVertOzone. Did you interpolate the observed ozone profile onto the vertical pressure of CCMs and integrate the modeled and observed partial ozone column using the data at the same pressure levels?

>> We have added detail to the paper: “BSVertOzone spans 70 pressure levels that are approximately 1km apart (878.4hPa to 0.046hPa). For the calculation of the partial columns, ozone was interpolated to the exact boundaries of the partial columns from the two closest BSVertOzone pressure levels, and then ozone was integrated between the determined levels. The boundaries for the partial columns were defined as follows: tropospheric column (surface-tropopause), lower stratospheric column (tropopause - 10hPa), upper stratospheric column (10hPa and above; for BSVertOzone this means up to 0.046hPa). The tropopause pressure was defined as 100hPa in the tropics (20S-20N), 150hPa in the mid-latitudes (20-60N/S), and 200hPa in the polar regions (60-90N/S). CCM partial columns were integrated between the same partial column boundaries, but directly from the CCM pressure levels. No additional interpolation of CCM ozone profiles or BSVertOzone profiles was performed.”

Page 9, L13-14: This sentence is hard to understand. Please rephrase.

>> We have rewritten this.

Page 9 L36-38 The sentence is fragile. Please rephrase.

>> We have rephrased this.
Page 9, L46: is»>its

>> Corrected.

5 Page 10 L12 notably to climate »>notably by climate change.

>> We have modified the text, and split into two sentences.

>> OK. We have added a new sentence with citation to Wang et al and Revell et al, after the citation to an early Crutzen paper.

Page 12, L20-L39: I suggested that the author could move the discussion regarding GHG to the Section 4.4.

>> We understand the suggestion, but have decided to leave the text in place, because Section 4.4 focuses on the effect of climate change on ozone for a single GHG scenario, whereas Section 4.5 explores the sensitivity of future O₃ to how CH₄ and N₂O evolve.

Page 12, L45: Do you mean the red line and black dots for the three models in Fig.13? I don’t think they are accurate, but the GEOSCCM and SOCOL simulations are better.

>> Apologies. The text was not clear or accurate (and was left over from a previous version of the figure). In fact, many models perform well. The text has been updated.

Page 13 L28,32: SOC»SCO

>> Corrected.

Page 13, L36-39: The authors argued (P8, L20-22) that a decrease in tropical ozone column contributes a decline in the global TCO after 2080. Here, the authors suggested that the dynamical transport process has no significant impact on the return date of global TCO. Which argument is correct?

>> P8 referred to total column ozone (TCO). This page discusses the stratosphere only (SCO), the difference being the tropospheric column (see Figure 9). We have clarified the earlier TCO discussion to mention the tropospheric contribution.

Page 14 L25: but->by

>> Corrected.

Anonymous Referee #2
This paper details ozone return dates from the CCMI model intercomparison. As such, the new estimates of the return dates are the primary new finding of the paper and most of the other results discussed are previously known results. The paper is clearly written and outlining the latest results on ozone return dates is an important task for the upcoming ozone assessment. I have a number of comments but most are relatively minor and thus I recommend publishing the paper after the comments are adequately addressed.

As stated above most of the results outside of the specific details that are derived from the models simulations were already known. It would be good if you could highlight the new results from this paper in the abstract and conclusion and state more clearly the results that support earlier work.

>> We appreciate the comment but this is not a general point that was raised by the other reviewers. While dealing with the other review comments we have rewritten the abstract and conclusions to add content and clarify some points. However, based on the other review comments, we think that the overall main results of the paper are clear. The paper does present up-to-date, state-of-the-art estimates of return dates in support of the WMO/UNEP Ozone Assessment and also (especially with the revisions) discusses the uncertainties in the concept and numerical value of return dates.

It is important to state more prominently that since the models all use mixing ratio boundary conditions an important source of uncertainty has not been included. Thus, the uncertainty given are likely underestimated.

>> This is stated in the Introduction, which now includes the following sentence: “This shortening of the ozone recovery was also found by Morgenstern et al. (2018) for the models represented in this study, although it is important to note that the use of surface mixing ratios in studies largely removes the feedback between circulation changes and ODS return dates.”

The resolution of the figures is poor, making them hard to read. This should be fixed in the final versions.

