Abstract. We present the results of birch pollen characterization using lidar measurements based on a 11-day period of birch pollination from 5 to 15 May 2016 at the European Aerosol Research Lidar Network (EARLINET) station in Vehmasmäki (Kuopio, 62°44′N, 27°33′E), Finland. The ground-based multi-wavelength Raman lidar PollyXT performed continuous measurements at this rural forest site and has been combined with a Hirst-type volumetric air sampler which measured the pollen type and concentration on roof level (4 m). The period was separated into two parts due to different atmospheric conditions and detected pollen types. During the first period, high concentrations of birch pollen were measured with a maximum two-hour average pollen concentration of 3700 grains/m³. Other pollen types represented less than 3% of the total pollen count. In observed pollen layers, the mean particle depolarization ratio at 532 nm was 10 ± 6% during the intense birch pollination period. Mean lidar ratios were found to be 45 ± 7 and 55 ± 16 sr at 355 and 532 nm, respectively. During the second period, birch pollen was still dominant but a significant contribution of spruce pollen was observed. Spruce pollen grains are highly non-spherical, leading to a larger mean depolarization ratio of 26 ± 7% of the birch-spruce pollen mixture. Furthermore, higher lidar ratios were observed during this period with a mean value of 60 ± 3 and 62 ± 10 sr at 355 and 532 nm, respectively. The presented study shows the potential of the particle depolarization ratio to track pollen grains in the atmosphere.

1 Introduction

Atmospheric pollen is a well-known health threat as it can irritate the respiratory system and cause asthmatic symptoms (Bousquet et al., 2008). The number of people suffering from pollen triggered diseases is rising (Schmidt, 2016) and the prevalence of pollen allergies is likely to further increase due to climate change as the pollination season becomes longer and the pollen production increases (Lake et al., 2018). In addition to the well-known allergenic impacts, pollen also affect the climate (IPCC, 2013; WHO, 2003). Steiner et al. (2015) suggested that fragments of pollen act as cloud condensation nuclei (CCN) and therefore influence cloud optical properties. Pollen can furthermore change ice cloud formation processes by acting as ice nuclei (IN) (von Blohn et al., 2005; Diehl et al., 2001, 2002).
Worldwide, 879 active stations continuously monitor pollen type and concentration near ground level in 2016 (Buters et al., 2018). Systematic information on the vertical distribution, however, is missing. Models are using phenological and meteorological data to forecast concentration and dispersion of pollen in the atmosphere. But observations, especially in the vertical direction, to evaluate the model results are rare or missing. Light detection and ranging (LIDAR) is an effective method to investigate the vertical distribution of aerosols, as it enables measurements with high vertical and temporal resolution under ambient conditions. Recently, the signature of pollen grains have been observed in lidar measurements (Noh et al., 2013a, 2013b; Sassen, 2008; Sicard et al., 2016). It has been revealed that non-spherical pollen generate strong laser depolarization and thus the information on particle shape can be retrieved. For example, Sassen (2008) measured a linear depolarization ratio at 694 nm up to 30% for paper birch in Alaska. In controlled laboratory experiments, Cao et al. (2010) measured the linear depolarization ratio of different pollen types and determined a linear depolarization ratio at 532 nm for paper birch of 33%. In the absence of other depolarizing particles, the particle depolarization ratio could therefore be used to track pollen grains. Information about the vertical distribution of pollen could result in an improvement of the model input parameters and serve as validation for model results.

Within our study, we want to improve and deepen the knowledge of optical properties of pollen in the atmosphere by using a multi-wavelength Raman lidar. Finland provides suitable conditions for the observation of pollen as 78% of Finland’s total area is forest land and sources of other highly depolarizing particles like dust are absent. Hence the contamination with other aerosols is considered to be small. During a four months measurement campaign in 2016, the multi-wavelength Raman lidar PollyXT (Engelmann et al., 2016) performed continuous measurements at the rural forest station in Vehmasmäki (Kuopio) which is part of the European Aerosol Research Lidar Network (EARLINET). Simultaneously, a Hirst-type volumetric air sampler was operated to obtain pollen type and concentration at roof level. Twenty-one different pollen types were detected from May to August 2016. In this study, we focus on the description of birch pollen and the mixture of birch and spruce pollen as birch is among the most allergenic pollen types and the most allergenic tree pollen in northern, central and eastern Europe (D’Amato et al., 2007).

2 Measurement site and instrumentation

Our measurement campaign took place from the beginning of May to end of August 2016 at Vehmasmäki, Finland (62°44′ N, 27°33′E, 190 m asl); a rural forest site 18 km from the city center of Kuopio, Eastern Finland. The measurement site was equipped with a multi-wavelength Raman polarization lidar PollyXT (Sect.2.1) and a Hirst type pollen sampler (Sect.2.2). With this set-up it is possible to combine vertical profiles of the aerosol properties above the site and the pollen concentration on ground. Due to the location of the site, far from major aerosol sources like dust or anthropogenic aerosol, mainly surrounded by forest, the atmosphere is relatively clean and suitable for pollen studies.
2.1 Lidar: Polly\textsuperscript{XT}

Lidar measurements were conducted with the multi-wavelength Raman polarization lidar Polly\textsuperscript{XT} (Althausen et al., 2009; Engelmann et al., 2016). Polly\textsuperscript{XT} has three emission wavelengths (355, 532 and 1064 nm) and seven detection channels. In addition to the three emitted wavelengths, the backscattered signals at the in-elastic Raman-shifted wavelengths (387, 407 and 607 nm) and the cross-polarized signal at 532 nm are detected. During nighttime, extinction and backscatter coefficient profiles at 355 and 532 nm can be determined independently using the Raman method (Ansmann et al., 1992). During daytime, the Klett-Fernald method (Fernald, 1984; Klett, 1981) is applied using the elastic signals due to the low signal-to-noise ratio at the Raman channels. The signal at the Raman-shifted wavelength (407 nm) is used to determine water vapor mixing ratio profiles during dark hours (Filioglou et al., 2017). The simultaneous measurement of the cross-polarized and total backscattered light at 532 nm enables the determination of the linear particle depolarization ratio (PDR, Freudenthaler et al. (2009)), which allows the characterization of particle shape (Sassen, 2005). The measurement of multiple wavelengths allows the retrieval of Ångström exponents (Å), which are related to the particle size. The ratio of extinction to backscatter coefficient is called lidar ratio (LR). It is considered an important criterion for particle characterization, as it depends on single scattering albedo and backscatter phase function and therefore on the size distribution and the chemical composition of the aerosol particle. The lidar ratio is therefore aerosol type dependent.

The operated lidar system has an initial spatial resolution of 30 m and a temporal resolution of 30 s. Due to the bi-axial set-up of emission and detection units, the height of complete overlap between the laser and the receiver field-of-view is reached at about 800-900 m (Engelmann et al., 2016). An overlap correction is applied on the basis of a simple technique proposed by Wandinger and Ansmann (2002). This correction allows to extend profiles down to around 500 m. Uncertainties in nighttime lidar-products are mainly determined by signal noise and the correction of Rayleigh scattering. The overall relative errors of the lidar-derived optical properties retrieved with the Raman method are in the range of 5–10\% for backscatter coefficients and depolarization ratios and 10–20\% for extinction coefficients (Ansmann et al., 1992; Baars et al., 2012). These uncertainties propagate to the retrieved Ångström exponents and lidar ratios.

Further details on the set-up, principle and error propagation of Polly\textsuperscript{XT} can be found in Althausen et al. (2009) and Engelmann et al. (2016). Near-real-time measurements and Polly\textsuperscript{XT} data can be accessed at the PollyNET website (http://polly.tropos.de/).