>> Yes, it will be. The figures appeared fine in our submitted pdf but the conversion to the ACP pdf (adding the journal information on each page) seemed to degrade the figures.

Page 2, lines 16-18: Are your later return dates within the uncertainly estimates given in the 2014 Ozone Assessment? This would be interesting to add.

>> The uncertainty range from our and previous studies (e.g. WMO (2014)) are given in Table 3. It is difficult to compare uncertainty ranges concisely in the abstract so we have added some text indicating that the previous (WMO (2014)) best estimates are often outside the uncertainty ranges that we quote.

Page 2, line 38: Change “also changes ozone return” to “also increases the ozone return” so the reader knows the direction of the change.

>> OK. We have changed the word to ‘lengthens’.

Page 3, line 5: I think you mean tropospheric chlorine and bromine peaked in 1993 and 1997, although I’ll leave it to you to double check.
> Yes, corrected, thank you.

Page 3, line 16: The statement “therefore requires” is unjustified from what comes before. I’m not saying it is does not “require” 3D models, but just that you have not presented evidence that would support the claim.

> OK. We have added some words about the possible changes to polar vortex dynamics to the end of the previous paragraph to better motivate the need for 3-D models (as opposed to just 2-D).

Page 3, lines 47 to end of paragraph: The “faster removal of ODSs” is largely uncaptured by the models here since they have fixed mixing ratio BCs. I say “largely uncaptured” since while the ODS loss term in the stratosphere is affected, it does not affect the surface mixing ratio as it should. This needs to be made clearer since this discussion is likely to mislead the uninformed reader.

> OK, we have added some text to note this.

Related to this effect it would be useful to have a figure of the CFC-11 lifetime (or some other long lived tracer) as a function of time from all the models.

> Unfortunately the information needed for this comparison was not saved by the CCMI models. However, as the reviewer points out, the use of vmr boundary conditions constrains the models to more similar chlorine distributions more than would be the case for differing lifetimes. The SPARC lifetime assessment did compile this information from a subset of models used here. The comparison of Cly shown in this paper does depend on the modelled halocarbon lifetimes.

Page 7, line 17: Using the period 1980-1984 is a bit unfortunate since there is significant ozone loss during this period, especially in the Antarctic region. Depending on how you have done the calculation this will bias your return dates to earlier values. Since you have model data starting much earlier I would suggest using 1978-1982 instead, or at least discussing the sensitivity of your results are to this choice. I suspect you made this choice due the availability of SBUV data but it should be possible to derive an adjustment for the data for your figures.

> We don’t think that this will bias the return dates. The mean value for the period 1980-84 is used to estimate the adjustment, but the adjusted model values still vary during this period. Also, 1980 is the specific year chosen for the reference date. The fact that ozone loss may occur more strongly later in this period should not matter. In any case, satellite observations are not available for 1978.

Page 7, line 28: I don’t see any shading. Is this in reference to figure 1?

> Yes. The shading is very pale and was affected by the conversion to the ACPD pdf. This will be made clearer in the final figure versions.

Page 9, lines 10-35: It is curious that nearly all of the model simulations are below the data. Any idea why? Seems worthy of mention and speculation.

> We have updated the BSVertOzone dataset, which was revised before the submission of Hassler et al. (2018). The lower stratospheric comparisons are improved. We have added some
sentences to point out the remaining upper stratospheric difference and to say that we do not think differences in this region will greatly affect column ozone return dates.

Page 10, lines 1-9: The variation shown on figure 7 at 5 hPa is worrisome, a fact that should be highlighted in the paper. At 5 hPa most of the organic chlorine should be liberated (as can be seen by the similarity of the left and right panels) and thus both the plots should be close to the surface values with a 2-4 year lag to account for the age of air. The peak should be close to the peak in total chlorine in the surface concentrations and the values during the falloff should be very close to the surface values (since a 2-4 year shift is a small change). Thus, the models that are outliers on this plot are evidently not conserving chlorine and their results throughout the paper should be in question. This needs to be stated.

>> The models do show a variation in Cly at 5 hPa, but it is not possible from this plot alone to conclude that they do not conserve mass. The differences could be due to incorrect scenarios of the long-lived halocarbons or differences in the treatment of short-lived sources. Nevertheless, we agree that we should not be seeing models with chlorine a lot different to the prescribed scenarios. We have added the sentences: “Moreover, in the upper…..of around 2-4 years”.