2.2 Pollen collector: Hirst-type volumetric air sampler

A Hirst-type volumetric air sampler located next to the lidar, 4 m above ground, monitored the pollen concentration and type. This type of spore sampler enables continuous 7-day collection of pollen grains with 2 hour time resolution. The sampling principle is based on the design described by Hirst (1952). With a flow rate of 10 l/min air is drawn into the sampling device through a 14 mm × 2 mm orifice. A large wind vane on a rotatable sampler head makes the sampler sensitive to changes in wind direction and ensures that the orifice is always oriented towards the wind. Particles impact on an
adhesive-coated plastic tape beneath the orifice. For this study, the tape, fixed on a rotating drum, was changed every seven days and the pollen grains were further analyzed under the microscope. The pollen type was determined using characteristic features of the examined pollen grains. By converting the counted spores on the sample tape surface in relation to the inlet air flow, the pollen concentration was obtained.

3 Methodology

Figure 1a shows the temporal variation of the pollen concentration, the range corrected signal at 1064 nm (Fig. 1b) and the volume depolarization ratio at 532 nm (Fig. 1c) during the period 5 – 15 May 2016. This period represents the main birch pollination season of 2016 as 83% of the annual birch pollen have been collected during this time. A large aerosol load was observed within the planetary boundary layer up to ~ 3.5 km. As shown in Fig. 1c, the volume depolarization ratio ranges between 4-10% suggesting the presence of non-spherical particles. A detailed examination of the air masses arriving during this period along with modelled dust load using the BSC-DREAM8b model (Basart et al., 2012) confirms the absence of dust in middle and northern Europe. Additionally, MODIS data were synergistically used to exclude smoke aerosol layers from biomass burning. Hence, the highly depolarizing aerosol layers were likely attributed to pollen, keeping in mind that some contamination with local anthropogenic aerosol is always possible.

Ground-level pollen concentration values presented in Fig. 1a were used to verify the strong pollination event in the beginning of May which provides 50% of the annual birch pollen concentration. The event started in the evening (17:00 UTC) of 5 May and lasted until 9 May noon (hereafter called period 1). During period 1, the two-hour average pollen concentration exceeded 1000 grains/m³ in 53% of the time. The majority of pollen type identified was birch (97%) with a very small contribution of willow (2%) and other pollen types (1%). The mean wind direction in this first period was northwest.

From 12 to 15 May (period 2), the mean pollen concentration was significantly lower. Only 8% of the time, the total pollen concentration was higher than 1000 grains/m³. In addition to birch (82%), spruce pollen (14%) and other pollen types (4%) were detected. During this period the air masses were mainly advected from southeast.

The ground-near aerosol layers are assumed to contain the highest concentration of local pollen and defined as pollen layers in this study. The gradient method was applied to determine the bottom and top layer heights of the pollen layers (Flamant et al., 1997; Bösenberg et al., 2003; Mattis et al., 2008). The local maximum in the first derivative of 1064 nm backscatter coefficient was considered to be the bottom of the layer. The local minimum was considered to be the layer top. To verify the determined layers, the layer boundaries identified by the gradient method were compared with the bottom and top heights of coherent structures in the height-time illustration of the range-corrected signal (Giannakaki et al., 2015). The layer identification was based on the assumption that the optical properties should be relatively homogeneous, which means within one layer, the variability of the optical properties should be lower than the statistical uncertainty of the individual data points. Two layers with a vertical distance less than 100 m apart from each other were combined to one layer.
All layers detected during the 11 days period are shown in Fig. 2. Black, magenta, blue and yellow bars show the first, second, third and fourth layer, respectively. Triangles mark the part of the layer which was used for calculations of the mean optical properties of the layer. The lower limit for reliable profiles during our measurement period was at around 1 km. Since the closest layer to the ground is assumed to contain the highest pollen concentration and share, we only consider the lowest layer (black) in the following analysis.

4 Results & Discussion

4.1 Case studies

We present two case studies representative for different pollen mixtures: in the first case study only birch pollen have been detected by the Hirst sampler. In the second case study, spruce pollen was detected in addition to birch. Figure 3 shows, from left to right, the particle backscatter coefficient at 355 (blue), 532 (green) and 1064 nm (red); the particle extinction coefficient at 355 (dashed blue) and 532nm (dashed green); the lidar ratio at 355 (blue) and 532 nm (green); linear particle depolarization ratio at 532 nm (light green); the Ångström exponents calculated both from the backscatter coefficient at 355-532nm (blue) and 532-1064 nm (red) and from extinction coefficients at 355-532 nm (black); and the relative humidity from lidar-derived water vapor profiles (black) and temperature profiles from radiosonde launched at 18 UTC (orange). Lidar-derived optical properties were vertically smoothed using a sliding average of 25 bins (750 m). Four-day backward trajectories ending at the height of the layers and the middle of the time period are shown as well. The first case study was selected during the intense birch pollination event (period 1). On 6 May 2016 between 23:00 and 01:00 UTC only birch pollen was detected. Using the layer definition methodology (Sect. 3), three layers were determined and the two lowest ones have been combined to one pollen layer for this analysis since their distance is less than 100 m.

Four-day HYSPLIT (Hybrid Single Particle Lagrangian Integrated Trajectory) backward trajectories (Stein et al., 2015) ending at 450 m and 1.1 km on 7 May 0:00 UTC show that the air masses are advected from western directions and have travelled over the British Isles, the North Sea and southern Sweden. The contamination with depolarizing aerosol like dust is therefore considered to be negligible, however the mixture with other anthropogenic cannot be ruled out. The presumed birch pollen layer was observed up to 1.2 km. Extinction coefficient at 355 nm is about 22 ± 2 Mm⁻¹ and 13 ± 1 Mm⁻¹ at 532 nm. The mean lidar ratio for the observed layer is 49 ± 4 sr and 70 ± 7 sr at 355 and 532 nm, respectively. Mean backscatter and extinction-related Ångström exponents at 355-532 nm are 2.1 ± 0.04 and 1.1 ± 0.5, respectively. The backscatter-related Ångström exponent between 532 and 1064 nm is 0.9 ± 0.1. The mean particle depolarization ratio at 532 nm within the layer is 14 ± 1%. Note that it can be even higher close to the ground, below the height of complete overlap. The particle depolarization decreases with increasing height, while the lidar ratio is constant. Thus the measured lidar ratio may not be a good indicator for characterizing the observed birch pollen in these cases as the contribution of pollen is assumed to decrease with increasing distance to the pollen source.
During our second case study on 15 May 2016 between 19:00 and 21:00 UTC, spruce pollen have been measured simultaneously to the birch pollen. Profiles and trajectories are shown in the lower panel of Fig.3. The pollen layer reaches up to 1.7 km.

The extinction coefficients at 355 and 532 nm are higher than in the previous case, accounting to $61 \pm 5 \text{ Mm}^{-1}$ at 355 nm and $44 \pm 6 \text{ Mm}^{-1}$ at 532 nm. The mean LR is $55 \pm 6 \text{ sr}$ at 355 nm and $51 \pm 9 \text{ sr}$ at 532 nm. The backscatter and extinction-related Ångström exponents at 355-532 nm are lower than in the first case with values of 0.5 to 0.7 and 0.1 to 1.7, respectively. The backscatter-related Ångström exponent at 532-1064 nm is 0.8 to 1.0.