Page 10, line 40: Title should probably be “Sensitivity of ozone return to GHG concentrations and climate change”

>> Section 4.5 deals with the impact of the GHGs CH4 and N2O. Section 4.4 is about the effect of climate in general and therefore to distinguish it from 4.5 we would like to keep the title as it is.

Page 10, line 47: The tropospheric impact of CH4 has been pointed out in many papers before Morgenstern et al. 2018, so why chose this reference.

>> We have added additional references to the earlier papers of Shindell et al (2009) and Eyring et al (2013b).

Page 11, line 4-6: Actually, the effect of GHG is as comparable in the Antarctic to the other regions. It is just harder to see because the scale of the chlorine depletion is so much larger. From you graph, I estimate a 20, 30, 5, and 8 DU change between RCP45 and RCP85 scenarios at 2100 in the 1st four panels. Thus, the Antarctic appears to be second largest instead of “small”. This makes sense since the effect of the GHG is primarily above the ozone hole and thus should be similar. The main complication to this is the increased importance of Cl+CH4 in the ozone hole.

>> We agree that the absolute variation is similar (or larger) in the Antarctic (Oct) relative to the other regions/periods but we wish to compare the relative variations. We have modified text to include: “The relative change is smaller in the Antarctic, where recovery is largely determined by Cly loading, but larger in all other regions. However, the absolute changes between, for example, the Antarctic (October) and Arctic (March) are similar”.

Page 11, lines 14-17: You state what is on figure 12 but say nothing of what it tells the reader. Either discuss or remove.

>> We understand the reviewer’s point for the first mention of Figure 12. Figure 12 (along with Table 4) is meant to be a summary figure of the discussion surrounding "Figure 11". We have added additional information on how this figure relates to the MMM1S return date for SEN-C2-
RCP45 and SEN-C2-RCP85 relative to REF-C2 (Figure 4). This figure is also discussed several times in sections 4.4 (Sensitivity of ozone return to climate change) and 4.5 (Sensitivity of ozone return to methane and nitrous oxide).

Page 12, line 3: Change “chemically inert” to “chemically inert in the troposphere and stratosphere” since CO2 is broken down in the mesosphere and above.

>> OK, we have added ‘below about 60km’.

Page 12, line 10-11: Change “most important” to “most important for dynamical changes” or something similar.

>> OK, we have added ‘for dynamical processes’.

Page 12, line 48-49: As above I disagree with this statement. It seems comparable to me looking at your plots if one adjusts to the greatly different scales. If you plotted the difference between the scenarios it would be clear.

>> The statement above was for Figure 13, not Figure 11. Here eight models were shown with identical y-axis ranges. To make the sentence clearer, we have modified the sentence to read: "In summary, when one examines the relative impact on the ozone return date across the eight models from the four SEN-C2 scenarios, there is not a consistent pattern. Therefore, the result suggests that the Antarctic region is not sensitive to the perturbations presented in this work.”

Page 13, lines 39-44: The fact that the global value for the return date is seemingly inconsistent with the different latitude regions implies that it is poorly constrained and you can conclude little to nothing about the effect of N2O changes.

>> The effect of N2O on ozone is complicated, but we can still draw conclusions. We have changed the text in question to read:

In this comparison, one would expect that SEN-C2-fN2O with 1960 abundances of N2O would bring forward the SCO recovery date. This is certainly true for the near-global (annual) average comparison, where the MMM1S SEN-C2-fN2O SCO recovery date is shortened by ~20 years relative to the REF-C2 case. This is mostly due to a shortening of the return date in the tropics; at mid-high latitudes there is little change. As mentioned above the future rise in N2O can lead to significant increases in lower-stratospheric ozone, particularly for regions where the loss rate of ozone due to halogens exceeds that due to NOx prior to the perturbation of N2O. The effect of N2O on ozone varies as a function of latitude and altitude (Wang et al., 2014), complicating the sensitivity to the ozone return date to variations in N2O (Morgenstern et al., 2018).

The new text now includes a citation to the Wang et al. (2014) paper, pointed out by reviewer #1, which had not originally been cited.