The PDR at 532 nm is on average $19 \pm 2\%$ and $24\%$ at its maximum and is clearly higher than in the only-birch case (period 1). The air masses arriving in the height of the layers on 15 May 20 UTC have been advected from Russia and remained close to the ground only the last 12 hours before reaching the site. The contamination with depolarizing dust can therefore be neglected. An explanation for the higher depolarization of the backscattered light is the non-spherical shape of the spruce pollen grains which have been detected in addition to birch pollen. Figure 4 shows micrographs of birch and spruce pollen grains. Spruce pollen (right picture) possess air bladders, which allow those relatively big grains (70-100 μm) to be dispersed by wind. Birch pollen on the other hand are smaller (20-30 μm), almost spherical and possess three pores on the edge of the grain which seem to cause less depolarization. The retrieved Ångström exponents during the birch and spruce pollination event are smaller than during the first period which could also be explained by the mixture of birch pollen with the larger spruce pollen grains.

4.2 Lidar derived optical parameters

All pollen layers between 5 and 15 May have been identified and analyzed to determine the relationship between pollen type and the lidar-derived optical properties of the aerosol layer. Figure 5a shows the lidar ratio at 532 nm against the particle depolarization ratio at the same wavelength for all Raman measurements during nighttime. Measurements during the first intense birch pollination period are shown in green color, while measurements during the second period, when spruce pollen was detected simultaneous to birch pollen, are shown in black. The size of the dots represents the measured pollen concentration by the Hirst-type sampler on ground-level. The standard deviation is shown by the error bars. Lidar ratio values range from 31 to 74 sr. This wide range of lidar ratios suggest that the lidar ratio alone is not a suitable parameter for the characterization of pollen as other aerosol types also show characteristic values in this range. However, the mean particle depolarization ratio within the pollen layers during the first period is $10 \pm 6\%$, which is significantly higher than that of anthropogenic pollution. In the absence of other depolarizing aerosol, e.g. dust, pollen is therefore likely the dominant aerosol causing this depolarization. Depolarization ratios higher than 15% are only observed during the second period (12-15 May) in which spruce pollen were present. The mean lidar ratio and PDR at 532 nm during this period are $62 \pm 10 \text{ sr}$ and $21 \pm 3\%$, respectively. The significantly higher depolarization ratio is caused by the non-spherical shape of spruce pollen in those layers. In Fig. 5b, the backscatter-related Ångström exponent between 532 and 1064 nm is shown against the particle depolarization ratio at 532 nm for all measurements between 5 and 15 May, including Klett retrievals for daytime.
measurements (dotted markers). A clear tendency to smaller Ångström exponents with increasing depolarization ratios in both periods can be seen. This correlation indicates that the influence of non-spherical particles on the backscattered signal increases with decreasing Ångström exponent, i.e. bigger particles. The Ångström exponent in the second period is around 0.8, whereas it is around 1 in the first period, demonstrating the effect of the larger spruce pollen (~70-100 μm), even with a small contribution (~14%) to the total pollen count. However the effect of the background particles has to be considered. Because the background aerosol on our measurement site is supposed to be non-depolarizing, the depolarization ratio is a good indicator for pollen. The Ångström exponent on the other hand can be also related to the amount and kind of background aerosol and is therefore less representative here.

Earlier studies show that the relative humidity can affect size and shape of the pollen grains and therefore lead to different optical properties (Franchi et al., 1984; Griffiths et al., 2012; Katifori et al., 2010). When pollen grains dehydrate, the pollen wall can fold onto itself to prevent further dehydration, this phenomena is known as harmomegathy (Katifori et al., 2010). The shape of the pollen grain changes, which could lead to significantly higher depolarization of the backscattered light. At humid conditions, pollen grains swell by taking up water internally and after reaching a relative humidity over 89% external wetting of the pollen surface can occur (Griffiths et al., 2012). To check whether the ambient relative humidity affects our measurements, the Ångström exponent (532-1064 nm) and the PDR at 532 nm are presented against the relative humidity in Fig. 6. In the selected measurement period, the relative humidity ranged between 40-65%. In this humidity range, Ångström exponent (Fig. 6a) and depolarization ratio (Fig. 6b) do not show any correlation with the relative humidity. Thus, our measurements were not affected by extreme humidity events and represent values for pollen under ambient atmospheric conditions in the spring season in Finland. However, lidar measurements of relative humidity profiles are only available during nighttime. The relative humidity in the observed pollen layers during daytime could be smaller. This could result in occasional folding of the pollen grains and higher depolarization ratios. This hypothesis could also explain the higher depolarization ratios of about 25% of few Klett measurements of birch pollen during the first period Table 1 summarizes the mean intensive properties together with the associated standard derivation (STD), range and median in the first (birch) period of our campaign. The contribution of other pollen types in this period was small. Those values, therefore, can be considered to be characteristic for birch pollen dominated aerosol conditions. Table 2 shows the same properties for the spruce contaminated period. Lidar ratio and PDR are higher when spruce is detected simultaneously with birch. The PDR values for birch pollen are considerably lower than previously determined in lidar studies. A linear depolarization ratio up to 30% at 694 nm was detected by Sassen (2008) for paper birch in Alaska. And under controlled laboratory environment, Cao et al. (2010) measured a linear depolarization ratio at 532 nm of 33% for dried paper birch pollen. We assume that those high depolarization values can be caused by dry birch pollen grains, which fold and change their shape when dehydrating. Under ambient conditions the pollen grains are more spherical and therefore less depolarizing.
5 Conclusion

Particle depolarization ratios of about 10% have been observed during a birch pollination event in Vehmasmäki, Finland. When more non-spherical pollen, e.g. spruce, are present, the depolarization ratio can be as high as 26%. Those depolarization ratios are similar to dust and biomass burning aerosol mixtures (Tesche et al., 2011) or dust mixtures with marine aerosol (Groß et al., 2011), thus pollen could easily be misclassified as dusty mixtures. The mean lidar ratios show a wide range of values depending on the mixing of different pollen types in the atmosphere. The mean lidar ratio at 355 nm vary between 46±8 sr (first period) and 60±3 sr (second period) and at 532 nm between 52±12 sr (first period) and 62±10 sr (second period). Those lidar ratios are characteristic for dust or dust-smoke mixtures (Tesche et al., 2011), which complicates the characterization of pollen using the lidar ratio. Also the Ångström exponents, which are between 1.0 and 1.7 for the intense birch pollination period and around 0.8 for the spruce contaminated period, are similar to characteristic values for smoke and dust-smoke mixtures, respectively. Thus, in order to distinguish between pollen and other aerosol types, all three parameters and backward trajectories as well as possible dust and biomass-burning aerosol sources have to be considered.

The presented data show the potential of lidar measurements to detect pollen in the atmosphere. Nevertheless, there are challenges which need to be addressed in order to improve the characterization of optical properties of airborne pollen. First, the minimum height of the usable lidar signal needs to be as low as possible. With the system used for this study, profiles can be retrieved down to around 500 m when applying overlap correction. Second, the contribution of other aerosol types like anthropogenic pollution has to be determined. Therefore, more multi-wavelength lidar studies with depolarization characterization on atmospheric pollen are necessary.

20 Data availability

Lidar data is available upon request from the authors and data quicklooks are available on PollyNET website (http://polly.tropos.de/). Trajectories are calculated with the NOAA (National Oceanic and Atmospheric Administration) HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) model (https://ready.arl.noaa.gov/HYSPLIT.php, accessed: 30/04/2019). Fire data is available at the NASA Worldview application (https://worldview.earthdata.nasa.gov, accessed: 30/04/2019). BSC-DREAM8b model simulations are operated by the Barcelona Supercomputing Center and are available at https://ess.bsc.es/bsc-dust-daily-forecast/ (accessed: 30/04/2019).

Author contribution

SB, XS and MF performed the lidar data analysis. AS analyzed the pollen samples. MK and EG initiated the measurement campaign. All authors contributed to the scientific discussion and the manuscript preparation.
Competing interests

The authors declare that they have no conflict of interest.