Page 14, line 39: Again, it is not the weakest but only less evident.

>> OK, we have changed to ‘least evident’.

Page 15, line 7-9: You need to point out there are still serious issues with the chemical and/or transport schemes in some models.
The points made in these final two paragraphs are important and should be made in the abstract as well.

Some of the points were already in the abstract (e.g. impact of N2O and CH4, also starting with text ‘As noted by previous studies…’, and comments on how to use models in future assessments). The points that were not mentioned relate to uncertainties in scenarios and models. We have added sentences on this to the abstract.

You should mention the shaded regions in the caption.

Add the abbreviations SCO and TCO to the caption in the correct places to help the reader who doesn’t read the paper.

The manuscript uses the latest CCMI simulations to derive new estimates of the ozone layer return dates. The study is an important update of the existing CCMVal2 evaluations and will provide valuable input for the next WMO ozone assessment. The paper is clearly written and well-structured and I recommend publication after the following comments have been addressed.

1) The authors adjust the model results to avoid biases when comparing to historical data and to reduce the spread in the predictions of the ozone column. However, this method can introduce new errors if the bias is not constant over time but process related and time dependent. The manuscript misses a discussion of possible shortcomings of this method. What do the return dates look like before the adjustment? Is the mean return date the same and only the spread is reduced or are the models on average over/underestimating the atmospheric ozone abundance?

In this context it is not clear what the difference between Figure 1a and 1b is. From the text and the captions it sounds like, the only difference is the adjustment to the 1980-1984 values, but the lines look like the models have been smoothed as well. Furthermore, it is also not clear what the impact of excluding models outside the 1 sigma uncertainty range is. Is this only reducing the uncertainty or also changing the mean values?

Figure 1 shows the impact of the adjustment on the return dates (compare panels a and b) and this is discussed in Section 4.1. The aim of the adjustment is to improve the visualisation of the different models on the same plots will not impact the return date for any single model; it is a case of just displacing the ozone curve on the y axis so the return to the 1980 value will still occur at the same time. The impact of excluding the models outside the 1-sigma uncertainty is shown by comparison of the MMM and MMM1S results (e.g. Figure 1 and Table 3). Overall there is a small impact of the return date but a decrease in the uncertainty. Yes, the reviewer is correct that there also additional smoothing between Fig 1a and Fig 1b (and Fig 2a and 2b). This is the application of the 10-point boxcar smoothing. Text had been added to clarify this.
2) The comparison of the modeled lower and upper stratospheric ozone columns with the BSVertOzone data set gives large differences for some regions (even after the bias adjustment). I miss a discussion of possible reasons for the over- and underestimation of ozone loss and possible implications for the projected return dates.

>> We have updated the BSVertOzone dataset, which was revised before the submission of Hassler et al. (2018). The lower stratospheric comparisons are improved. We have added some sentences to point out the remaining upper stratospheric difference and to say that we do not think differences in this region will greatly affect column ozone return dates.

3) In parallel with the CCMI activities, the stratospheric ozone community has undergone large efforts to provide updates of the ozone profile trends from observational data sets (e.g. Steinbrecht et al., 2017). How do the models compare to these new results? Do they agree on the upper stratosphere ozone recovery quantified for the 2000-2016 time period?

>> Results from CCMI models have been included in the LOTUS report. That report is not finalised (and so we cannot cite it yet) but there will be information in there. A separate analysis in this current paper is beyond the scope of our current work.

4) How different are the chlorine comparisons if HCl+ClO instead of Cly is used in order to have a consistent comparison between models and measurements? How does the amount of stratospheric bromine differ from model to model and how do such differences impact the return dates? Why not use the EESC instead of Cly?

>> The MLS ClO + HCl is a good surrogate for total Cly for the regions that we compare. The differences between the observed sum and true Cly will be small compared to the model-model spread that we wish to illustrate. Also, we do not have the CCMs sampled as the MLS local time for a true comparison of ClO. We now present the modelled Bry loadings in the Supplementary Material. As more models provided Cly output compared to Bry it is simpler to use Cly than EESC, and avoids the complication of selecting an alpha value for the models.

Page 8, line 41: Do you mean 2046?

>> Yes, corrected.

53
